ORACLE

Oracle Communications Session Border Controller Configuration Guide, Release S-Cz9.3.0

F92218-08

Contents

3 System Configuration

4 Realms and Nested Realms

5 SIP Signaling Services

7 IWF Services

8 Application Layer Gateway Services

9 Session Routing and Load Balancing

10 Session Translation

11 Admission Control and QoS

13 High Availability Nodes

14 Security

18 IMS Support

19 SBC Processing Language (SPL)

20 Transcoding

21 DTMF Interworking

22 RCS Services

23 Local Media Playback

24 Advanced Media Termination Support

25 STIR/SHAKEN Client

A RTC Support

B SIP Compatibility Options

About this Guide

The ACLI Configuration Guide provides information about:

- Basic concepts that apply to the key features and abilities of your Oracle Communications Session Border Controller
- Information about how to load the Oracle Communications Session Border Controller system software image you want to use and establish basic operating parameters
- System-level functionality for the Oracle Communications Session Border Controller
- Configuration of all components of the Oracle Communications Session Border Controller

Documentation Set

The following table describes the documentation set for this release:

Document Name	Document Description
Acme Packet 3900 Hardware Installation Guide	Contains information about the components and installation of the Acme Packet 3900.
Acme Packet 4600 Hardware Installation Guide	Contains information about the components and installation of the Acme Packet 4600.
Acme Packet 4900 Hardware Installation Guide	Contains information about the components and installation of the Acme Packet 3950 and Acme Packet 4900.
Acme Packet 6100 Hardware Installation Guide	Contains information about the components and installation of the Acme Packet 6100.
Acme Packet 6300 Hardware Installation Guide	Contains information about the components and installation of the Acme Packet 6300.
Acme Packet 6350 Hardware Installation Guide	Contains information about the components and installation of the Acme Packet 6350.
Release Notes	Contains information about the current documentation set release, including new features and management changes.
Known Issues & Caveats	Contains known issues and caveats
Configuration Guide	Contains information about the administration and software configuration of the Service Provider Session Border Controller (SBC).
ACLI Reference Guide	Contains explanations of how to use the ACLI, as an alphabetical listings and descriptions of all ACLI commands and configuration parameters.
Maintenance and Troubleshooting Guide	Contains information about SBC logs, performance announcements, system management, inventory management, upgrades, working with configurations, and managing backups and archives.

Document Name	Document Description
MIB Guide	Contains information about Management Information Base (MIBs), Oracle Communication's enterprise MIBs, general trap information, including specific details about standard traps and enterprise traps, Simple Network Management Protocol (SNMP) GET query information (including standard and enterprise SNMP GET query names, object identifier names and numbers, and descriptions), examples of scalar and table objects.
Accounting Guide	Contains information about the SBC's accounting support, including details about RADIUS and Diameter accounting.
HDR Guide	Contains information about the SBC's Historical Data Recording (HDR) feature. This guide includes HDR configuration and system-wide statistical information.
Admin Security Guide	Contains information about the SBC's support for its Administrative Security license.
Security Guide	Contains information about security considerations and best practices from a network and application security perspective for the SBC family of products.
Platform Preparation and Installation Guide	Contains information about upgrading system images and any pre-boot system provisioning.
Call Traffic Monitoring Guide	Contains information about traffic monitoring and packet traces as collected on the system. This guide also includes WebGUI configuration used for the SIP Monitor and Trace application.
HMR Guide	Contains information about configuring and using Header Manipulation Rules to manage service traffic.
REST API	Contains information about the supported REST APIs and how to use the REST API interface.

Documentation Accessibility

For information about Oracle's commitment to accessibility, visit the Oracle Accessibility Program website at http://www.oracle.com/pls/topic/lookup?ctx=acc&id=docacc.

My Oracle Support

My Oracle Support (https://support.oracle.com) is your initial point of contact for all product support and training needs. A representative at Customer Access Support (CAS) can assist you with My Oracle Support registration.

Call the CAS main number at 1-800-223-1711 (toll-free in the US), or call the Oracle Support hotline for your local country from the list at http://www.oracle.com/us/support/contact/index.html. When calling, make the selections in the sequence shown below on the Support telephone menu:

1. Select `2` for New Service Request.
2. Select `3` for Hardware, Networking, and Solaris Operating System Support.
3. Select one of the following options:
   - For technical issues such as creating a new Service Request (SR), select `1`.
   - For non-technical issues such as registration or assistance with My Oracle Support, select `2`.

You are connected to a live agent who can assist you with My Oracle Support registration and opening a support ticket.

My Oracle Support is available 24 hours a day, 7 days a week, 365 days a year.

Emergency Response

In the event of a critical service situation, emergency response is offered by the Customer Access Support (CAS) main number at 1-800-223-1711 (toll-free in the US), or call the Oracle Support hotline for your local country from the list at http://www.oracle.com/us/support/contact/index.html. The emergency response provides immediate coverage, automatic escalation, and other features to ensure that the critical situation is resolved as rapidly as possible.

A critical situation is defined as a problem with the installed equipment that severely affects service, traffic, or maintenance capabilities, and requires immediate corrective action. Critical situations affect service and/or system operation resulting in one or several of these situations:

- A total system failure that results in loss of all transaction processing capability
- Significant reduction in system capacity or traffic handling capability
- Loss of the system's ability to perform automatic system reconfiguration
- Inability to restart a processor or the system
- Corruption of system databases that requires service affecting corrective actions
- Loss of access for maintenance or recovery operations
- Loss of the system ability to provide any required critical or major trouble notification

Any other problem severely affecting service, capacity/traffic, billing, and maintenance capabilities may be defined as critical by prior discussion and agreement with Oracle.

Locate Product Documentation on the Oracle Help Center Site

Oracle Communications customer documentation is available on the web at the Oracle Help Center (OHC) site, http://docs.oracle.com. You do not have to register to access these documents. Viewing these files requires Adobe Acrobat Reader, which can be downloaded at http://www.adobe.com.

1. Access the Oracle Help Center site at http://docs.oracle.com.
2. Click **Industries**.
3. Under the Oracle Communications sub-header, click the **Oracle Communications documentation** link.
   The Communications Documentation page appears. Most products covered by these documentation sets appear under the headings "Network Session Delivery and Control Infrastructure" or "Platforms."
4. Click on your Product and then Release Number.
   A list of the entire documentation set for the selected product and release appears.
5. To download a file to your location, right-click the **PDF** link, select **Save target as** (or similar command based on your browser), and save to a local folder.

Access to Oracle Support

Oracle customers that have purchased support have access to electronic support through My Oracle Support. For information, visit http://www.oracle.com/pls/topic/lookup?ctx=acc&id=info or visit http://www.oracle.com/pls/topic/lookup?ctx=acc&id=trs if you are hearing impaired.

Revision History

The following table shows the dates and descriptions of revisions to the S-Cz9.2.0 ACLI Configuration Guide.

Date	Description
March 2024	• Initial release.
March 2024	• Adds corrID for authentication feature content.
May 2024	• Updates NTP Using an FQDN - Wancom with a note regarding the configuration of network interfaces on a wancom interface. • Updates SDES Profile Configuration for accuracy. • Updates IDS Phase 2 (Advanced Reporting) to clarify that it is supported on both Enterprise and Service Provider platforms and does not require a special license. • Clarifies the impact of changing the add-icmp-ip and remove-icmp-ip parameters on established calls. • Removes Note on limitation to Surrogate Agent SPL feature.
July 2024	• Updates the Add an SSH Known Host Key to correct the ssh-key command syntax. • Adds a note to the Manual Trigger Confirmation topic regarding the show sipd endpoint-ip <phone-number> output. • Updates the Manipulation Modes and Manipulation Modes in Codec Policies with note about using the Force attribute. • Adds features for S-Cz9.2.0p2. • Adds AHNT example with TCP CWIN behavior.

Date	Description
October 2024	• Clarifies the NTP sync process for a standby system. • Removes unsupported Enhanced Reason Header Configuration copy. • Adds features for S-Cz9.3.0p3. • Adds missing cipher for DTLS-SRTP. • Removes eap-md5 value from eap-protocol. • Updates Many-to-Many Support within Early Dialog Support for accuracy. • Removes outdated note on add-sdp-baseBehavior. • Corrects the RTC behavior for the access-control element. • Adds conditions for populating the Flow-Status AVP (511) over the Rx interface. • Adds note indicating the HeaderNat SPL is not supported on the Session Router. • Adds note confirming the system brings SAs in service when receiving any SIP request. • Updates TLS Session Caching Configuration to note that the session-caching parameter is not RTC supported. • Adds change-contact-user to SIP Interface Options. • Updates Media Interface Link Detection and Gateway Polling Configuration 2 for accuracy. • Updates Access Control Lists Configuration for accuracy. • Corrects Opus transcoding bit rates. • Clarifies the UDP+TCP SA transport-method parameter. • Updates HA Node Parameter Configuration to correct the becoming-standby-time parameter's default and maximum acceptable values. • Corrects examples for the P-Asserted-Identity-For parameter in PAI Header Manipulation and Configure Manipulation Attributes on a Realm. • Makes assorted corrections to EVS Codec Transcoding Support. • Updates Setting Up an IPSec Profile for IMS-AKA Use to correct the red-ipsec-port parameter's default and valid values. • Updates P-Early-Media ACLI Configuration to add support as a valid p-early-media-header value. • Removes erroneous references to the deprecated TSCF feature. • Clarifies SSH key authentication.

Date	Description
December 2024	• Adds note to clarify format the system uses to map a JSON claim object or array to a target-header. • Clarifies entry requirements for running test-translation. • Adds features for S-Cz9.3.0p4. • Adds an extended key usage configuration requirement for the certificate of a TLS profile with mutual authentication. • Updates Configuring SDP Insertion for SIP INVITEs and Configuring SDP Insertion for SIP ReINVITEs for accuracy. • Corrects Accommodating m=line Omissions During Call Setup to state that the fix-missing-mlines option is configured under media-manager.
February 2025	• Adds 15 second check and trap interval for memory utilization alarms/traps. • Adds features for S-Cz9.3.0p5. • Updates certificate examples to use sha256 signature. • Adds missing CA Store feature

1

Oracle Communications Session Border Controller Basics

This chapter introduces some basic concepts that apply to your Oracle Communications Session Border Controller (SBC). Understanding these concepts is necessary to configure your SBC. This chapter provides only a high-level overview of some important SBC concepts. Specific configuration instructions are found in later chapters.

What Is a Realm

A realm is a logical way of identifying a domain, a network, a collection of networks, or a set of addresses. Realms are used when an Oracle Communications Session Border Controller (SBC) communicates with multiple network elements over a shared connection. Defining realms allows flows to pass through a connection point between two networks.

From an external perspective, a realm is a collection of systems that generates real-time sessions comprised of signaling messages and media flows, or a group of multiple networks containing these systems. These systems may be session agents such as call agents, softswtiches, SIP proxies, H.323 gatekeepers, IP PBXs, etc., that can be defined by IP addresses. These systems can also be IP endpoints such as SIP phones, IADs, MTAs, media gateways, etc.

From an internal perspective, a realm is associated with SBC configurations to define interfaces and resources in a logical way. Realms are used to support policies that control the collection of information and statistics from systems or networks that generate media sessions. Realms are referenced by other configuration elements and the SBC uses realms to make routing decisions.

Nested Realms

Nested Realms is a Oracle Communications Session Border Controller feature that supports hierarchical realm groups. One or more realms may be nested within higher order realms. Realms and sub-realms may be created for media and bandwidth management purposes. This feature supports:

- Separation of signaling & media on unique network interfaces
- Signaling channel aggregation for Hosted IP Services applications
- Configuration scalability
- Per-realm media scalability beyond single **phy-interface** capacity
- Nested bandwidth admission control policies

What Is a Session Agent

A session agent defines an internal signaling endpoint. It is an internal next hop signaling entity that applies traffic shaping attributes to flows. For each session agent, concurrent session capacity and rate attributes can be defined. Service elements such as gateways, softswitches,

and gatekeepers are defined automatically within the Oracle Communications Session Border Controller as session agents. The Oracle Communications Session Border Controller can also provide load balancing across the defined session agents.

SIP session agents

SIP session agents can include the following:

- Softswitches
- SIP proxies
- Application servers
- SIP gateways

H.323 session agents

H.323 session agents can include the following:

- gatekeepers
- gateways
- MCUs

Why You Need Session Agents

You can use session agents to describe next or previous hops. You can also define and identify preferred carriers to use for traffic coming from session agents. This set of carriers is matched against the local policy for requests coming from the session agent. Constraints can also be set for specific hops.

In addition to functioning as a logical next hop for a signaling message, session agents can provide information regarding next hops or previous hops for SIP packets, including providing a list of equivalent next hops.

How to Use Session Agents

You can use session agents and session agent groups (along with local policies) to define session routing for SIP and H.323 traffic. You can associate a realm with a session agent to identify the realm for sessions coming from or going to the session agent.

What is a Session Agent Group

A session agent group contains individual session agents bundled together. A SAG indicates that its members are logically equivalent and can be used interchangeably. This allows for the creation of constructs like hunt groups for application servers or gateways. Session agent groups also assist in load balancing among session agents.

Session agent groups can be logically equivalent to the following:

- Application server cluster
- Media gateway cluster
- Softswitch redundant pair
- SIP proxy redundant pair

- Gatekeeper redundant pair

High Availability

High Availability (HA) is a network configuration used to ensure that planned and unplanned outages do not disrupt service. In an HA configuration, Oracle Communications Session Border Controllers (SBC) are deployed in a pair to deliver continuous high availability for interactive communication services. Two SBCs operating in this way are called an HA node. The HA node design ensures that no stable call is dropped in the event of an outage.

In an HA node, one SBC operates in the active mode and the other SBC operates in the standby mode.

- Active. The active member of the HA node is the system actively processing signal and media traffic. The active member continuously monitors itself for internal processes and IP connectivity health. If the active member detects a condition that can interrupt or degrade service, it hands over its role as the active member of the HA node to the standby member.
- Standby. The standby member of the HA node is the backup system. The standby member is fully synchronized with the active member's session status, but it does not actively process signal and media traffic. The standby member monitors the status of the active member and it can assume the active role without the active system having to instruct it to do so. When the standby system assumes the active role, it notifies network management using an SNMP trap.

The SBC establishes active and standby roles in the following ways.

- If an SBC boots up and is alone in the network, it is automatically the active system. If you pair a second SBC with the first one to form an HA node, the second system automatically establishes itself as the standby.
- If both SBCs in the HA node boot up at the same time, they negotiate with each other for the active role. If both systems have perfect health, then the SBC with the lowest HA rear interface IPv4 address becomes the active SBC. The SBC with the higher HA rear interface IPv4 address becomes the standby SBC.

If the rear physical link between the two SBCs is unresponsive during boot up or operation, both will attempt to become the active SBC. In this circumstance, processing does not work properly.

The standby SBC assumes the active role when:

- it does not receive a checkpoint message from the active SBC for a certain period of time.
- it determines that the active SBC health score declined to an unacceptable level.
- the active SBC relinquishes the active role.

To produce a seamless switch over from one SBC to the other, the HA node members share their virtual MAC and virtual IP addresses for the media interfaces in a way that is similar to Virtual Router Redundancy Protocol (VRRP). Sharing these addresses eliminates the possibility that the MAC address and the IPv4 address set on one SBC in an HA node will be a single point of failure. Within the HA node, the SBCs advertise their current state and health to one another in checkpointing messages to apprise each one of the other one's status. Using the Oracle HA protocol, the SBCs communicate with UDP messages sent out and received on the rear interfaces. During a switch over, the standby SBC sends out an ARP request using the virtual MAC address to establish that MAC address on another physical port within the Ethernet switch. To the upstream router, the MAC address and IP address are still alive. Existing sessions continue uninterrupted.

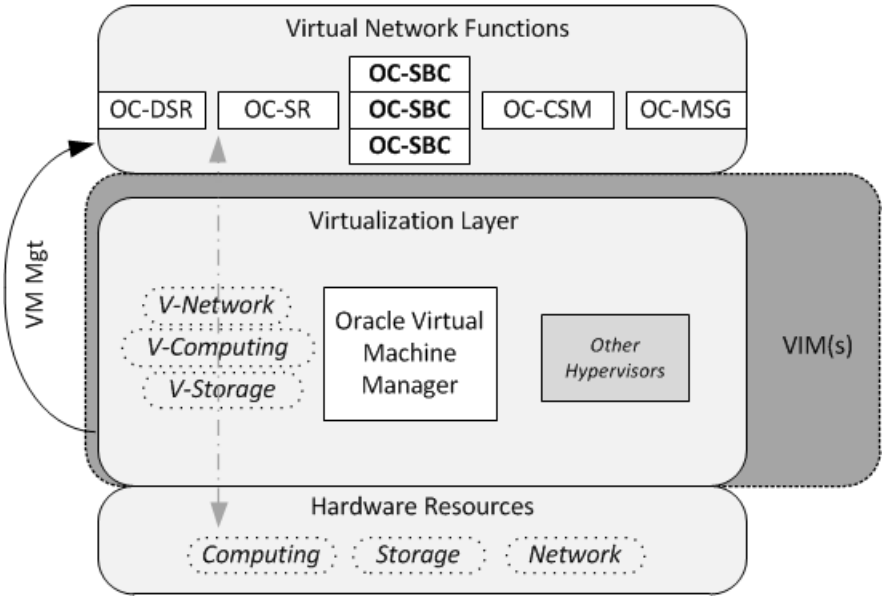
Network Functions Virtualization Overview

Network Functions Virtualization (NFV) is a set of architectural standards to leverage enterprise and cloud technologies for virtualization and lifecycle resource automation in telecommunications core networks. It is focused on identifying the use cases and needs of communications service providers for automated, virtualized infrastructure and network functions, along with an architecture to frame discussions on meeting those needs, and an analysis of the gaps with existing technologies. Standards defining the NFV architecture addressed in this document include "ETSI GS NFV 002 Architectural Framework", ETSI GS NFV 004 "Virtualization Requirements" and related. Oracle can provide its OCSBC and OCSR, as well as other network systems, as Virtual Network Functions (VNFs) or Management Systems for operation within an NFV-enabled environment.

One of the main drivers for NFV is capital equipment cost reduction for CSPs. Virtual functions running on fewer COTS servers is much cheaper than using multiple purpose built appliances. NFV meets the needs for cost reduction in addition to allowing the CSP to turn up new services and capacity more rapidly.

It is generally recognized now that operators desire to move their core network functions into automated and virtualized environments based on these technologies, starting with large operators in North America, Europe, and Asia. To accomplish this requires changes in the infrastructure that hosts the network functions, changes in the network functions, and additions to the management and automation of the life cycle of network services.

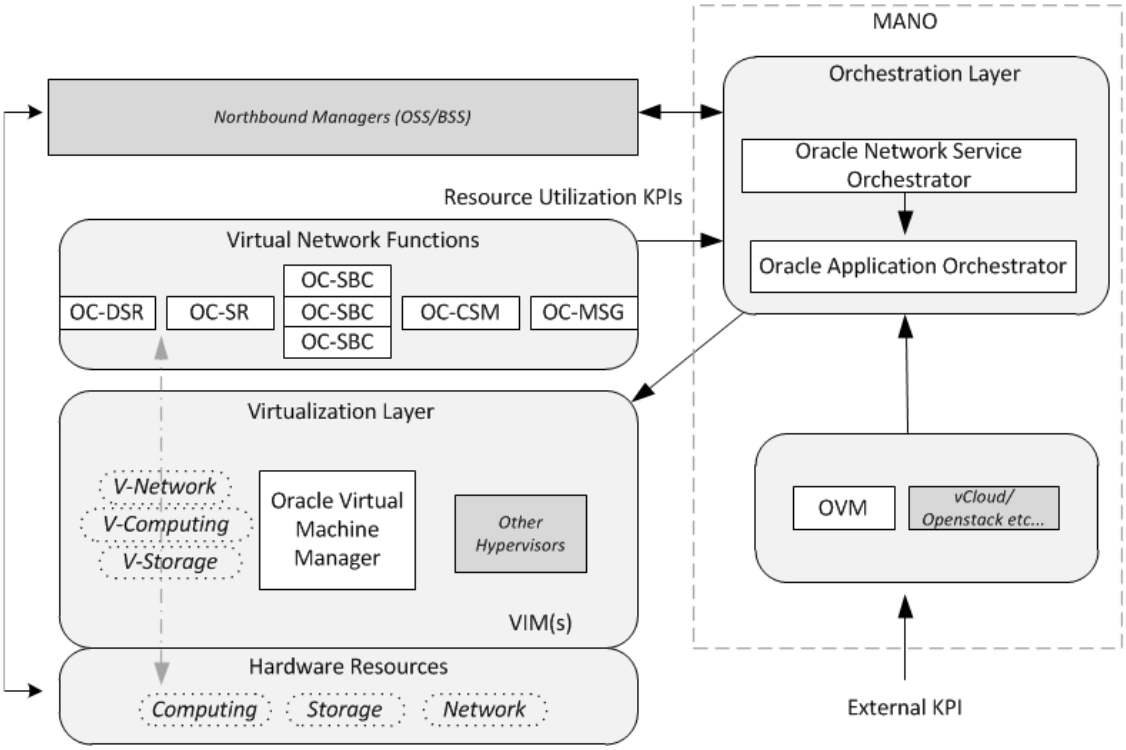
In the NFV Industry Specification Group under ETSI, which is where the bulk of industry focus on defining the use cases and architecture for NFV have been, an architectural framework, shown below, has been defined that is the basis for most discussions of the various functional components needed for an NFV environment. These components are divided into the Hardware, the VNFs and the virtualization layer. Commodity hardware provides the physical components for computing, and are the same as those without virtualization. The virtualization layer provides the means through which virtual machines can operate. The VNFs are the virtual machines themselves, instantiated as Virtual Network Functions (VNFs). These components establish a VNF deployment that can be fully operational, but without orchestration.



Extending upon these basic operational components are the Management and Orchestration components (MANO) components. MANO provides a means by which operators approach a

zero-touch orchestration, operation and management deployment. The resulting automated, elastic construct more fully addresses the OPEX efficiencies and real-time responsiveness desired from NFV.

To complete the NFV picture, MANO components are included in the diagram below, consisting of the orchestration layer and VIM components associated with managing your NFV. This diagram also adds the northbound OSS/BSS systems. The orchestration layer supports NFV instantiating and de-commissioning based on operational requirements and status, as well as on business requirements and preferences. The MANO model also provides for basic FCAPS management, encapsulating those management functions outside of orchestration.



Network operators establish criteria for automated VNF instantiation within the orchestration layer, by configuring the overall system to use external and internal status within KPIs to define the triggers for changes to VNF resources. VNFs themselves provide critical status information that, when combined with organizational policy and other status triggers, the MANO uses to adjust network resources to network requirements in real time.

Oracle's NFV solution harnesses the extensive assets from its portfolio to deliver a vision of a network orchestration being driven by a business orchestration, which in turn delivers business value to the customer. This vision builds on the investment that Oracle Communications has made in the BSS/OSS domain to deliver a BSS/OSS that is orchestrated along business processes. The Oracle Communication Network Service Orchestrator bridges Network Orchestration and Business Orchestration.

Oracle's NFV solution builds on the investment Oracle has made in the network domain to have an extensive portfolio of Network Functions as well as network orchestration.

2
Getting Started

Prior to configuring your Oracle Communications Session Border Controller for service, we recommend that you review the information and procedures in this chapter.

This chapter offers information that will help you:

- Review hardware installation procedures
- Connect to your Oracle Communications Session Border Controller using a console connection or SSH (secure shell)
- Become familiar with the Oracle Communications Session Border Controller's boot parameters and how to change them if needed
- Set up product-type, features, and functionality
- Load and activate a Oracle Communications Session Border Controller software image
- Choose a configuration mechanism: ACLI, Oracle Communcations Session Element Manager or ACP/XML
- Enable RADIUS authentication
- Customize your login banner

Installation and Start-Up

After you have completed the hardware installation procedures outlined in the the relevant *Hardware Installation Guide*, you are ready to establish a connection to your Oracle Communications Session Border Controller. Then you can load the software image you want to use and establish basic operating parameters.

Hardware Installation Process

Installing the Oracle Communications Session Border Controller hardware in a rack requires the following process.

1. Unpack the Oracle Communications Session Border Controller hardware.
2. Install the Oracle Communications Session Border Controller hardware into the rack.
3. Install the power supplies.
4. Install the fan modules.
5. Install the physical interface cards.
6. Cable the Oracle Communications Session Border Controller hardware.

> **Note:**
>
> Complete installation procedures fully and note the safety warnings to prevent physical harm to yourself and damage to the Oracle Communications Session Border Controller hardware.

For more information, see the hardware documentation.

Connecting to Your Oracle Communications Session Border Controller

You can connect to your Oracle Communications Session Border Controller either through a direct console connection, or by creating a remote SSH session. Both of these access methods provide you with the full range of configuration, monitoring, and management options.

> **Note:**
>
> By default, SSH and SFTP connections to your Oracle Communications Session Border Controller are enabled.

Create a Console Connection

Using a serial connection, you can connect your laptop or PC directly to the Acme Packet hardware. If you use a laptop, you must take appropriate steps to ensure grounding.

One end of the cable plugs into your terminal, and the other end plugs into the RJ-45 Console port on the NIU (or management ports area on the Acme Packet 6300).

To make a console connection to your hardware:

1. Set the connection parameters for your terminal to the default boot settings:
   - Baud rate: 115,200 bits/second
   - Data bits: 8
   - Parity: No
   - Stop bit: 1
   - Flow control: None
2. Connect a serial cable to between your PC and the hardware's console port.
3. Apply power to the hardware.
4. Enter the appropriate password information when prompted to log into User mode of the ACLI.

   You can set the amount of time it takes for your console connection to time out by setting the **console-timeout** parameter in the system configuration. If your connection times out, the login sequence appears again and prompts you for your passwords. The default for this field is 0, which means that no time-out is being enforced.

SSH Remote Connections

Connect to the Oracle Communications Session Border Controller (SBC) using SSH. The SBC supports five concurrent SSH and SFTP sessions. Only one SSH session may be in configuration mode at a time.

To SSH to your SBC, you need to know the IP address of its administrative interface (wancom0/eth0). The wancom0/eth0 IP address of your SBC is found by checking the **IP Address** value in the boot parameters or visible from the front panel display.

You can manage incoming SSH connections from the ACLI:

- SSH service is enabled by default.
- To view the users who are currently logged into the system, use the ACLI **show users** command. You can see the ID, timestamp, connection source, and privilege level for active connections.
- From Superuser mode in the ACLI, you can terminate the connections of other users in order to free up connections. Use the **kill <sftp | ssh | web>** command with the corresponding connection ID.
- If you reboot your SBC from a SSH session, you lose IP access and therefore your connection.

There are two ways to use SSH to connect to the SBC. Either connect via SSH without specifying users and SSH user passwords, or initiate the SSH connection using custom SSH credentials.

> Old SSH and SFTP clients that use weak ciphers may not be able to connect to the SBC. If a verbose connection log shows the server and client cannot agree on a cipher, upgrade your client.

Accessing the System Via User and Admin Accounts

You may access the Oracle Communications Session Border Controller via SSH connection without specifying users and SSH user passwords.

1. Open your SSH client (with an open source client, etc.).
2. At the prompt in the SSH client, type the **ssh** command, a Space, the IPv4 address of your Oracle Communications Session Border Controller, and then press Enter.
   The SSH client prompts you for a password before connecting to the Oracle Communications Session Border Controller. Enter the Oracle Communications Session Border Controller's User mode password. After it is authenticated, an SSH session is initiated and you can continue with tasks in User mode or enable Superuser mode.

Manage SSH Keys

Use the **ssh-key** command to manage SSH keys for the SBC.

Add an SSH Authorized Key

To authenticate to the SBC using public key authentication rather than a password, use the **ssh-key** command with the **authorized-key import** argument.

1. On the SSH client, convert the public key of the SSH client into RFC 4716 format.

> **Note:**
>
> Valid RSA key sizes are 2048, 3072, or 4096 bytes. The only valid DSA key size is 1024 bytes.

To do this on Oracle Linux, use the **ssh-keygen** command.

```
[bob@client ~]$ ssh-keygen -e -f .ssh/id_rsa.pub
---- BEGIN SSH2 PUBLIC KEY ----
Comment: "4096-bit RSA, converted by bob@client from OpenSSH"
AAAAB3NzaC1yc2EAAAADAQABAAACAQDOTDujYoQXzjTt9I8YvJMvfSVlWZ6iDzfRx06R3l
Rj/lrjxlWDMc/Y/uEd2sJ+5wdlCnJPREOuCGbU8S6295486D1kbu76cEDxE+adca3/9+qo
7FQVugkRJBD0ZOj/3qcuKDOh6ZsalF9LaaNMPNWNiQ5n3bWBnQ1tMMEes58JvoNgjn9FOz

CWQHHw9J1fYS4w==
---- END SSH2 PUBLIC KEY ----
[user@client ~]$
```

2. On the SBC, use the **ssh-key** command with the **authorized-key import** argument.

   The command syntax:

   ```
   ssh-key authorized-key import <name> <class>
   ```

   The `<name>` parameter is the identifier for the SSH client. The `<class>` is one of the two authorization classes on the SBC: either `user` or `admin`.

   ```
   ORACLE# ssh-key authorized-key import bob admin

   IMPORTANT:
           Please paste SSH public key in the format defined in RFC 4716.
           Terminate the key with ";" to exit.......

   ---- BEGIN SSH2 PUBLIC KEY ----

   CWQHHw9J1fYS4w==
   ---- END SSH2 PUBLIC KEY ----;
   ```

> **Note:**
>
> If the Admin Security entitlement is enabled, the SSH client keys must be at least 2048 bits.

> **Note:**
>
> Oracle recommends keys be at least 2048 bits.

3. Save and activate the configuration.

Export an Authorized Key

To export a previously imported SSH public key, use the **ssh-key** command with the **authorized-key export** argument.

1. List the available **ssh-key** elements.

```
ORACLE# show running-config ssh-key
ssh-key
        name                                    bob
        type                                    authorized-key
        encryption-type                         rsa

ORACLE#
```

Delete an Authorized Key

To delete a previously imported SSH public key, use the **ssh-key** command with the **authorized-key delete** argument.

1. List the available **ssh-key** elements.

```
ORACLE# show running-config ssh-key
ssh-key
        name                                    bob
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.20
        last-modified-date                      2020-05-12 13:58:39
ssh-key
        name                                    alice
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.37
        last-modified-date                      2020-05-12 14:23:47
ssh-key
        name                                    logserver
        type                                    known-host
        encryption-type                         rsa
        size                                    2048
        last-modified-by                        admin@10.0.0.37
        last-modified-date                      2020-05-11 15:18:36
```

2. For any **ssh-key** element whose type is **authorized-key**, use the **ssh-key authorized-key delete <name>** command to delete the user's public key.

```
ORACLE# ssh-key authorized-key delete bob
SSH public key deleted successfully....
WARNING: Configuration changed, run "save-config" command to save it
and run "activate-config" to activate the changes
ORACLE#
```

3. Save and activate the configuration.

Add an SSH Known Host Key

For the SBC to authenticate over SSH to an SFTP server, the public key of the SFTP server needs to be imported into the known_hosts file of the SBC.

1. Convert the public key of the SFTP server into RFC 4716 format.

   There are two ways to do this.

   a. SSH to the SFTP server and run the **ssh-keygen** command on the server's host key. For OpenSSH implementations, host keys are generally found at `/etc/ssh/ssh_host_rsa_key.pub`. Other SSH implementations may differ. To do this on Oracle Linux, use the **ssh-keygen** command.

   ```
   [user@logserver ~]$ ssh-keygen -e -f /etc/ssh/ssh_host_rsa_key.pub
   ---- BEGIN SSH2 PUBLIC KEY ----
   Comment: "2048-bit RSA, converted by user@logserver from OpenSSH"
   AAAAB3NzaC1yc2EAAAADAQABAAABAQDwifpOpBKoDhzJXglzdoOfZ39TiU7jhygbPGQTw0
   j3zISW57PRbSulVw1hBHwqJwZZc6nr1JXaiHN7ieYT/96QCXQ56JH9Lcjej6iHplfhJO44
   qIgZIlRtD0e5y6YBzDgcI3T8J6n0jHwksvwKttObk8SoZl1mqE4xPXSiTVB1PzMNxF0dWV
   rgvGK227PsOfPLypL3RhnmqFbVRIhMKW7a80p7I+T6mAoq8UdzejbyhEK+e0Ge3F9i1g49
   oHWHNnSvU64F1ADybbZrclvvt8vofIzraGMBRjLs5Yl8bbdId/4UBci1fONmIUzxVse5NM
   PwNj0cjvNPS1/LOcKUgQxN
   ---- END SSH2 PUBLIC KEY ----
   [user@logserver ~]$
   ```

   b. Run the **ssh-keyscan** command from a Linux client and convert that key with the **ssh-keygen** command.

   ```
   ssh-keyscan -t rsa 10.0.0.6 | sed 's/.*ssh/ssh/' > key.pub
   ssh-keygen -ef key.pub
   ```

2. On the SBC, use the **ssh-key** command to import the host key of the SFTP server into the known_hosts file of the SBC.

   The command syntax:

   ```
   ssh-key known-host import <name>
   ```

   For SFTP to work properly, the <name> parameter must be the valid and reachable IP address of the SFTP server.

   The following example shows adding multiple servers with different IP addresses. Note that you must add each server in an individual command.

   ```
   ssh-key known-host import 10.10.10.1
   ssh-key known-host import 192.168.1.1
   ```

   Alternatively, you may prepend a server "alias" to the start of the IP address string as follows.

   ```
   ssh-key known-host import serverA@10.10.10.1
   ssh-key known-host import serverB@192.168.1.1
   ```

   If you need to have multiple server aliases that have the same IP address, you can do the following.

   ```
   ssh-key known-host import serverA@10.10.10.1
   ssh-key known-host import serverB@10.10.10.1
   ```

3. Paste the public key with the bracketing Begin and End markers at the cursor point.
4. Enter a semi-colon (;) to signal the end of the imported host key.

   The entire import sequence is shown below.

```
ORACLE# ssh-key known-host import 10.0.0.12

IMPORTANT:
        Please paste SSH public key in the format defined in RFC 4716.
        Terminate the key with ";" to exit.......

---- BEGIN SSH2 PUBLIC KEY ----
Comment: "2048-bit RSA, converted by user@logserver from OpenSSH"

---- END SSH2 PUBLIC KEY ----;

SSH public key imported successfully....
WARNING: Configuration changed, run "save-config" command to save it
and run "activate-config" to activate the changes
```

   Import both the RSA key and the DSA key if you are not sure which one the SFTP server uses.

5. Save and activate the configuration.

Delete an SSH Known Hosts Key

Delete expired SSH keys from the known_hosts file of the SBC.

1. List the available **ssh-key** elements.

```
ORACLE# show running-config ssh-key
ssh-key
        name                                    bob
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.20
        last-modified-date                      2020-05-12 13:58:39
ssh-key
        name                                    alice
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.37
        last-modified-date                      2020-05-12 14:23:47
ssh-key
        name                                    10.0.0.12
        type                                    known-host
        encryption-type                         rsa
        size                                    2048
```

```
last-modified-by                        admin@10.0.0.37
last-modified-date                      2020-05-11 15:18:36
```

2. Use the **ssh-key** command to remove a key whose type is known-host.

   The command syntax:

   ```
   ssh-key known-host delete <name>
   ```

   The <name> parameter is an alias or handle assigned to the imported host key.

   ```
   ORACLE# ssh-key known-host delete 10.0.0.12
   ```

3. Save and activate the configuration.

Add a Certificate Authority Key

When authenticating with certificates, clients send certificates to establish their identity and authorization. The public key of the Certificate Authority (CA) used for signing these client certificates must be imported into the SBC.

1. On the server you'll use for a certificate authority, create a `keys` directory for storing keys.

   ```
   [user@host ~]$ mkdir keys
   [user@host ~]$ cd keys/
   ```

2. Generate an SSH key pair to use for signing certificates.

   ```
   [user@host keys]$ ssh-keygen -t rsa -b 4096 -f ./ca_key
   ```

3. Export the CA key to RFC 4716 format.

   ```
   [user@host keys]$ ssh-keygen -ef ./ca_key.pub
   ---- BEGIN SSH2 PUBLIC KEY ----
   Comment: "4096-bit RSA, converted by user@host from OpenSSH"
   AAAAB3NzaC1yc2EAAAADAQABAAACAQDOTDujYoQXzjTt9I8YvJMvfSVlWZ6iDzfRx06R3l
   Rj/lrjxlWDMc/Y/uEd2sJ+5wdlCnJPREOuCGbU8S6295486D1kbu76cEDxE+adca3/9+qo
   7FQVugkRJBD0ZOj/3qcuKDOh6ZsalF9LaaNMPNWNiQ5n3bWBnQ1tMMEes58JvoNgjn9FOz
   hbOdOe91K/OdRA0/YzrguaCA6/vE/tUP+xDD/GOu7KyvN1dsgo1vnYZLG7p8vGgt61eTyC
   V6qMEkceGatQvfiBb4XZCeODtC2KBv4pbJpt1zPKOpF4XFb2LferPxAL9rsSRSUOk9tZNc
   x1GM3+UUYwT9dF8bcUfomZCKd07kzPh206nZr/uCElXVtCqghgVRQW8uiFRh6ycVWY/pBq
   uhPfihKHilZEahOOc08ax14XTK89ovJzjbHezaV/NghkfWpn3W7gDNJTbLbxpbrLDkJBPJ
   IltJ5QqwVK/Hi+69x9CxFOkyNpxWFexHPIeq4q0liPoah42MBPAQl30bWULgBP+K0ugzqQ
   cSPAhi9FMq6ZVFTmaiPX8JH8JAceswd500x9jMmV91obzTZmXAQsfVpi0asxRhfficEIfs
   UJ/FHwW2p13YmDVH1AjVmCDn9T46I05Cq+ImrUBX+JAEa6yQU6R6/s7maVDqpdtkpFp0ql
   CWQHHw9J1fYS4w==
   ---- END SSH2 PUBLIC KEY ----
   [user@host keys]$
   ```

4. Import the CA key into the SBC using the **ssh-key** command with the **ca-key import** argument.

   The command syntax:

   ```
   ssh-key ca-key import <key-name> <class>
   ```

The <key-name> parameter is the key identifier or key ID that will be used when signing client keys as the value of the -I argument in the ssh-keygen command. The <class> is one of the two authorization classes on the SBC: either user or admin.

```
ORACLE# ssh-key ca-key import rootCA admin

IMPORTANT:
        Please paste SSH public key in the format defined in RFC 4716.
        Terminate the key with ";" to exit.......

CWQHHw9J1fYS4w==
---- END SSH2 PUBLIC KEY ----;
```

> **Note:**
>
> If the Admin Security entitlement is enabled, the key must be at least 2048 bits.

5. Save and activate the configuration.
6. For each SSH client, copy the client's public key into the keys directory.

```
[user@host keys]$ scp acme@client1.com:.ssh/id_rsa.pub ./id_rsa.pub
```

7. Sign the key with the **ssh-keygen** command.

   Use the following arguments:

   - Use -s to identify the private key of the CA key used to sign.
   - Use -z to specify the serial number to be embedded in the certificate to distinguish this certificate from others signed by the same CA.
   - Use -n to specify the username of the client to be included in the certificate.
   - Use -I to specify the key ID. This key ID must match the <key-name> specified when importing the signing CA key into the SBC.
   - Use -V to set the validity interval. To set the validity for one year, starting the previous day, use -1d:+52w.

> **Important:**
>
> The username passed with the `-n` argument of the **ssh-keygen** command must match the username used to authenticate.

> **Note:**
>
> If the **type** attribute of the **authentication** element is set to **local**, the username passed with the -n argument must be set to admin.

```
[user@host keys]$ ssh-keygen -s ca_key -z 1 -n admin -I rootCA -V -1d:+52w
id_rsa.pub
Signed user key id_rsa.pub: id "rootCA" serial 1 for admin valid from
2020-06-21T09:26:41 to 2021-06-21T09:26:41
[user@host keys]$
```

8. Copy the certificate to the client's `.ssh` directory.

```
[user@host keys]$ scp id_rsa-cert.pub acme@client1.com:.ssh/
```

9. Verify the SSH client can connect with the certificate.

Delete a Certificate Authority Key

To delete a previously imported Certificate Authority (CA) key, use the **ssh-key** command with the **ca-key delete** argument.

1. List the available **ssh-key** elements.

```
ORACLE# show running-config ssh-key
ssh-key
        name                                    bob
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.20
        last-modified-date                      2020-05-12 13:58:39
ssh-key
        name                                    alice
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.37
        last-modified-date                      2020-05-12 14:23:47
ssh-key
        name                                    rootCA
        type                                    ca-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.37
        last-modified-date                      2020-05-11 15:18:36
```

2. For any **ssh-key** element whose type is **ca-key**, use the **ssh-key ca-key delete <key-name>** command to delete the CA key.

```
ORACLE# ssh-key ca-key delete rootCA
SSH public key deleted successfully....
WARNING: Configuration changed, run "save-config" command to save it
and run "activate-config" to activate the changes
ORACLE#
```

3. Save and activate the configuration.

Revoke a User Key

To revoke access to a specific user whose public key was signed by your CA key, import the user's public key into the revocation list.

1. On the SBC, use the **ssh-key** command with the **ca-user-revoke import** argument.

   The command syntax:

```
ssh-key ca-user-revoke import <key-name>
```

   The `<key-name>` parameter uniquely identifies the key you want to revoke.

```
ORACLE# ssh-key ca-user-revoke import bob

IMPORTANT:
        Please paste SSH public key in the format defined in RFC 4716.
        Terminate the key with ";" to exit.......

---- BEGIN SSH2 PUBLIC KEY ----
Comment: "4096-bit RSA, converted by user@server from OpenSSH"
AAAAB3NzaC1yc2EAAAADAQABAAACAQDOTDujYoQXzjTt9I8YvJMvfSVlWZ6iDzfRx06R3l

CWQHHw9J1fYS4w==
---- END SSH2 PUBLIC KEY ----;
```

2. Save and activate the configuration.

The user's key is added to the revocation list. When authenticating to the SBC, the user may no longer use his or her key or certificate, even though that key was signed by the CA key.

Unrevoke a Revoked User Key

If a user key is added to the revocation list, that user will not be able to authenticate to the SBC. To delete a key from the revocation list, use the **ssh-key** command with the **ca-user-revoke delete** argument.

1. List the available **ssh-key** elements.

```
ORACLE# show running-config ssh-key
ssh-key
        name                                    bob
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.20
        last-modified-date                      2020-05-12 13:58:39
ssh-key
        name                                    alice
        type                                    authorized-key
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.37
        last-modified-date                      2020-05-12 14:23:47
ssh-key
        name                                    alice
        type                                    ca-user-revoke
        encryption-type                         rsa
        size                                    4096
        last-modified-by                        admin@10.0.0.37
        last-modified-date                      2020-05-11 15:18:36
```

2. For any **ssh-key** element whose type is **ca-user-revoke**, use the **ssh-key ca-user-revoke delete <key-name>** command to delete the CA key.

```
ORACLE# ssh-key ca-user-revoke delete alice
SSH public key deleted successfully....
WARNING: Configuration changed, run "save-config" command to save it
and run "activate-config" to activate the changes
ORACLE#
```

3. Save and activate the configuration.

Once the user key is removed from the revocation list, the functionality of any existing key is restored.

Configure SSH Ciphers

The **ssh-config** configuration element controls which ciphers the SBC offers during SSH session negotiation when the SBC acts as an SSH server. The ciphers offered when the SBC acts as an SSH client are not configurable.

Each command takes an argument which is either a single word or a comma-separated list within double quotes. Type `?` to see the available algorithms for this release.

1. Access the **ssh-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# security
ORACLE(security)# ssh-config
```

2. **encr-algorithms**—Select the ciphers for SSH encryption.
3. **hmac-algorithms**—Select the HMAC algorithm.

4. **keyex-algorithms**—Select the Diffie-Hellman key exchange algorithm.
5. **hostkey-algorithms**—Select the algorithm for generating host keys.
6. Type **done**.
7. Save and activate the configuration.

Verify SSH Ciphers

After configuring which ciphers the Oracle Communications Session Border Controller offers during SSH negotiations, verify the settings from an SSH client by starting a new SSH session with verbosity level 2.

1. SSH to the SBC with verbosity level 2.

```
ssh -vv user@10.0.0.1
```

2. Confirm the SBC offers the selected ciphers.

```

```

System Boot

When your Oracle Communications Session Border Controller boots, the following information about the tasks and settings for the system appear in your terminal window.

- System boot parameters
- From what location the software image is being loaded: an external device or internal flash memory
- Requisite tasks that the system is starting
- Log information: established levels and where logs are being sent
- Any errors that might occur during the loading process

After the loading process is complete, the ACLI login prompt appears.

Boot Parameters

Boot parameters specify the information that your device uses at boot time when it prepares to run applications.

This section explains how to view, edit, and implement device's boot parameters, and boot flags. Boot parameters:

- Allow you to set the IP address for the management interface (wancom0).
- Allow you to set a system prompt. The target name parameter also specifies the title name displayed in your web browser and SNMP device name parameters.
- Specify the software image to boot and from where the system boots that image.

> **Note:**
>
> You must configure all three components of an IPv6 address, including address, mask and gateway, in your system's boot parameters for wancom0 addressing. Configure the mask as a forslash (/) after the address followed by the mask in number of bits. The system requires all three components for IPv6 Neighbor Discovery to work properly.

Boot flags are arguments to a specific boot parameter, and allow functional settings, such as the use of DHCP for acquiring a management port address, as well as various diagnostic startup configurations.

Configuring boot parameters has repercussions on your system's physical and network interface configurations. When you configure these interfaces, you can set values that might override the boot parameters.

The bootparam configuration list is shown below.

```
[Acme Boot]: p
Boot File         : /boot/bzImage
IP Address        : 172.44.12.89
VLAN              :
Netmask           : 255.255.0.0
Gateway           : 172.44.0.1
IPv6 Address      : 3fff:ac4:6001:0:208:25ff:fe05:f470/64
IPv6 Gateway      : 3fff:ac4:6001::ac4:6001
Host IP           :
FTP username      :
FTP password      :
Flags             : 0x00000040
Target Name       : ORACLE
Console Device    : COM1
Console Baudrate : 115200
Other             :

[Acme Boot]: ?
 ?                    - print this list
 @                    - boot (load and go)
 p                    - print boot params
 c                    - change boot params
 v                    - print boot logo with version
 r                    - reboot
 s                    - show license information
```

Boot Parameter Definitions

The system displays all boot parameters when you configure them after a boot interrupt. The system hides some boot parameters from the ACLI so that you do not attempt to configure them. If changed improperly, these parameters can cause the system to sop responding.

The following table defines each of the parameters that the system displays when you perform configuration after a boot interrupt.

Boot Parameter	Description
Boot File	The name and path of the software image you are booting. Include the absolute path for a local boot from the local /boot volume and for a net boot when a path on the FTP server is needed.
IP Address	IP address of wancom0.
VLAN	VLAN of management network over which this address is accessed. **Note:** VLANs over management interfaces are supported only on the Acme Packet 1100. **Note:** The acquire-config command is not supported on management interfaces that use both VLANs and IPv6.
Netmask	Netmask portion of the wancom0 IP Address.
Gateway	Network gateway that this wancom0 interface uses.
IPv6 address	Version 6 IP address/mask of wancom0. Configure the mask as a forslash (/) after the address followed by the mask in number of bits.
IPv6 Gateway	Version 6 network gateway that this wancom0 interface uses.
Host IP	IP Address of FTP server from which to download and execute a software image.
FTP Username	FTP server username
FTP password	FTP server password
Flags	Codes that signal the system from where to boot. Also signals the system about which file to use in the booting process. This sequence always starts with 0x (these flags are hexadecimal).
Target Name	Name of the Oracle Communications Session Border Controller as it appears in the system prompt. For example, ORACLE> or ORACLE#. You need to know the target name if you are setting up an HA node. This name must be unique among Oracle Communications Session Border Controllers in your network. This name can be 63 characters or less.
Console Device	Serial output device type, dependent on platform. COM1 applies to virtual serial consoles, VGA to virtual video console. VGA is the default on VMware and KVM. COM1 is the default on OVM .

Boot Parameter	Description
Console Baud Rate	The speed in bits per second which the console port operates at. It operates at 115200 BPS, 8 data bits, no stop bit, parity NONE.
Other	Allows miscellaneous and deployment-specific boot settings.

Boot Flags

Boot flags enable system boot behavior(s). The user can set a single flag, or add hex digits to set multiple flags.

- 0x00000008 Bootloader ~7 seconds countdown
- 0x00000040 Autoconfigure wancom0 via DHCP enable - VM platforms only
- 0x00000080 Use TFTP protocol (instead of FTP) enable - VM platforms only
- 0x00000100 Bootloader ~1 seconds quick countdown - VM platforms only

The following boot flags should only be used as directed by Oracle support:

- 0x00000001 acme.ko network module security override
- 0x00000002 Kernel debug enable
- 0x00000004 Crashdump disable
- 0x00000010 Debug sshd enable
- 0x00000020 Debug console enable getty
- 0x00001000 Userspace debug enable
- 0x00100000 Uniprocessor enable (SMP disable)
- 0x20000000 Fail-safe boot enable
- 0x40000000 Process startup disable (flatspin mode)

Never enter any other values without the direction of Oracle support. Some diagnostic flags are not intended for normal system operation.

Setting Up System Basics

Before configuring and deploying the Oracle Communications Session Border Controller, you might want to establish some basic attributes such as a system prompt, new User and Superuser passwords, and NTP synchronization.

New System Prompt

The ACLI system prompt is set in the boot parameters. To change it, access the boot parameters and change the **target name** value to make it meaningful within your network. The target name may be up to 38 characters. A value that identifies the system in some way is often helpful.

Set Initial Passwords for Admin and User

The Oracle Communications Session Border Controller (SBC) requires you to set passwords for the Admin and User accounts the first time you power up a new or factory reset system by way of local access. You cannot access the Admin and User accounts until you set the

corresponding passwords. Use either an SSH or console connection when setting passwords. The following procedure is for local access. If you use remote access, for example, RADIUS or TACACS, use your passwords for those services.

Before you begin, plan your passwords to meet the following requirements:

- 8-64 characters
- Include three of the following:
  - Lower case letters
  - Uppercase letters
  - Numerals
  - Punctuation

The system leads you through the process for setting the Admin and User passwords, as follows:

1. Power up the SBC.

   The system prompts you to set the User account password.
2. At the prompt, type **acme**, and press ENTER.

   The system prompts you to enter the password that you want for the User account.
3. Type the User account password, and press ENTER.
4. Type **enable**, and press ENTER.

   The system prompts you to set the Admin account password.
5. Type **packet**, and press ENTER.

   The system prompts you to enter the password that you want for the Admin account.
6. Type the Admin account password, and press ENTER.

   The system logs you in as Admin.

Using the Oracle Communications Session Border Controller Image

The Oracle Communications Session Border Controller arrives with the most recent, manufacturing-approved run-time image installed on the flash memory. If you want to use this image, you can install the Oracle Communications Session Border Controller as specified in the *Acme Packet Hardware Installation Guide* , establish a connection to the Oracle Communications Session Border Controller, and begin to configure it. On boot up, the system displays information about certain configurations not being present. You can dismiss these displays and begin configuring the Oracle Communications Session Border Controller.

If you want to use an image other than the one installed on the Oracle Communications Session Border Controller when it arrives, you can use the information in this section to obtain and install the image.

Obtaining a New Image

You can download a software image onto the Oracle Communications Session Border Controller platform from the following sources.

- Obtain an image from the SFTP site and directory where you or your Oracle customer support representative placed the image. For example, this may be a special server that you use expressly for images and backups.
- Obtain an image from your Oracle customer support representative, who will transfer it to your system.

Regardless of the source, use SFTP to copy the image from the source to the Oracle Communications Session Border Controller.

Copy an Image to the Oracle Communications Session Border Controller using SFTP

The /boot directory on the Oracle Communications Session Border Controller has 32mb available, and operating system files of approximately 9mb each. Oracle recommends storing no more than two images at a time in this location. One of these should be the latest version. The /boot directory is used for the on-board system flash memory. If you do not put the image in this directory, the Oracle Communications Session Border Controller will not find it, unless the boot parameters have been modified to boot from a file in a different directory.

To copy an image on your Oracle Communications Session Border Controller using SFTP:

1. Go to the directory where the image is located.
2. Check the IP address of the Oracle Communications Session Border Controller's management port (wancom0).
3. Create the connection to the Oracle Communications Session Border Controller.

   There is a wide variety of methods to establish SFTP access to your system. For example, Linux systems allow SFTP operation from a terminal. For a Windows system, there are many GUI applications that provide SFTP.

   Using your SFTP application, start an SFTP session to the IPv4 address of the Oracle Communications Session Border Controller management port (wancom0). An SFTP username and SFTP password is required to start the session. The username is always admin, and the password is the local admin login password.

   Only the local admin user can write to the /boot directory.
4. Set your SFTP application to copy the image to the **/boot** folder using binary transfer mode.
5. Invoke and confirm your SFTP file transfer to the device.
6. Boot the Oracle Communications Session Border Controller using the image you just transferred.

   In the ACLI, change any boot configuration parameters that need to be changed. It is especially important to change the filename boot parameter to the filename you used during the SFTP process. Otherwise, your system will not boot properly.

   Alternatively, from the console you can reboot to access the boot prompt and then configure boot parameters from there.
7. In the ACLI, execute the **save-config** command in order to save your changes.
8. Reboot the Oracle Communications Session Border Controller.
9. The Oracle Communications Session Border Controller runs through its loading processes and returns you to the ACLI prompt.

System Image Filename

The system image filename is a name you set for the image. This is also the filename the boot parameters uses when booting your system. This filename must match the filename specified in the boot parameters. When you use it in the boot parameters, it should always start with /boot to signify that the Oracle Communications Session Border Controller is booting from the /boot directory.

If the filename set in the boot parameters does not point to the image you want sent to the Oracle Communications Session Border Controller via SFTP, then you could not only fail to load the appropriate image, but you could also load an image from a different directory or one that is obsolete for your purposes. This results in a boot loop condition that you can fix by stopping the countdown, entering the appropriate filename, and rebooting the Oracle Communications Session Border Controller.

Booting an Image on Your Oracle Communications Session Border Controller

You can either boot your SBC from the system's local storage or from an external device. Both locations can store images from which the system can boot. This section describes both booting methods.

For boot parameters to go into effect, you must reboot your SBC. Since a reboot stops all call processing, Oracle recommends performing tasks that call for a reboot during off-peak hours. If your SBCs are set up in an HA node, you can perform these tasks on the standby system first.

> **Note:**
>
> Only the local admin user can SFTP a boot image to the `/boot` directory.

Use the local admin user account to SFTP your boot image to the `/boot` directory or use a supplementary administrator user account (such as a TACACS+ or RADIUS administrator) to upload your boot image to the `/code/images` directory. Then set the Boot File parameter to your uploaded boot file.

Boot Parameter Definitions

The system displays all boot parameters when you configure them after a boot interrupt. The system hides some boot parameters from the ACLI so that you do not attempt to configure them. If changed improperly, these parameters can cause the system to sop responding.

The following table defines each of the parameters that the system displays when you perform configuration after a boot interrupt.

Boot Parameter	Description
Boot File	The name and path of the software image you are booting. Include the absolute path for a local boot from the local /boot volume and for a net boot when a path on the FTP server is needed.
IP Address	IP address of wancom0.

Boot Parameter	Description
VLAN	VLAN of management network over which this address is accessed. **Note:** VLANs over management interfaces are supported only on the Acme Packet 1100. **Note:** The acquire-config command is not supported on management interfaces that use both VLANs and IPv6.
Netmask	Netmask portion of the wancom0 IP Address.
Gateway	Network gateway that this wancom0 interface uses.
IPv6 address	Version 6 IP address/mask of wancom0. Configure the mask as a forslash (/) after the address followed by the mask in number of bits.
IPv6 Gateway	Version 6 network gateway that this wancom0 interface uses.
Host IP	IP Address of FTP server from which to download and execute a software image.
FTP Username	FTP server username
FTP password	FTP server password
Flags	Codes that signal the system from where to boot. Also signals the system about which file to use in the booting process. This sequence always starts with 0x (these flags are hexadecimal).
Target Name	Name of the Oracle Communications Session Border Controller as it appears in the system prompt. For example, ORACLE> or ORACLE#. You need to know the target name if you are setting up an HA node. This name must be unique among Oracle Communications Session Border Controllers in your network. This name can be 63 characters or less.
Console Device	Serial output device type, dependent on platform. COM1 applies to virtual serial consoles, VGA to virtual video console. VGA is the default on VMware and KVM. COM1 is the default on OVM .
Console Baud Rate	The speed in bits per second which the console port operates at. It operates at 115200 BPS, 8 data bits, no stop bit, parity NONE.
Other	Allows miscellaneous and deployment-specific boot settings.

Booting from Local Storage

Once you have installed an image, you can boot your Oracle Communications Session Border Controller from its local storage.

To boot from your local storage:

1. Confirm that the boot parameters are set up correctly and make any necessary changes.

You can check the boot configuration parameters by accessing the **bootparam** command from the configure terminal menu.

```
ORACLE# configure terminal
ORACLE# bootparam
```

2. Change any boot configuration parameters that you need to change. It is especially important to change the file name boot configuration parameter. The file name parameter needs to use the /boot value so that the Oracle Communications Session Border Controller boots from the local storage.
3. You can boot from a different image files using the l (small letter L) option from the boot menu prompt. This allows you to select an alternate image file when the boot file gets corrupted. This option is available only when FIPS mode is disabled. You can view the files in a page view when there are more than 15 files in the directories. When Oracle Communications Session Border Controller boots over network using ftp/sftp with the selected image file, this option does not update the boot param. This option displays image files from both /boot and /code/images directories irrespective of R226 license.

```

[Acme Boot]:[Boot Image]: 3
```

4. Reboot your Oracle Communications Session Border Controller.
5. You are be returned to the ACLI login prompt. To continue with system operations, enter the required password information.

Setting Up Product-Type, Features, and Functionality

You enable features and functionality primarily through the Setup Entitlements task, where you self-provision features and certain session capacities. The Oracle Communications Session Border Controller is seeded with a default feature set when you first follow the Setup Product task, and is based on software version, the platform on which the software runs, and the product type that you choose.

> **Note:**
>
> Refer to the *Self-Provisioned Entitlements and License Keys* section in the *Release Notes* for a list of the methods used to enable features in this release.

Initial Setup

Prior to system configuration, you must set up the product, self-provision entitlements, and optionally install license keys to activate features as required. If you log onto an unconfigured Oracle Communications Session Border Controller, the system displays a warning message that a valid product type is required.

System Setup

Before you begin configuring the Oracle Communications Session Border Controller, you will set the product type with the **setup product** command, and the features with the **setup entitlements** command.

> **Note:**
>
> Not all of the features are available on all platforms.

Setup Product

1. Type **setup product** at the ACLI. If this is the first time running the command on this hardware, the product will show as Uninitialized.
2. Type **1 <Enter>** to modify the uninitialized product.
3. Type the number followed by **<Enter>** for the product type you wish to initialize.
4. Type **s <Enter>** to commit your choice as the product type of this platform.
5. Reboot your Oracle Communications Session Border Controller.

```
ORACLE# setup product

-----------------------------------------------------------------
WARNING:
Alteration of product alone or in conjunction with entitlement
changes will not be complete until system reboot

Last Modified
-----------------------------------------------------------------
 1 : Product       : Uninitialized

Enter 1 to modify, d' to display, 's' to save, 'q' to exit. [s]: 1

  Product
    1 - Session Border Controller
    2 - Session Router - Session Stateful
    3 - Session Router - Transaction Stateful
    4 - Subscriber-Aware Load Balancer
    5 - Enterprise Session Border Controller
    6 - Peering Session Border Controller
  Enter choice     : 1

Enter 1 to modify, d' to display, 's' to save, 'q' to exit. [s]: s
save SUCCESS
```

> **Note:**
>
> When configuring an HA pair, you must provision the same product type and features on each system.

Setup Entitlements

1. Type **setup entitlements** at the ACLI. Currently provisioned features are printed on the screen.

2. Type the number of the feature you wish to setup followed by pressing the **<Enter>** Key. Some features are set as enabled/disabled (provisionable features), and some features are provisioned with a maximum capacity value (provisionable capacity features). The command will let you provision these values as appropriate.
3. Type **enabled** or **disabled** to set a provisionable feature, or type an integer value for a provisionable capacity feature. Both input types are followed by pressing the **<Enter>** key.
4. Repeat steps 2 and 3 to setup additional entitlements.
5. Type **d** followed by the **<Enter>** key to review the full range of your choices. Note that disabled entitlements display their state as blank.
6. Type **s** followed by the **<Enter>** key to commit your choice as an entitlement for your system. After saving the value succeeds you will be returned to the ACLI.
7. Save and activate your configuration.
8. Reboot your Oracle Communications Session Border Controller.

Editing and Viewing Features

If you are not changing the product type, and you are changing only the features, you can edit the existing feature with the **setup entitlements** command. Executing this command will display existing features before giving you the option to modify their settings.

The **show entitlements** command displays the currently provisioned features and controlled features. You may also use the **setup entitlements** command and type **d** to display the current features. Upon first executing the **setup entitlements** command, all features (excluding controlled features) are displayed on the screen.

License Keys and Self-Provisioned Entitlements Compatibility

The Oracle Communications Session Border Controller continues to support any license keys originally purchased and installed pre-self-provisioned-entitlements for enabling system features.

The licensing and entitlements processes work with each other, as follows.

- You must use self-provisioning to enable features and session capacity on all platforms.
- Oracle only provides license keys to enable specific features and capacities not available for self-provisioning, such as codecs and regulatory features .
- Upon migrating to self-provisioned entitlements, the system seeds the current range of your installed license keys to the self-provisioned entitlements. The system's functionality remains identical.
- When you upgrade to self-provisioned entitlements and then downgrade the software to an older version that requires license keys, any pre-existing license keys will still function.
- When you upgrade to self-provisioned entitlements and then change the functionality (such as, adding more SIP sessions or removing a feature set), the new functionality will not be present upon downgrade to an older version that requires license keys.

System Setup with Existing License Keys

When changing the Oracle Communications Session Border Controller licensing technique from the legacy license key method to the self-provisioned method, be aware of the following:

- After running **setup product** and **setup entitlements**, the system will be seeded with the existing license keys' functionalities.

- When the system is seeded with its previous functionality to the provisioned entitlements system, functionality may be changed with the **setup entitlements** command.
- You may notice that there are fewer entitlements than there were with license keys. This is normal.
- After setting up self-provisioned features, the **show features** command will still function to display the previously installed license keys.

Concurrent Session License Usage

This feature allows the SBC to track the maximum values of it's licensed session usage over time. Specific 'high water marks' that the system stores includes total sessions, SRTP sessions, and transcoding Sessions on a rolling 365-day period with timestamps for auditing purposes. This can inform the customer and Oracle if and when it has exceeded its licensed session usage over specific windows for up to one year. You configure this feature by setting the **peak-concurrent-license** parameter within the **system-config**.

When enabled, the SBC writes maximum sessions count values, along with timestamps indicating when maximum values occurred, for the applicable sessions types into the following files every fifteen minutes:

- TotalSessions.csv
- SRTPSessions.csv
- AMRSessions.csv
- AMRWBSessions.csv
- EVRCSessions.csv
- EVRCBSessions.csv
- OPUSSessions.csv
- SILKSessions.csv
- EVSSessions.csv

> **Note:**
>
> If your device does not support any transcoding type or you have not added the applicable licenses, the device does not create the applicable files and entries.

These files include rolling data for the past 365 days. The system stores these files in the /code/peakLicenseData/ folder, which is only visible to those with admin privileges. The system accumulates data for a year, and then drops the oldest day of data each day forward.

When the SBC performs these session capacity checks, it compares the values you configured for your entitlements with the numbers of all active/concurrent sessions on the system. Each time it creates a new session, the SBC compares the active sessions counter with session capacity entitlements setting. If the active sessions are less than session capacity counter, the system increments the active sessions counter by one and creates the new session. Similarly, the system reduces the active sessions counter each time it deletes a session, which occurs when the session state changes to “terminated”.

For the purposes of this feature, the SBC maintains 2 key variables that it uses to track session use high water marks:

- peakValue
- peakTimestamp

The system stores these values after polling in each of the applicable files listed above. Whenever you run the **show peak-concurrent-license-usage** command or load the **Peak Concurrent License Usage** widget from the GUI, the SBC reads each line from file and compares the current peakValue with the peakValue in the file. If the new high value is greater than the stored value, the system updates the file with the new high. Whenever the system updates peakValue, it also updates the peakTimestamp. After finishing reading all lines in one file, the system dumps peakValue and peakTimestamp and repeats the same steps on the next file.

Configuration

You configure the system to use this feature by setting the **peak-concurrent-license** parameter within the **system-config**. No other configuration is required, and the feature is not dependent on or affected by any other configuration. If you disable the option, the system stops increasing and decreasing counters and stops writing to the files.

```
ORACLE(system-config)# peak-concurrent-license enabled
```

ACLI Reporting

The SBC displays the highest watermarks and timestamp for each data file in a rolling 365-day period when you execute the ACLI command **show peak-concurrent-license-usage**.

```
ORACLE# show peak-concurrent-license-usage
SessionType      PeakValue      TimeStamp
Total Sessions   4000           2023-03-08 06:32:22.321
SRTP Sessions    400            2023-03-08 06:15:41.225
AMR Sessions     150            2023-03-08 06:08:38.198
AMRWB Sessions   100            2023-03-08 06:38:27.777
EVS Sessions     25             2023-03-08 06:25:54.330
OPUS Sessions    17             2023-03-08 06:33:06.456
SILK Sessions    90             2023-03-08 06:37:09.688
EVRC Sessions    98             2023-03-08 06:34:09.622
EVRCB Sessions   86             2023-03-08 06:26.34.786
```

When you enable this feature the **show peak-concurrent-license-usage** command displays the highest watermark entry for each session type in a rolling 365-day period. If you disable the feature, this command prints **Feature is Disabled**. If there are multiple entries with the same value, the system displays the least recent entries.

SNMP

You can access the data captured by this feature using SNMP. The data returned by SNMP includes a response with the timestamp on which the most recent 15-minute window collection event occurred, and the data captured within that window. Note that you cannot retrieve the output of the **show peak-concurrent-license-usage** command via SNMP.

See the **MIB Guide** for a detailed reference of the applicable SNMP OIDs.

HDR

You can access the data captured by this feature using the system's HDR feature. This requires that you enable collection on the **latest-peak-license-usage** HDR group. This data provided by this function is equivalent to that collected available using SNMP.

If the feature is disabled and you try to start the collection using, for example, the **request collection start latest-peak-license-usage** command, the system throws the following Error, does not create the applicable CSV files and does not attempt to write any of this data.

```
ORACLE# request collection start latest-peak-license-usage
Conflict
% ERROR: Collection not started because peak-concurrent-license flag is
disabled
ORACLE
```

See the **HDR Guide** for a detailed reference of the applicable HDR output files.

Adding and Deleting License Keys

Certain features may only be enabled with license keys, like royalty-based codecs. The following guidelines apply to these license keys:

- Each license key is bound to a specific Oracle Communications Session Border Controller by serial number.
- Oracle does not allow transferring a license key from one Oracle Communications Session Border Controller to another.
- Multiple license keys can be active on the same Oracle Communications Session Border Controller simultaneously.
- If a feature is covered by more than one license key, the latest expiration date applies.
- You can activate and deactivate license keys in real time.

You can request license keys via the License Codes website at http://www.oracle.com/us/support/licensecodes/acme-packet/index.html

> **Note:**
>
> For a list of features enabled with license keys in your software, see the Feature Entitlements section in your version of the Release Notes.

License Key Expiration

When a license expires, you are no longer able to use the features associated with it. The Oracle Communications Session Border Controller automatically disables all associated functionality.

To avoid a license unexpectedly expiring and therefore potentially disrupting service, you should track expiration dates and renew licenses well in advance of expiration.

Expired licenses appear in the **show features** command until you delete them, although you cannot use those features. Deleting an expired license requires that you take the same steps as you do for deleting a valid one.

Add a License Key

Once you have obtained a license key, you can add it to your Oracle Communications Session Border Controller and activate it.

1. Access the **license** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# license
ORACLE(license)#
```

2. Using the **add** command and the license key you received from Oracle, add the license to your Oracle Communications Session Border Controller.

```
ORACLE(license)# add sl25o39pvtqhas4v2r2jc1oaen9e01o21b1dmh3
```

> **Note:**
>
> Do not type **done** after you add the license. If you do, the system will return an error.

3. You can check that the license has been added by using the ACLI **show** command within the license configuration.

> **Note:**
>
> Do not type **done** before exiting the **license** configuration element.

4. Type **exit** until you return to the top-level superuser prompt.

```
ORACLE(license)# exit
ORACLE(system)# exit
ORACLE(configure)# exit
ORACLE#
```

5. Perform a save- and activate- on the configuration.

```
ORACLE#  save-config
checking configuration
-------------------------------------------------------------------------------
-----
Results of config verification:
   0 configuration error
-------------------------------------------------------------------------------
-----
Save-Config received, processing.
waiting for request to finish
Request to 'SAVE-CONFIG' has Finished,
Save complete
Currently active and saved configurations do not match!
```

```
To sync & activate, run 'activate-config' or 'reboot activate'.
ORACLE# activate-config
Activate-Config received, processing.
waiting for request to finish
Setting phy on Slot=0, Port=0, MAC=00:08:25:22:81:B0,
VMAC=00:08:25:22:81:B0
Setting phy on Slot=0, Port=1, MAC=00:08:25:22:81:B1,
VMAC=00:08:25:22:81:B1
Request to 'ACTIVATE-CONFIG' has Finished,
Activate Complete
```

Delete a License Key

You can delete a license from your Oracle Communications Session Border Controller, including licenses that have not expired. If you want to delete a license that has not expired, you need to confirm the deletion.

To delete a license from the Oracle Communications Session Border Controller:

1. Access the **license** configuration element.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# system
   ORACLE(system)# license
   ORACLE(license)#
   ```

2. Type **no** and press Enter. A list of possible licenses to delete appears.
3. Type the number corresponding to the license you want to delete and press Enter.

   ```
   selection:1
   ```

4. If the license has not expired, you will be asked to confirm the deletion.

   ```
   Delete unexpired license [y/n]?: y
   ORACLE(license)#
   ```

   > **Note:**
   >
   > Do not type **done** before leaving the **license** configuration element.

5. Type **exit** until you return to the top-level superuser prompt.

   ```
   ORACLE(license)# exit
   ORACLE(system)# exit
   ORACLE(configure)# exit
   ORACLE#
   ```

6. Perform a save- and activate- on the configuration.

   ```
   ORACLE#  save-config
   checking configuration
   ---------------------------------------------------------------------------
   -----
   ```

```
Results of config verification:
   0 configuration error
-------------------------------------------------------------------------------
-----
Save-Config received, processing.
waiting for request to finish
Request to 'SAVE-CONFIG' has Finished,
Save complete
Currently active and saved configurations do not match!
To sync & activate, run 'activate-config' or 'reboot activate'.
ORACLE# activate-config
Activate-Config received, processing.
waiting for request to finish
Setting phy on Slot=0, Port=0, MAC=00:08:25:22:81:B0,
VMAC=00:08:25:22:81:B0
Setting phy on Slot=0, Port=1, MAC=00:08:25:22:81:B1,
VMAC=00:08:25:22:81:B1
Request to 'ACTIVATE-CONFIG' has Finished,
Activate Complete
```

View Installed Features, Entitlements, and Licenses

Use the **show entitlements** command to display all self-provisioned entitlements and features enabled with license keys.

```
ORACLE# show entitlements
Provisioned Entitlements:
-------------------------
Session Border Controller Base    : enabled
Session Capacity                  : 16000
  Accounting                      : enabled
  IPv4 - IPv6 Interworking        :
  IWF (SIP-H323)                  :
  Load Balancing                  : enabled
  Policy Server                   : enabled
  Quality of Service              : enabled
  Routing                         : enabled
  SIPREC Session Recording        :
Admin Security                    :
IMS-AKA Endpoints                 : 0
IPSec Trunking Sessions           : 0
MSRP B2BUA Sessions               : 0
SRTP Sessions                     : 0

Keyed (Licensed) Entitlements
-----------------------------
LI
Transcode Codec AMR (25 AMR transcoding sessions)
Transcode Codec EVRC (25 EVRC transcoding sessions)
Transcode Codec Opus (25 OPUS transcoding sessions)
Transcode Codec SILK (25 SILK transcoding sessions)
```

Use the **show features** to display currently active features on the system. This command shows the union of features enabled with license keys and with the self-provisioning method.

```
ORACLE# show features
 Total session capacity: 16000
Enabled features:
        16000 sessions, SIP, H323, QOS, ACP, Routing, Load Balancing,
        Accounting, High Availability, LI, External BW Mgmt,
        External CLF Mgmt, External Policy Services, ENUM, NSEP RPH,
        Transcode Codec AMR (25 AMR transcoding sessions),
        Transcode Codec EVRC (25 EVRC transcoding sessions), IDS,
        IDS Advanced,
        Transcode Codec Opus (25 OPUS transcoding sessions),
        Transcode Codec SILK (25 SILK transcoding sessions)
```

Use the **licenses**' **show** command to see all features enabled by license keys.

```
ORACLE(license)# show
License #1: 16000 sessions, SIP, LI,
            Transcode Codec AMR (25 AMR transcoding sessions),
            Transcode Codec EVRC (25 EVRC transcoding sessions),
            Transcode Codec Opus (25 OPUS transcoding sessions),
            Transcode Codec SILK (25 SILK transcoding sessions)
            expires at 06:28:15 Feb 07 2020
            installed at 17:08:15 May 08 2030
```

> **Note:**
>
> Examples in this section are provided for illustration and may not reflect all available features on your system.

Setup Features on an HA Pair

An HA pair requires that you set up identical features on both systems during the same service window. Peers with mismatched features may exhibit unexpected behavior. You should carefully confirm system synchronization at every step.

This procedure uses the designations system-1 as the original active and system-2 as the original standby.

1. Confirm that system-1 and system-2 are healthy and synchronized. First check system health with the **show health** command on both systems to confirm they are in identical states and healthy.
   - Verify that both systems are in identical health with all processes synchronized with the **show health** command.

> **Note:**
>
> The following examples may not accurately portray your Oracle Communications product and version combination.

```
ORACLE-1# show health

               Media Synchronized           true
               SIP Synchronized             true
               REC Synchronized             disabled
               MGCP Synchronized            disabled
               H248 Synchronized            disabled
               XSERV Synchronized           disabled
               Config Synchronized          true
               Collect Synchronized         disabled
               RADIUS CDR  Synchronized     true
               Rotated CDRs Synchronized    true
               IPSEC Synchronized           true
               Iked Synchronized            disabled
               Active Peer Address

Redundancy Protocol Process (v3):
               State
Active
               Health                                              100
               Lowest Local Address                  169.254.1.2:9090
               1 peer(s) on 2 socket(s):
               system-2: v3, Standby, health=100, max silence=1050
                      last received from 169.254.1.1 on wancom1:0

ORACLE-2# show health
               Media Synchronized           true
               SIP Synchronized             true
               REC Synchronized             disabled
               MGCP Synchronized            disabled
               H248 Synchronized            disabled
               XSERV Synchronized           disabled
               Config Synchronized          true
               Collect Synchronized         disabled
               RADIUS CDR  Synchronized     true
               Rotated CDRs Synchronized    true
               IPSEC Synchronized           true
               Iked Synchronized            disabled
               Active Peer Address          169.254.2.2

Redundancy Protocol Process (v3):
               State
Standby
               Health                                              100
               Lowest Local Address                  169.254.1.1:9090
               1 peer(s) on 2 socket(s):
```

```
                    system-1: v3, Active, health=100, max silence=1050
                           last received from 169.254.2.2 on wancom2:0
```

Next, confirm that both the saved and running configurations across both systems are at the same version number. The following example verifies that system-1 and system-2 all share version 5 of their current and running configurations. If the configurations are out of sync, use the **save-config** and **activate-config** commands to fix this.

- Verify that the current configurations are in sync on both system-1 and system-2 with the **display-current-cfg-version** command.

```
ORACLE-1# display-current-cfg-version
Current configuration version is 5

ORACLE-2# display-current-cfg-version
Current configuration version is 5
```

- Verify that the running configurations are in sync on both system-1 and system-2 with the **display-running-cfg-version** command.

```
ORACLE-1# display-running-cfg-version
Running configuration version is 5

ORACLE-2# display-running-cfg-version
Running configuration version is 5
```

2. Self-provision features on system-1 with the **setup entitlements** command. This procedure is explained in the Setup Entitlements task, but DO NOT reboot the system at this point.
3. Save and activate the configuration on system-1.

```
ORACLE-1# save-config
checking configuration
Save-Config received, processing.
waiting for request to finish
Request to 'SAVE-CONFIG' has Finished,
Save complete
Currently active and saved configurations do not match!
To sync & activate, run 'activate-config' or 'reboot activate'.
ORACLE-1# activate-config
Activate-Config received, processing.
waiting for request to finish
Request to 'ACTIVATE-CONFIG' has Finished,
Activate Complete
```

4. Install License-key enabled features on system-1 with the **licenses** configuration element. This procedure is explained in the Add a license task, but DO NOT reboot the system at this point. Perform a save- and activate- as performed in the previous step.
5. Repeat steps 2 and 4 on system-2, with the exception of saving and activating on system-2. Saving and activating is not relevant on a system that is currently a standby. The system synchronization process include synchronizing configuration changes.

   At the end of this step, identical features are installed, synchronized, and verified both system-1 and system-2.

6. Confirm once again that system-1 and system-2 are synchronized exactly as you did in step 1.
7. Reboot the standby system-2.

```
ORACLE-2# reboot
```

8. Wait for system-2 to startup and synchronize, then confirm that system-1 and system-2 are fully synchronized as explained in step 1.
9. Trigger a switchover from system-1 so that the standby system transitions to active, and vice-versa.

```
ORACLE-1# notify berpd force
```

10. Wait while system-2 transitions to the active state, then confirm that system-1 and system-2 are fully synchronized as explained in step 1.
11. Reboot the newly-standby system-1.

```
ORACLE-1# reboot
```

12. Wait for system-1 to complete rebooting, then confirm that system-1 and system-2 are fully synchronized as explained in step 1.

    At this point both systems should be healthy, synchronized, and contain identical feature configurations.
13. If desired, trigger a switchover between the two systems in the HA node so the originally active system (system-1) assumes the active role again.

Configuration Assistant Operations

When you first log on to the Oracle Communications Session Border Controller (SBC), the system requires you to set the configuration parameters necessary for basic operation. To help you set the initial configuration with minimal effort, the SBC provides the Configuration Assistant. The Configuration Assistant, which you can run from the Web GUI or the Acme Command Line Interface (ACLI), asks you questions and uses your answers to set various parameters for managing and securing call traffic. You can use the Configuration Assistant for the initial set up as well as for subsequent changes that you want to make to the basic configuration.

The SBC provides many additional configuration and management capabilities, which do not require configuration to get the system running. You can set the additional functions to fit your deployment needs through the ACLI Configuration tree after running the Configuration Assistant.

Topics:

The Configuration Assistant Work Flow

The Oracle Communications Session Border Controller (SBC) Configuration Assistant guides you through the minimum number of steps necessary to make the software operational on the

SBC. Each step requires you to enter information or make a choice based on the configuration template that you choose before beginning the configuration work flow.

While the steps displayed in the work flow may vary from one template to another, the behavior and process for using the Configuration Assistant is consistent. Regardless of the template you choose, the Configuration Assistant informs you of any prerequisites that you need to address and allows you to review the configuration and make changes before you Activate the configuration. Go to https://www.oracle.com/technical-resources/documentation/acme-packet.html and see "Configuration Assistant Templates" to get detailed instructions for each template available.

> **Note:**
>
> In the ACLI, the Configuration Assistant work flow uses the word "deployment" to mean "template".

The process for using the Configuration Assistant includes the following steps.

Acquire a Template to Use

You can get templates from the following sources:

- Included in the software image.
- Upload a configuration from another SBC and save it locally.
- Download the latest Oracle Template Package from Oracle and save it locally. Use this method to get updated templates. Available as a compressed file (template-package.tar.gz), the download overwrites the existing templates and re-populates the Select a PBX Template and SIP Template lists. Using SFTP, save the template package to /code/configAssistantUploads.

Save the acquired template or package locally. You will select it in the Select a Deployment step.

Launch the Configuration Assistant

> **Caution:**
>
> Running the Configuration Assistant removes all of the configuration on the SBC, including the High Availability (HA) configuration. You must reconfigure HA after running the Configuration Assistant.

Log on to the SBC using the ACLI and type `run configuration-assistant`. The system displays the list of available deployments (templates).

Select a Template or Configuration for Deployment

When the Configuration Assistant prompts you to select a deployment, it displays the list of PBX side templates first followed by the list of SIP Trunk side templates. Select a PBX template and then select the corresponding SIP Trunk template. To select a template, type the number of the template that you want to use and press Enter.

After you select the templates and press Enter, the Configuration Assistant displays any Warnings, Prerequisites, and Recommendations that you might need to address before proceeding.

Configure the Prerequisites

The template you select may require prerequisites to complete before performing the configuration. When the system detects prerequisites that you need to address, the Configuration Assistant lists them. If setting any of the prerequisites requires a reboot, the system displays a confirmation message about the need to reboot. Type **y** to reboot.

After the reboot the Configuration Assistant re-starts with the most recently selected template and allows you to proceed with the configuration, if all the prerequisites are satisfied. If not, the Configuration Assistant displays the list again and the process repeats.

> **Note:**
>
> If you Quit before the reboot, the Configuration Assistant closes. When you open the Configuration Assistant again, in either the current session or a new one, the system displays a reminder to reboot.

Perform the Configuration

The configuration work flow starts after you complete the prerequisites and the system reboots. As you complete each section of the work flow, the Configuration Assistant displays the next section.

A typical work flow begins with configuring the PBX side followed by the SIP Trunk side. You must complete all of the sections for a new configuration. In an existing configuration, you can move through the sections without changing anything to get go to a section that you want to edit.

Review the Configuration

After you complete last step, the Configuration Assistant, displays the Summary page. From the Summary page, you can go back to edit any of the preceding sections. See Configuration Assistant ACLI Navigation Commands.

If you chose CSR as the certificate provisioning type, the Configuration Assistant displays the Certificate Signing Request with the Summary. Copy or download the CSR and send it to the Certificate Authority.

Apply the Configuration

When you are ready to Save and Activate the configuration, type **s** and press Enter. The Configuration Assistant displays the Epilogue page, which may list actions you need to perform for the PBX side, the SIP Trunk side, or both sides before applying the configuration. After you resolve any outstanding PBX or SIP Trunk actions, the Configuration Assistant displays a confirmation message.

- First-time configuration (new SBC)—The Configuration Assistant displays the Apply Confirmation message. Type **y**, and press Enter. The system applies the configuration and restarts.
- Previous configuration—The Configuration Assistant displays the Apply Confirmation message. Type **y**, and press Enter. The system erases the previous configuration, applies the new configuration, and restarts.

Address the Post-Configuration Tasks

- If you chose CSR as the certificate provisioning type, import the certificate after the system restarts. The name of the certificate-record must be the name of the downloaded file minus the .csr extension. For example, suppose the downloaded CSR file name is TeamsCSR.csr. The name to enter in the certificate-record configuration is TeamsCSR.
- Optional—If you want to customize your SBC deployment, you can access more configuration objects from the ACLI navigation tree. (Configuration, Monitor and Trace, Widgets, and System)

Configuration Assistant ACLI Navigation Commands

Use the following commands to navigate the within the Configuration Assistant while using the Acme Command Line Interface (ACLI).

-—Previous

?—Help. Highlight a parameter and type ? to see a description or requirement of the parameter. For example,for Realm Name the Help states that the realm name must be unique.

.—Clear

q—Quit

d—Display Summary

s—Save

g—Display the configuration

<integer>—The Configuration Assistant numbers each parameter in the template. To edit a parameter, enter its number and press Enter.

User Accounts

In addition to the two factory accounts user and admin, you may also authenticate using local accounts, RADIUS, or TACACS+.

Named SSH Keys

SSH authorized keys take precedence over other authentication methods and account types. For example, if an administrator imported Alice's SSH key into the admin class, then Alice can authenticate with `ssh alice@10.0.0.1` whether or not a local account, TACACS+ account, or RADIUS account exists. Moreover, if a local account, TACACS+ account, or RADIUS account named `alice` exists in the user class but Alice's SSH authorized-key exists in the admin class, Alice can still authenticate as an administrator because SSH keys take precedence over other authentication methods and account types. Conversely, if Alice's SSH key were imported into the user class but a local account, TACACS+ account, or RADIUS account in the admin class were created for Alice, she would by default log in as an ordinary user and not as an administrator. This happens because SSH clients usually try public key authentication before attempting password-based authentication. To authenticate using password-based authentication when public key authentication is an option, use the `-o` option:

```
ssh -o PubkeyAuthentication=no alice@10.0.0.1
```

SSH authorized keys also take precedence over the default factory accounts. If you disable the factory accounts but import an SSH key as the admin user, you can still authenticate with `ssh admin@10.0.0.1` even when factory accounts are disabled.

When removing a user from a system, remember to remove any named SSH keys.

Local User Accounts

The SBC comes with two local, factory accounts for access. System administrators may create additional local accounts for each user or administrator who needs to access the SBC. Local accounts ensure your ability to audit an individual's activity on the SBC.

When creating local accounts, you must specify the username and the user class. Usernames must be unique, and neither `user` nor `admin` may be used.

There are two user classes: `user` and `admin`. Local accounts in the user class have the same access level as the factory user account, and local accounts in the admin class have the same access level as the factory admin account.

After a second administrator account has been created, you may disable the factory user and admin accounts. The SBC requires at least one administrator account. Only administrators may delete accounts, and administrators may not delete their own account. Use the command `factory-accounts` to disable or re-enable the factory accounts.

The file `cli.audit.log` records the timestamp, the local account name, the connecting IP address, and the command run by any user or administrator.

```
2020-10-01 15:35:06.530 TaskID: 0xab7c8710, admin@10.2.2.7 : 'show users'
2020-10-01 15:36:14.112 TaskID: 0xab7c8710, alice@10.2.2.8 : 'show users'
```

Local Accounts and TACACS+

When the `tacacs-authentication-only` attribute is enabled in the `security` configuration element or when the Admin Security entitltement is enabled, authentication to a local account changes when TACACS+ is configured. If a TACACS+ server is configured and available, then authentication uses TACACS+ and the SBC rejects attempts to authenticate to local accounts. If a TACACS+ server is configured but unavailable, the SBC allows authentication to local accounts. This ensures that, when TACACS+ is configured, authentication to local accounts is only possible when the TACACS+ server is down. If no TACACS+ server is configured, local accounts are accessible.

Manage Local Accounts

Use the `local-accounts` command to create, delete, or modify individual accounts. Use the `factory-accounts` command to disable or re-enable the default user and admin accounts.

Create a Local Account

The syntax to add a local account:

```
local-accounts add <username> <class>
```

Usernames must start with a lower case letter or an underscore; use only lower case letters, digits, underscores, or dashes; and not exceed 31 characters. The two options for `<class>` are `user` and `admin`.

1. Create an account.
   To create an account for a user named Jamie:

   ```
   ORACLE# local-accounts add jamie user
   ```

   To create an account for an administrator named Jamie:

   ```
   ORACLE# local-accounts add jamie admin
   ```

2. Enter and confirm the password for the new account.
3. Save and activate the configuration.

Modify the Password of a Local Account

Local administrator accounts may change the password of any local account, but they may not change the password of the factory default accounts.

The syntax to change the password of a local account:

```
local-accounts change-password <username>
```

1. Log in as an administrator.
2. Use the `local-accounts` command to change the password of a local account.

   ```
   local-accounts change-password jamie
   ```

3. Enter the current password for that local account.
4. Enter and confirm a new password for that local account.

The SBC saves and activates the configuration.

Reset a Local Account Password

The syntax to reset a local account password:

```
local-accounts reset <username>
```

1. Log in as an administrator.
2. Reset a user's password by creating a temporary password.

   ```
   ORACLE# local-accounts reset jamie
   ```

3. Confirm you want to reset the local account password.
4. Enter and confirm the temporary password for that user.
5. Communicate the temporary password to that user.

The SBC saves and activates the configuration.

The SBC will force the user `jamie` to choose a new password the next time that user logs in.

Delete a Local Account

The syntax to delete a local account:

```
local-accounts delete <username>
```

1. Log in as an administrator.
2. Delete the account.

   ```
   ORACLE# local-accounts delete jamie
   ```

3. Confirm you want to delete the account.
4. Save and activate the configuration.
5. Delete any saved authorized keys for that user.

   ```
   ORACLE# ssh-key authorized-key delete jamie
   ```

6. Use the `show users` command to display active sessions.

   ```
   ORACLE# show users
   Index     remote-address    IdNum  duration  type         state        User
   ------------------------------------------------------------------------------
   ---
       2 10.0.0.1:59378        7849  00:01:46      ssh       priv *
   admin
       1 10.0.0.1:59373        7842  00:01:57      ssh       user
   jamie
       0 127.0.0.1             2701  04:17:39  console       user
   ```

7. Kill any active sessions of the old user.

   ```
   ORACLE# kill ssh 1
   Killing ssh session [1]
   Successfully killed session [ssh-jamie@10.0.0.1] at index[1]
   ```

Viewing Local Accounts

To view the local accounts on the SBC, use the `show configuration local-accounts` command.

```
ORACLE# show configuration local-accounts
local-accounts
        user-name                               jamie
        user-class                              user
        user-password                           ******
        last-modified-by                        admin@10.0.0.1
        last-modified-date                      2020-09-28 17:11:38
ORACLE#
```

> **Note:**
>
> The `local-accounts` argument to the show command must be written out in full.

Disable the Default Accounts

If you have created a second administrator account, you can disable the default user and admin accounts.

1. Log in as an administrator.
2. Run the `factory-accounts` command.

```
ORACLE# factory-accounts disable
```

3. Save and activate the configuration.

Re-enable the Default Accounts

If you have disabled the default user and admin accounts, you can re-enable them.

1. Run the `factory-accounts` command.

```
ORACLE# factory-accounts enable
```

2. Save and activate the configuration.

RADIUS Authentication

A security feature that extends beyond the designation of ACLI User and Superuser privileges, the User Authentication and Access control feature supports authentication using your RADIUS server(s). In addition, you can set two levels of privilege, one for all privileges and more limited set that is read-only.

User authentication configuration also allows you to use local authentication, localizing security to the SBC ACLI log-in modes. These modes are User and Superuser, each requiring a separate password.

The components involved in the RADIUS-based user authentication architecture are the SBC and your RADIUS server(s). In these roles:

- The SBC restricts access and requires authentication via the RADIUS server; the SBC communicates with the RADIUS server using either port 1812 or 1645, but does not know if the RADIUS server listens on these ports
- Your RADIUS server provides an alternative method for defining SBC users and authenticating them via RADIUS; the RADIUS server supports the VSA called ACME_USER_CLASS, which specifies what kind of user is requesting authentication and what privileges should be granted. Supported values are `admin` or `user`, and must be lowercase.

The SBC also supports the use of the Cisco Systems Inc.™ Cisco-AVPair vendor specific attribute (VSA). This attribute allows for successful administrator login to servers that do not support the Oracle authorization VSA. While using RADIUS-based authentication, the SBC authorizes you to enter Superuser mode locally even when your RADIUS server does not return the ACME_USER_CLASS VSA or the Cisco-AVPair VSA. For this VSA, the Vendor-ID is

1 and the Vendor-Type is 9. The list below shows the values this attribute can return, and the result of each:

- shell:priv-lvl=15—User automatically logged in as an administrator
- shell:priv-lvl=1—User logged in at the user level, and not allowed to become an administrator
- Any other value—User rejected

When RADIUS user authentication is enabled, the SBC communicates with one or more configured RADIUS servers that validates the user and specifies privileges. On the SBC, you configure:

- What type of authentication you want to use on the SBC
- If you are using RADIUS authentication, you set the port from which you want the SBC to send messages
- If you are using RADIUS authentication, you also set the protocol type you want the SBC and RADIUS server to use for secure communication

Although most common set-ups use two RADIUS servers to support this feature, you are allowed to configure up to six. Among other settings for the server, there is a class parameter that specifies whether the SBC should consider a specific server as primary or secondary. As implied by these designation, the primary servers are used first for authentication, and the secondary servers are used as backups. If you configure more than one primary and one secondary server, the SBC will choose servers to which it sends traffic in a round-robin strategy. For example, if you specify three servers are primary, the SBC will round-robin to select a server until it finds an appropriate one; it will do the same for secondary servers.

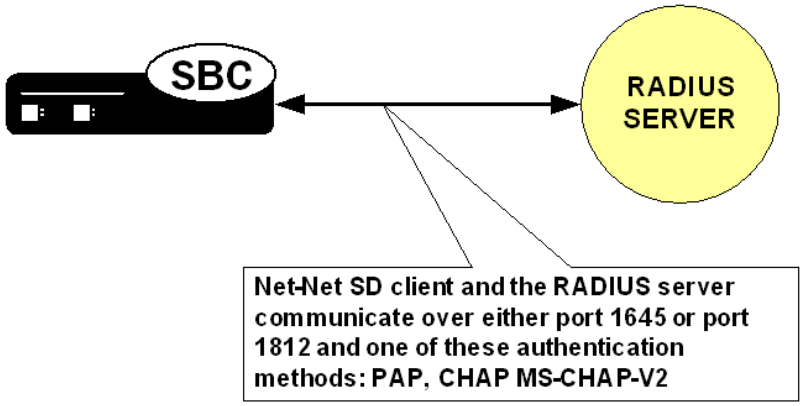
The VSA attribute assists with enforcement of access levels by containing one of the three following classes:

- None—All access denied
- User—Monitoring privileges are granted; your user prompt will resemble ORACLE>
- Admin—All privileges are granted (monitoring, configuration, etc.); your user prompt will resemble ORACLE#

After it selects a RADIUS server, the SBC initiates communication and proceeds with the authentication process. The authentication process between the SBC and the RADIUS server takes place using one of three methods, all of which are defined by RFCs:

Protocol	RFC
PAP (Password Authentication Protocol)	B. Lloyd and W. Simpson, PPP Authentication Protocols, RFC 1334, October 1992
CHAP (Challenge Handshake Authentication Protocol)	B. Lloyd and W. Simpson, PPP Authentication Protocols, RFC 1334, October 1992 W. Simpson, PPP Challenge Handshake Authentication Protocol (CHAP), RFC 1994, August 1996
MS-CHAP-V2	G. Zorn, Microsoft PPP CHAP Extensions, Version 2, RFC 2759, January 2000

> **Note:**
>
> MS-CHAP-V2 support includes authentication only; password exchange is not supported or allowed on the SBC.



PAP Handshake

For PAP, user credentials are sent to the RADIUS server include the user name and password attribute. The value of the User-Password attribute is calculated as specified in RFC 2865.

PAP Client Request Example

```
Radius Protocol
Code: Access Request (1)
  Packet identifier: 0x4 (4)
  Length: 61
  Authenticator: 0x0000708D00002C5900002EB600003F37
  Attribute value pairs
    t:User Name(1) l:11, value:"TESTUSER1"
      User-Name: TESTUSER1
    t:User Password (2) l:18, value:739B3A0F25094E4B3CDA18AB69EB9E4
    t:NAS IP Address(4) l:6, value:168.192.68.8
      Nas IP Address: 168.192.68.8(168.192.68.8)
    t:NAS Port(5) l:6, value:118751232
```

PAP RADIUS Response

```
Radius Protocol
  Code: Access Accept (2)
  Packet identifier: 0x4 (4)
  Length: 20
  Authenticator: 0x36BD589C1577FD11E8C3B5BB223748
```

CHAP Handshake

When the authentication mode is CHAP, the user credentials sent to the RADIUS server include "username," "CHAP-Password," and "CHAP-Challenge." The "CHAP-Password"

credential uses MD-5 one way. This is calculated over this series of the following values, in this order: challenge-id (which for the Oracle Communications Session Border Controller is always 0), followed by the user password, and then the challenge (as specified in RFC 1994, section 4.1).

CHAP Client Request Example

```
Radius Protocol
  Code: Access Request (1)
  Packet identifier: 0x5 (5)
  Length: 80
  Authenticator: 0x0000396C000079860000312A00006558
  Attribute value pairs
    t:User Name(1) l:11, value:”TESTUSER1”
      User-Name: TESTUSER1
    t:CHAP Password (3) l:19, value:003D4B1645554E881231ED7A137DD54FBF
    t:CHAP Challenge (60) l:18, value: 000396C000079860000312A00006558
    t:NAS IP Address(4) l:6, value:168.192.68.8
      Nas IP Address: 168.192.68.8(168.192.68.8)
    t:NAS Port(5) l:6, value:118751232
```

CHAP RADIUS Response

```
Radius Protocol
  Code: Access Accept (2)
  Packet identifier: 0x4 (4)
  Length: 20
  Authenticator: 0x3BE89EED1B43D91D80EB2562E9D65392
```

MS-CHAP-v2 Handshake

When the authentication method is MS-CHAP-v2, the user credentials sent to the RADIUS server in the Access-Request packet are:

- username
- MS-CHAP2-Response—Specified in RFC 2548, Microsoft vendor-specific RADIUS attributes
- MS-CHAP2-Challenge—Serves as a challenge to the RADIUS server

If the RADIUS authentication is successful, the Access-Accept packet from the RADIUS server must include an MS-CHAP2-Success attribute calculated using the MS-CHAP-Challenge attribute included in the Access-Request. The calculation of MS-CHAP2-Success must be carried out as specified in RFC 2759. The Oracle Communications Session Border Controller verifies that the MS-CHAP2-Success attribute matches with the calculated value. If the values do not match, the authentication is treated as a failure.

MS-CHAP-v2 Client Request Example

Some values have been abbreviated.

```
Radius Protocol
  Code: Access Request (1)
  Packet identifier: 0x5 (5)
```

```
  Length: 80
  Authenticator: 0x0000024C000046B30000339F00000B78
  Attribute value pairs
    t:User Name(1) l:11, value:”TESTUSER1”
      User-Name: TESTUSER1
    t:Vendor Specific(26) l:24, vendor:Microsoft(311)
    t:MS CHAP Challenge(11) l:18, value:0000024C000046B30000339F00000B78
    t:Vendor Specific(26) l:58, vendor:Microsoft(311)
    t:MS CHAP2 Response(25) l:52,
value:00000000024C000046B30000339F00000B78...
    t:NAS IP Address(4) l:6, value:168.192.68.8
      Nas IP Address: 168.192.68.8(168.192.68.8)
    t:NAS Port(5) l:6, value:118751232
```

MS-CHAP-v2 RADIUS Response

```
Radius Protocol
  Code: Access Accept (2)
  Packet identifier: 0x6 (6)
  Length: 179
  Authenticator: 0xECB4E59515AD64A2D21FC6D5F14D0CC0
  Attribute value pairs
    t:Vendor Specific(26) l:51, vendor:Microsoft(311)
      t:MS CHAP Success(11) l:45, value:003533s33d3845443532443135453846313...
    t:Vendor Specific(26) l:42, vendor:Microsoft(311)
      t:MS MPPE Recv Key(17) l:36, value:96C6325D22513CED178F770093F149CBBA...
    t:Vendor Specific(26) l:42, vendor:Microsoft(311)
      t:MS MPPE Send Key(16) l:36, value:9EC9316DBFA701FF0499D36A1032678143...
    t:Vendor Specific(26) l:12, vendor:Microsoft(311)
      t:MS MPPE Encryption Policy(7) l:6, value:00000001
    t:Vendor Specific(26) l:12, vendor:Microsoft(311)
      t:MS MPPE Encryption Type(8) l:6, value:00000006
```

Management Protocol Behavior

When you use local authentication, management protocols behave the same way that they do when you are not using RADIUS servers. When you are using RADIUS servers for authentication, management protocols behave as described in this section.

- SSH in pass-through mode—The “user” or admin accounts are authenticated locally, not via the RADIUS server. For all other accounts, the configured RADIUS servers are used for authentication. If authentication is successful, the user is granted privileges depending on the ACME_USER_CLASS VSA attribute.
- SSH in non-pass-through mode—When you create an SSH account on the Oracle Communications Session Border Controller, you are asked to supply a user name and password. Once local authentication succeeds, you are prompted for the ACLI user name and password. If your user ACLI name is user, then you are authenticated locally. Otherwise, you are authenticated using the RADIUS server. If RADIUS authentication is successful, the privileges you are granted depend on the ACME_USER_CLASS VSA attribute.
- SFTP in pass-through mode—If you do not configure an SSH account on the Oracle Communications Session Border Controller, the RADIUS server is contacted for authentication for any user that does not have the user name user. The Oracle

Communications Session Border Controller uses local authentication if the user name is user.

- SFTP in non-pass-through mode—The “user” or admin accounts are authenticated locally, not via the RADIUS server. For all other accounts, the configured RADIUS servers are used for authentication.

RADIUS Authentication Configuration

To enable RADIUS authentication and user access on your Oracle Communications Session Border Controller, you need to configure global parameters for the feature and then configure the RADIUS servers that you want to use.

Global Authentication Settings

To configure the global authentication settings, which apply to your configured authentication type:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **security** and press Enter.

   ```
   ORACLE(configure)# security
   ```

3. Type **authentication** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(security)# authentication
   ORACLE(authentication)#
   ```

   From here, you can view the entire menu for the authentication configuration by typing a **?**. You can set global parameters for authentication. You can also configure individual RADIUS servers; instructions for configuring RADIUS server appear in the next section.

4. **type**—Set the type of user authentication you want to use on this Oracle Communications Session Border Controller. The default value is **local**. The valid values are:

   - local | radius | tacacs

5. **protocol**—If you are using RADIUS user authentication, set the protocol type to use with your RADIUS server(s). The default is **pap**. The valid values are:

   - pap | chap | mschapv2

6. **source-port**—Set the number of the port you want to use from message sent from the Oracle Communications Session Border Controller to the RADIUS server. The default value is 1812. The valid values are:

   - 1645 | 1812 | 3799

7. **allow-local-authorization**—Set this parameter to **enabled** if you want the Oracle Communications Session Border Controller to authorize users to enter Superuser (administrative) mode locally even when your RADIUS server does not return the ACME_USER_CLASS VSA or the Cisco-AVPair VSA. The default for this parameter is **disabled**.

When enabled, the Oracle Communications Session Border Controller ignores RADIUS or TACACS restrictions and allows all users to locally enable Superuser (administrative) mode.

RADIUS Server Settings

The parameters you set for individual RADIUS servers identify the RADIUS server, establish a password common to the Oracle Communications Session Border Controller and the server, and establish trying times.

Setting the class and the authentication methods for the RADIUS servers can determine how and when they are used in the authentication process.

To configure a RADIUS server to use for authentication:

1. Access the RADIUS server submenu from the main authentication configuration:

```
ORACLE(authentication)# radius-servers
ORACLE(radius-servers)#
```

2. **address**—Set the remote IP address for the RADIUS server. There is no default value, and you are required to configure this address.
3. **port**—Set the port at the remote IP address for the RADIUS server. The default port is set to **1812**. The valid values are:
   - 1645 | 1812 | 3799
4. **state**—Set the state of the RADIUS server. Enable this parameter to use this RADIUS server to authenticate users. The default value is **enabled**. The valid values are:
   - enabled | disabled
5. **secret**—Set the password that the RADIUS server and the Oracle Communications Session Border Controller share. This password is transmitted between the two when the request for authentication is initiated; this ensures that the RADIUS server is communicating with the correct client.
6. **nas-id**—Set the NAS ID for the RADIUS server. There is no default for this parameter.
7. **retry-limit**—Set the number of times that you want the Oracle Communications Session Border Controller to retry for authentication information from this RADIUS server. The default value is **3**. The valid range is:
   - Minimum—1
   - Maximum—5

     If the RADIUS server does not respond within this number of tries, the Oracle Communications Session Border Controller marks is as dead.
8. **retry-time**—Set the amount of time (in seconds) that you want theOracle Communications Session Border Controller to wait before retrying for authentication from this RADIUS server. The default value is **5**. The valid range is:
   - Minimum—5
   - Maximum—10
9. **dead-time**—Set the amount of time in seconds before the Oracle Communications Session Border Controller retries a RADIUS server that it has designated as dead because that server did not respond within the maximum number of retries. The default is **10**. The valid range is:

- Minimum—10
- Maximum—10000

10. **maximum-sessions**—Set the maximum number of outstanding sessions for this RADIUS server. The default value is **255**. The valid range is:
    - Minimum—1
    - Maximum—255
11. **class**—Set the class of this RADIUS server as either primary or secondary. A connection to the primary server is tried before a connection to the secondary server is tried. The default value is **primary**. Valid values are:
    - primary | secondary

      The Oracle Communications Session Border Controller tries to initiate contact with primary RADIUS servers first, and then tries the secondary servers if it cannot reach any of the primary ones.

      If you configure more than one RADIUS server as primary, the Oracle Communications Session Border Controller chooses the one with which it communicates using a round-robin strategy. The same strategy applies to the selection of secondary servers if there is more than one.
12. **authentication-methods**—Set the authentication method you want the Oracle Communications Session Border Controller to use with this RADIUS server. The default value is **pap**. Valid values are:
    - all | pap | chap | mschapv2

      This parameter has a specific relationship to the global protocol parameter for the authentication configuration, and you should exercise care when setting it. If the authentication method that you set for the RADIUS server does not match the global authentication protocol, then the RADIUS server is not used. The Oracle Communications Session Border Controller simply overlooks it and does not send authentication requests to it. You can enable use of the server by changing the global authentication protocol so that it matches.
13. Use the **management-servers** attribute to identify one or more RADIUS servers available to provide AAA services.

    Servers are identified by IP address, participate in the configured **management-strategy**, and must have been previously configured as described above.

    The following example identifies three available RADIUS servers. The list is delimited by left and right parentheses, and list items are separated by space characters.

    ```
    ORACLE(authentication)# management-servers (172.30.0.6 172.30.1.8
    172.30.2.10)
    ORACLE(authentication)#
    ```

    The following example deletes the current list.

    ```
    ORACLE(authentication)# management-servers ()
    ORACLE(authentication)#
    ```
14. Save your work and activate your configuration.

TACACS+

TACACS+ (Terminal Access Controller Access Control System Plus) is a protocol originally developed by Cisco Systems, and made available to the user community by a draft RFC, *TACACS+ Protocol, Version 1.78* (draft-grant-tacacs-02.txt). TACACS+ provides AAA (Authentication, Authorization, and Accounting) services over a secure TCP connection using Port 49.

TACACS+ Overview

Like Diameter and Remote Authentication Dial-In User Service (RADIUS), SBC uses a client-server model in which a Network Access Server (NAS) acts in the client role and a TACACS+ equipped device (a daemon in TACACS+ nomenclature) assumes the server role. For purposes of the current implementation, the SBC functions as the TACACS+ client. Unlike RADIUS, which combines authentication and authorization, TACACS+ provides three distinct applications to provide finer grade access control.

Authentication is the process that confirms a user's purported identity. Authentication is most often based on a simple username/password association, but other, and more secure methods, are becoming more common. The following authentication methods are support by the current implementation: simple password, PAP (Protocol Authentication Protocol), and CHAP (Challenge Handshake Authentication Protocol).

Authorization is the process that confirms user privileges. TACACS+ can provide extremely precise control over access to system resources. In the current implementation, TACACS+ controls access to system administrative functions.

TACACS+ provides secure communication between the client and daemon by encrypting all packets. Encryption is based on a shared-secret, a string value known only to the client and daemon. Packets are encrypted in their entirety, save for a common TACACS+ header.

The cleartext header contains, among other fields, a version number, a sequence number. and a session ID. Using a methodology described in Section 5 of the TACACS+ draft RFC, the sender encrypts outbound cleartext messages by repetitively running the MD5 hash algorithm over the concatenation of the session ID, shared-secret, version number, and sequence number values, eventually deriving a virtual one-time-pad of the same length as the message body. The sender encrypts the cleartext message with an XOR (Exclusive OR) operation, using the cleartext message and virtual one-time-pad as inputs.

The message recipient, who possesses the shared-secret, can readily obtain the version number, sequence number, session ID, and message length from the cleartext header. Consequently, the recipient employs the same methodology to derive a virtual one-time-pad identical to that derived by the sender. The recipient decrypts the encrypted message with an XOR operation, using the encrypted message and virtual one-time-pad as inputs.

Details on the TACACS+ functions and configuration can be found in the *Oracle Communications Session Border Controller ACLI Configuration Guide.*.

The TACACS+ implementation is based upon the following internet draft.

draft-grant-tacacs-02.txt, *The TACACS+ Protocol Version 1.78*

Other relevant documents include

RFC 1321, *The MD-5 Message Digest Algorithm*

RFC 1334, *PPP Authentication Protocols* .

RFC 1994, *PPP Challenge Handshake Authentication Protocol (CHAP)*

> **Note:**
>
> TACACs documentation in this guide excludes per-message definitions that duplicate IETF standards documentation.

TACACS+ Authentication

The Oracle Communications Session Border Controller (SBC) uses Terminal Access Controller Access-Control System Plus (TACACS+) authentication services solely for the authentication of user accounts. Administrative users must be authenticated locally by the SBC.

The current TACACS+ implementation supports three types of user authentication: simple password (referred to as ascii by TACACS+), PAP, and CHAP.

ASCII Log In

ASCII login is analogous to logging into a standard PC. The initiating peer is prompted for a username, and, after responding, is then prompted for a password.

PAP Log In

Password Authentication Protocol (PAP) is defined in RFC 1334, *PPP Authentication Protocols*. PAP offers minimal security because passwords are transmitted as unprotected clear text. PAP log in differs from ASCII log in because the username and password are transmitted to the authenticating peer in a single authentication packet, as opposed to the two-step prompting process used in ASCII log in.

CHAP Log In

Challenge Handshake Authentication Protocol (CHAP) is defined in RFC 1994, *PPP Challenge Handshake Authentication Protocol* . CHAP is a more secure than Password Authentication Protocol (PAP) because it is based on a shared-secret (known only to the communicating peers), and therefore avoids the transmission of clear text authentication credentials. CHAP operations occur as follows.

1. After a login attempt, the authenticator tests the initiator by responding with a packet containing a challenge value — an octet stream with a recommended length of 16 octets or more.
2. Receiving the challenge, the initiator concatenates an 8-bit identifier (carried within the challenge packet header), the shared-secret, and the challenge value, and uses the shared-secret to compute an MD-5 hash over the concatenated string.
3. The initiator returns the hash value to the authenticator, who performs the same hash calculation, and compares results. If the hash values match, authentication succeeds. If hash values differ, authentication fails.

Authentication Message Exchange

All TACACS+ authentication packets consist of a common header and a message body. Authentication packets are of three types: START, CONTINUE, and REPLY.

START and CONTINUE packets are always sent by the Oracle Communications Session Border Controller, the TACACS+ client. START packets initiate an authentication session, while

CONTINUE packets provide authentication data requested by the TACACS+ daemon. In response to every client-originated START or CONTINUE, the daemon must respond with a REPLY packet. The REPLY packet contains either a decision (pass or fail), which terminates the authentication session, or a request for additional information needed by the authenticator.

Restricting Logon to TACACS

For deployments that include TACACS authentication, the Oracle Communications Session Border Controller (SBC) allows the user to configure a restriction that prevents users from logging into the system using mechanisms other than TACACS. The function that manages this restriction evaluates the availability of TACACS infrastructure and allows alternate login mechanisms if TACACS servers are unavailable due to either network or server issues.

Users who wish to restrict SBC login authentication to TACACS enable the **authentication** element's **tacacs-authentication-only** parameter. If there are two or more TACACS+ servers configured and the SBC either fails to establish a connection or an exiting connection fails, it tries to connect to the next available server. If there are two or more TACACS+ servers configured, then the system shall try to connect to all of them for a single login attempt and determine that they are all unavailable before falling back to using local login authentication.

> **Note:**
>
> The **tacacs-authentication-only** parameter is not functional on systems that have the Admin Security feature enabled.

The SBC uses all of the following criteria to determine that a TACACS+ server is available for login authentication:

- The system is able to establish a TCP connection to a TACACS+ server, AND
- TACACS+ server is responsive (e.g., no timeouts), AND
- TACACS+ server responds with an authentication PASS or FAIL status

The SBC uses any of the following criteria to determine that a TACACS+ server is unavailable for login authentication:

- TACACS+ server is unreachable, OR
- TACACS+ server response is not received (e.g., timeout), OR
- TACACS+ server responds with an authentication ERROR status

For a login attempt that reach a TACACS server but subsequently fails, the SBC rejects the login attempt with a standard login failure and records the login attempt in the Audit log.

In addition to the above and when **tacacs-authentication-only** is enabled, the SBC responds to authentication attempts that fail to reach a TACACS server by generating an SNMP trap and an associated alarm. The system also applies both the clear-alarm and clear-trap logic when TACACS again becomes available.

Traps and Associated Alarms

Traps supporting this feature, in ap-smgmt.mib, include indications that local authentication was used, and that the condition that caused local authentication is cleared.

Table 2-1 Trap and Clear Trap for TACACS Authentication Failure

Trap	Description
apSysMgmtTacacsDownLocalAuthUsedTrap 1.3.6.1.4.1.9148.3.2.6.0.88	This trap is generated when a user remotely logs into a system configured for TACACS+ authentication and is authenticated locally by the system because all of the configured and enabled TACACS+ servers have become unreachable or unresponsive
apSysMgmtTacacsDownLocalAuthUsedClearTrap 1.3.6.1.4.1.9148.3.2.6.0.89	This trap is generated when a user remotely logs into a system configured for TACACS+ authentication and is successfully authenticated (i.e., access accepted or denied) remotely by a configured and enabled TACACS+ server.

The alarm associated with this trap is APP_ALARM_TACACS_DOWN_LOCAL_AUTH_USED (327721), shown below.

```
ID      Task    Severity       First Occurred        Last Occurred
327721  69      3         2017-10-31 07:17:37  2017-10-31 07:17:37
Count   Description
1       User Bob authenticated locally due to unavailability of TACACS+
server(s)
```

Process System and Audit Log Entries

This feature writes entries into the ACLI process log files (e.g., log.acliSSH) to record each occurrence of a user remotely logging into the system because the TACACS+ servers are unreachable or unresponsive.

```
Oct 31 13:55:56.280 [AUTH] (0) authenticate_secure_user: user 'user'
authenticated locally due to unavailability of TACACS+ server.
```

This feature also writes a syslog message to record each occurrence of a user remotely logging into the system because the TACACS+ servers are unreachable or unresponsive.

```
Oct 31 13:55:56 172.41.3.90 acliSSH0@SBC1: AUTH[] authenticate_secure_user:
user 'admin' authenticated locally due to unavailability of TACACS+ server.
```

In addition, the system creates an audit log for every login attempt.

```
2017-10-31 13:55:56,ssh-
user@172.41.3.90:34362,security,login,success,authentication,,.
2017-10-31 13:55:56,ssh-
user@172.41.3.90:34362,security,login,failure,authentication,,.
```

TACACS+ Authorization

The Oracle Communications Session Border Controller uses Terminal Access Controller Access-Control System Plus (TACACS+) services to provide administrative authorization. With TACACS+ authorization enabled, each individual ACLI command issued by an admin user is authorized by the TACACS+ authorization service. The Oracle Communications Session

Border Controller replicates each ACLI command in its entirety, sends the command string to the authorization service, and suspends command execution until it receives an authorization response. If TACACS+ grants authorization, the pending command is executed; if authorization is not granted, the Oracle Communications Session Border Controller does not execute the ACLI command, and displays an appropriate error message.

The daemon's authorization decisions are based on a database lookup. Data base records use regular expressions to associate specific command string with specific users. The construction of such records is beyond the scope of this document.

TACACS+ Authorization Command & Arguments Boundary

When sending the Authorization query to the TACACS+ server, by default the SBC sends everything typed at the ACLI in the `cmd` parameter. For commands, this includes the command plus all of its arguments (for example, `cmd=show interfaces brief`). For configurations, this includes the full path of the configuration element plus its attributes and values (for example, `cmd=configure terminal security authentication type tacacs`). In the TACACS+ query, the `cmd-arg` parameter is set to `<cr>`.

The parameter **tacacs-authorization-arg-mode** changes this default behavior. Parameter values, and their behavior with respect to splitting the entry values include:

- **disabled**—Retain default behavior.
- **enabled**—Applies the fully split cmd and cmd-arg behavior to all ACLI input through TACACS+, with the exception of the **show** command. Behavior includes:
  - All **show** commands follow the pattern: `cmd=show <required-word>`, `cmd-arg=<optional-word1>`, `cmd-arg=<optional-word2>`, and so on. If no optional words are used, the `cmd-arg` parameter is set to `<cr>`.
    For example:

    ```
    cmd=show uptime, cmd-arg=<cr>
    cmd=show tacacs, cmd-arg=stats
    cmd=show running-config, cmd-arg=authentication, cmd-arg=to-file, cmd-arg=auth.conf
    ```

  - All other commands follow the pattern: `cmd=<first-word>`, `cmd-arg=<second-word>`, `cmd-arg=<third-word>`, and so on. If the command is a single-word command, the `cmd-arg` parameter is set to `<cr>`.
    For example:

    ```
    cmd=verify-config, cmd-arg=<cr>
    cmd=configure, cmd-arg=terminal
    cmd=ssh-key, cmd-arg=authorized-key, cmd-arg=import, cmd-arg=admin, cmd-arg=admin
    ```

  - All configurations follow one of two patterns:
    - For navigating the ACLI: `cmd=<full-path>`, `cmd-arg=<cr>`.
    - For setting an attribute to a value: `cmd=<full-path> <attribute>`, `cmd-arg=<value>`

For example, the following ACLI interaction produces this sequence of TACACS+ queries.

```
ORACLE# conf term
ORACLE(configure)# security
ORACLE(security)# authentication
ORACLE(authentication)# select
ORACLE(authentication)# type tacacs

cmd=configure, cmd-arg=terminal
cmd=configure terminal security, cmd-arg=<cr>
cmd=configure terminal security authentication, cmd-arg=<cr>
cmd=configure terminal security authentication select, cmd-arg=<cr>
cmd=configure terminal security authentication select type, cmd-
arg=tacacs
```

- **enabled-for-show**—Applies the fully split cmd and cmd-arg behavior to all ACLI input through TACACS+, including the **show** command.
  - All **show** commands follow the pattern: `cmd=show`, `cmd-arg=<required-word>`, `cmd-arg=<optional-word1>`, `cmd-arg=<optional-word2>`, and so on. If no optional words are used, the `cmd-arg` parameter is set to `<cr>`.
    For example:

    ```
    cmd=show, cmd-arg=uptime
    cmd=show, cmd-arg=tacacs, cmd-arg=stats
    cmd=show, cmd-arg=running-config, cmd-arg=authentication, cmd-arg=to-
    file, cmd-arg=auth.conf
    ```

  - All configurations follow one of two patterns presented above in the explanation of the **enabled** value.

Authorization Message Exchange

All Terminal Access Controller Access-Control System Plus (TACACS+) authorization packets consist of a common header and a message body. Authorization packets are of two types: REQUEST and RESPONSE.

The REQUEST packet, which initiates an authorization session, is always sent by the Oracle Communications Session Border Controller. Upon receipt of every REQUEST, the daemon must answer with a RESPONSE packet. In the current TACACS+ implementation, the RESPONSE packet must contain an authorization decision (pass or fail). The exchange of a single REQUEST and the corresponding RESPONSE completes the authorization session.

TACACS+ Accounting

The Oracle Communications Session Border Controller uses Terminal Access Controller Access-Control System Plus (TACACS+) accounting to log administrative actions. With accounting enabled, each individual ACLI command executed by an admin user is logged by the accounting service.

Accounting Message Exchange

All Terminal Access Controller Access-Control System Plus (TACACS+) accounting packets consist of a common header and a message body. Accounting packets are of two types: REQUEST and REPLY.

The REQUEST packet has three variant forms. The START variant initiates an accounting session; the STOP variant terminates an accounting session; the WATCHDOG variant updates the current accounting session. REQUEST packets are always sent by the Oracle Communications Session Border Controller (SBC). Upon receipt of every REQUEST, the daemon must answer with a REPLY packet.

A TACACS+ accounting session proceeds as follows.

1. Immediately following successful authorization of an admin user, the SBC sends an accounting REQUEST START packet.
2. The daemon responds with an accounting REPLY packet, indicating that accounting has started.
3. For each ACLI command executed by an admin user, the SBC sends an accounting REQUEST WATCHDOG packet requesting accounting of the ACLI command. As the SBC sends the WATCHDOG only after an admin user's access to the ACLI command is authorized, the accounting function records only those commands executed by the user, not those commands for which authorization was not granted.
4. The daemon responds with an accounting REPLY packet, indicating that the ACLI operation has been recorded by the accounting function.
5. Steps 3 and 4 are repeated for each authorized ACLI operation.
6. Immediately following logout (or timeout) of an admin user, the SBC sends an accounting REQUEST STOP packet.
7. The daemon responds with an accounting REPLY packet, indicating that accounting stopped.

TACACS+ Configuration

Configuration of Terminal Access Controller Access-Control System Plus (TACACS+) consists of the following steps.

1. Enable TACACS+ client services
2. Specify one or more TACACS+ servers (daemons)

Enable TACACS+ Client Services

Use the following procedure to enable specific TACACS+ client AAA services.

1. Access the **authentication** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# security
ORACLE(security)# authentication
ORACLE(authentication)#
```

2. **type** — Configure this parameter to specify the authentication protocol. The default value is **local**. Specify **tacacs** to enable the TACACS+ AAA protocol.

- **diameter** — DIAMETER authentication (not yet supported)
- **local** — authentication determinations are referred to a local database (default)
- **radius** — RADIUS authentication
- **tacacs** — TACACS+ authentication

3. **tacacs-authentication-only**— Enable this parameter to require remote authentication via TACACS+ unless the TACACS+ infrastructure is not available.
   - **disabled** (default)
   - **enabled**
4. **tacacs-authorization**— Configure this parameter to enable or disable command-based user authorization. The default value is **enabled** when the value of **type** is **tacacs**.
   - **disabled**
   - **enabled** (default)
5. **tacacs-authorization-arg-mode** — Configure this parameter to enable or disable sending TACACS+ authorization commands and their arguments separately to the TACACS+ server. The default value is **disabled**.
   - **disabled** (default)
   - **enabled**
6. **tacacs-accounting** — Configure this parameter to enable or disable accounting of admin ACLI operations. The default value is **enabled** when the value of **type** is **tacacs**.
   - **disabled**
   - **enabled** (default)
7. **server-assigned-privilege** — Configure this parameter to enable or disable a proprietary TACACS+ variant that, after successful user authentication, adds an additional TACACS+ request/reply exchange. During the exchange, the Security Gateway requests the privilege level of the newly authenticated user. In response, the TACACS+ daemon returns the assigned privilege level, either user or admin. Set this attribute to **enabled** to initiate the proprietary variant behavior. User accounts are denied access to the **enabled** command, thus barring them from configuration level commands. The default value is **disabled** (no privilege level information is exchanged).
   - **disabled** (default)
   - **enabled**
8. **management-strategy** — Configure this parameter to identify the selection algorithm used to choose among multiple available TACACS+ daemons. Retain the default value of **hunt** when only a single daemon is available.
   - **hunt** (default) — for the first transaction the Security Gateway selects the initially configured TACACS+ daemon. When that daemon is online and operational, the Security Gateway directs all AAA transactions to it. Otherwise, the Security Gateway selects the second-configured daemon. If the first and second daemons are offline or non-operational, the next-configured daemon is selected, and so on through the group of available daemons.
   - **roundrobin** — for the first transaction the Security Gateway selects the initially configured TACACS+ daemon. After completing the first transaction, it selects each daemon in order of configuration — in theory, evenly distributing AAA transactions to each daemon over time.
9. Type **done** to save your configuration.

Specify TACACS+ Servers

Use the following procedure to specify one or more TACACS+ servers (daemons).

1. Access the **tacacs-servers**configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# security
ORACLE(security)# authentication
ORACLE(authentication)# tacacs-servers
ORACLE(tacacs-servers)#
```

2. Use the **address** attribute to specify the IP address of this TACACS+ daemon.

```
ORACLE(tacacs-servers)# address 172.30.0.6
ORACLE(tacacs-servers)#
```

3. Use the **port** attribute to identify the daemon port that receives TACACS+ client requests.

   Provide a port number within the range 1025 through 65535, or retain the default value, 49, the well-known TACACS+ port.

```
ORACLE(tacacs-servers)# port 49
ORACLE(tacacs-servers)#
```

4. Use the **state** attribute to specify the availability of this TACACS+ daemon.

   Select enabled (the default) or disabled.

   Only TACACS+ daemons that are in the enabled state are considered when running the server-selection algorithm.

```
ORACLE(tacacs-servers)# state enabled
ORACLE(tacacs-servers)#
```

5. Use the **realm-id** attribute to identify the realm that provides access to this TACACS+ deamon.

```
ORACLE(tacacs-servers)# realm-id accounting
ORACLE(tacacs-servers)#
```

6. Retain the default value for the **authentication-methods** attribute to specify support for all TACACS+ authentication methods (pap, chap, and ascii).

   - ascii — simple login, the Oracle Communications Session Border Controller (OCSBC) prompts user for username and password
   - pap — similar to ascii method, but username and password are encapsulated in a PAP header
   - chap — authentication based on a shared-secret, which is not passed during the authentication process

```
ORACLE(tacacs-servers)# authentication-methods all
ORACLE(tacacs-servers)#
```

7. Use the **secret** attribute to provide the shared-secret used by the TACACS+ client and the daemon to encrypt and decrypt TACACS+ messages. The identical shared-secret must be configured on associated TACACS+ clients and daemons.

   Enter a 16-digit string, and ensure that the identical value is configured on the TACACS+ daemon.

   ```
   ORACLE(tacacs-servers)# secret 1982100754609236
   ORACLE(tacacs-servers)#
   ```

8. Use the **dead-time** attribute to specify, in seconds, the quarantine period imposed upon TACACS+ daemons that become unreachable. Quarrantined servers are not eligible to participate in the server-selection algorithm.

   Supported values are integers within the range 10 through 10000 seconds, with a default value of 10 .

   ```
   ORACLE(tacacs-servers)# dead-interval 120
   ORACLE(tacacs-servers)#
   ```

9. Type **done** to save your configuration.
10. Repeat Steps 1 through 10 to configure additional TACACS+ daemons.

    > **Note:**
    >
    > After configuring TACACS+ daemons, complete TACACS+ configuration by compiling a list of available deamons.

11. From superuser mode, use the following command sequence to access authentication configuration mode.

    ```
    ORACLE# configure terminal
    ORACLE(configure)# security
    ORACLE(security)# authentication
    ORACLE(authentication)#
    ```

12. Use the **management-servers** attribute to identify one or more TACACS+ servers available to provide AAA services.

    Servers are identified by IP address, participate in the configured **management-strategy**, and must have been previously configured as described above.

    The following example identifies three available TACACS+ servers. The list is delimited by left and right parentheses, and list items are separated by space characters.

    ```
    ORACLE(authentication)# management-servers (172.30.0.6 172.30.1.8
    172.30.2.10)
    ORACLE(authentication)#
    ```

    The following example deletes the current list.

    ```
    ORACLE(authentication)# management-servers ()
    ORACLE(authentication)#
    ```

Managing TACACS+ Operations

Terminal Access Controller Access-Control System Plus (TACACS+) management is supported by the following utilities.

TACACS+ MIB

An Oracle proprietary MIB provides external access to Terminal Access Controller Access-Control System Plus (TACACS+) statistics.

MIB counters are contained in the apSecurityTacacsPlusStatsTable that is defined as follows.

```
SEQUENCE {
    apSecurityTacacsPlusCliCommands                Counter32
    apSecurityTacacsPlusSuccess Authentications    Counter32
    apSecurityTacacsPlusFailureAuthentications     Counter32
    apSecurityTacacsPlusSuccess Authorizations     Counter32
    apSecurityTacacsPlusFailureAuthorizations      Counter32
}
```

apSecuritysTacacsPlusStats Table (1.3.6.1.4.1.9148.3.9.9.4)

Object Name	Object OID	Description
apSecurityTacacsCliCommands	1.3.6.1.4.1.9148.3.9.1.4.3	Global counter for ACLI commands sent to TACACS+ Accounting
apSecurityTacacsSuccess Authentications	1.3.6.1.4.1.9148.3.9.1.4.4	Global counter for the number of successful TACACS+ authentications
apSecurityTacacsFailureAuthentications	1.3.6.1.4.1.9148.3.9.1.4.5	Global counter for the number of unsuccessful TACACS+ authentications
apSecurityTacacsSuccess Authorizations	1.3.6.1.4.1.9148.3.9.1.4.6	Global counter for the number of successful TACACS+ authorizations
apSecurityTacacsFailure Authorizations	1.3.6.1.4.1.9148.3.9.1.4.7	Global counter for the number of unsuccessful TACACS+ authorizations

SNMP Trap

SNMP traps are issued when

- a Terminal Access Controller Access-Control System Plus (TACACS+) daemon becomes unreachable
- an unreachable TACACS+ daemon becomes reachable
- an authentication error occurs
- an authorization error occurs

TACACS+ Faults

The Oracle Communications Session Border Controller (SBC) supports (TACACS+) traps to notify you of operational status. Traps from the apSysMgmt tree include:

- apSysMgmtTacacsDownTrap (1.3.6.1.4.1.9148.3.2.6.0.78) - Generated when a TACACS+ server becomes unreachable.
- apSysMgmtTacacsDownClearTrap (1.3.6.1.4.1.9148.3.2.6.0.79) - Generated when a TACACS+ server that was unreachable becomes reachable.

The SBC searches for a TACACS+ server until it finds an available one and then stops searching. However, in the TACACS+ SNMP implementation, SNMP expects the SBC to make connection attempts to all servers.

- When there is only one TACACS+ server and that server goes down, the SBC behaves normally, sending a apSysMgmtTacacsDownTrap trap when the server goes down, and a apSysMgmtTacacsDownClearTrap trap when the server comes back up.
- When there is more than one TACACS+ server and the active server goes down, an apSysMgmtTacacsDownTrap trap is sent, indicating that some servers are down and the next server is tried.
  - If all servers fail, an apSysMgmtTacacsDownTrap is sent indicating that all servers are down.
  - If one of the servers comes back up while the rest are still down, an apSysMgmtTacacsDownTrap is sent indicating that some servers are still down.

Traps from the apSecurity tree include:

- apSecurityTacacsFailureNotification (1.3.6.1.4.1.9148.3.9.3.1.0.4) - Generated when the system detects TACACS daemon reachability changes as well as TACACS authentication and authorization errors.
- apSecurityTacacsDownLocalAuthUsedTrap (1.3.6.1.4.1.9148.3.9.3.9.0.1) - Generated when a user remotely logs into a system configured for TACACS+ authentication and is authenticated locally by the system because all of the configured and enabled TACACS+ servers have become unreachable or unresponsive
- apSecurityTacacsDownLocalAuthUsedClearTrap (1.3.6.1.4.1.9148.3.9.3.9.0.2) - Generated when a user remotely logs into a system configured for TACACS+ authentication and is successfully authenticated (i.e., access accepted or denied) remotely by a configured and enabled TACACS+ server.

ACLI show Command

The **show tacacs stats** command displays the following statistics.

- number of ACLI commands sent for TACACS+ accounting
- number of successful TACACS+ authentications
- number of failed TACACS+ authentications
- number of successful TACACS+ authorizations
- number of failed TACACS+ authentications
- the IP address of the TACACS+ daemon used for the last transaction

TACACS+ Logging

All messages between the Oracle Communications Session Border Controller and the Terminal Access Controller Access-Control System Plus (TACACS+) daemon are logged in a clear text format, allowing an admin user to view all data exchange, except for password information.

TACACS+ over IKEv2/IPsec

You can configure the SBC to connect to a TACACS server over an IKEv2/IPsec secured connection. This communication must occur over the management interface wancom0. The **ikev2-ipsec-wancom0-params** element enables this configuration.

Before configuring the **ikev2-ipsec-wancom0-params** element, make sure you have an IPsec license installed. Then create the default **ike-config** element.

```
ORACLE# configure terminal
ORACLE(configure)# security
ORACLE(security)# ike
ORACLE(ike)# ike-config
ORACLE(ike-config)# select
ORACLE(ike-config)# done
```

This procedure ensures that IKEv2 is set globally on the SBC.

When booting up, the SBC reads the **ikev2-ipsec-wancom0-params** configuration element. If this element does not exist, no action is taken. If the element exists and **auto** is set to **ondemand**, an IKEv2/IPsec connection is set up between the SBC and the peer specified in the **remoteip** attribute. The SBC can also act as a responder.

The SBC can authenticate to its IKEv2 peer with an X.509 certificate or a pre-shared key (PSK). To use a PSK:

1. Set the **authby** attribute to **secret**.
2. Set the **shared-password** attribute to your PSK.

To use an X.509 certificate:

1. Review the TLS chapter in the *Configuration Guide*.
2. Create a **certificate-record** for the SBC.
3. Under **security**, **ike**, configure an **ike-certificate-profile** for the SBC.

> **Note:**
>
> The **identity** attribute should match the Subject Alternative Name of the SBC's end-entity certificate.

4. Under **security**, **ikev2-ipsec-wancom0-params**, set **local-certificate-profile-identity** to the **identity** attribute of your previously configured **ike-certificate-profile** for the local peer.
5. Set **authby** to **rsasig**.
6. Set **remote-certificate-identity** to the identity (email address, IP address, FQDN, DNS, or URI) of the remote peer.

> **Note:**
>
> The value should match the Subject Alternative Name of the remote peer's certificate.

Use the following commands to monitor the IKEv2/IPsec connections to the SBC's wancom0 port:

```
show security ipsec wancom0 <sad | spd | tunnels>
show security ike wancom0 <error-stats | sad>
```

Secure wancom0 with IKEv2/IPsec

You can secure TACACS or RADIUS authentication to the management wancom0 interface by tunneling your authentication protocol over IKEv2/IPsec.

1. Navigate to the **ikev2-ipsec-wancom0-params** element.

   ```
   ORACLE# conf term
   ORACLE(configure)# security
   ORACLE(security)# ikev2-ipsec-wancom0-params
   ORACLE(ikev2-ipsec-wancom0-params)#
   ```

2. **name**—Provide a name for this configuration element.

   For example:

   ```
   ORACLE(ikev2-ipsec-wancom0-params)# name SecureTacacs
   ```

3. **remoteip**—Enter the IPv4 or IPv6 address of the remote peer.
4. **remotesubnet**—Enter the IPv4 or IPv6 subnet of the remote peer.

   Omit the number of bits for an exact match. For example, 10.1.1.1 is the same thing as 10.1.1.1/32.

5. **remoteproto**—Keep the default value of ALL or select the remote peer's transport protocol that will be protected within the IPsec tunnel.

   If running TACACS+ over IKEv2/IPsec, you can select TCP because TACACS+ uses TCP as its transport protocol.

6. **remoteport**—Keep the default 0 to match any port or select the port which the remote peer will use to communicate within the IPsec tunnel.

   The default TACACS+ port is 49.

7. **localip**—Confirm the IP address is the SBC's wancom0 IP address.
8. **localsubnet**—Enter the subnet of the local peer.

   This value defaults to a /32 for IPv4 or a /128 for IPv6.

9. **localproto**—Keep the default value of ALL or select the transport protocol of the local peer.

   This is the transport protocol you're going to protect within the tunnel. If running TACACS+ over IKEv2/IPsec, select TCP because TACACS+ uses TCP as its transport protocol. This should be the same value as **remoteproto**.

10. **localport**—Keep the default 0 or select the port that the local peer will communicate on.

    Enter 0 to use ephemeral ports when the SBC acts as a TACACS+ client.

11. **auto**—Keep the default **ondemand** to establish IKEv2/IPsec tunnels on demand.
12. Confirm that the remote peer accepts the default algorithms specified in the **ike-algorithms**, **ipsec-protocol**, and **ipsec-algorithms** attributes.

13. **authby**—Specify how the two peers should authenticate to each other.

    Use **rsasig** for X.509 certificates and use **secret** for a PSK.

14. **shared-password**—If you set **authby** to **secret**, enter a passphrase.

15. **local-certificate-profile-identity**—If you set **authby** to **rsasig**, specify the **identity** attribute of your previously configured **ike-certificate-profile** element for the local peer.

16. **remote-certificate-identity**—If you set **authby** to **rsasig**, specify the email address, IP address, FQDN, DNS, or URI of the remote peer.

> **Note:**
>
> This value should match the Subject Alternate Name of the peer's certificate.

Customizing Your ACLI Settings

This section describes several ways you can customize the way you log into the ACLI and the way the ACLI displays information. Where applicable, these descriptions also contain instructions for configuration.

Disabling the Second Login Prompt

With this feature enabled, the SBC logs you in as a Superuser (i.e., in administrative mode) regardless of your configured privilege level for an SSH session. However, if you log via SSH, you still need to enter the password for local or RADIUS authentication.

Disabling the Second Login Prompt Configuration

You disable the second login prompt in the authentication configuration.

To disable the second login prompt:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **security** and press Enter.

```
ORACLE(configure)# security
ORACLE(security)#
```

3. Type **authentication** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(security)# authentication
ORACLE(authentication)#
```

4. **login-as-admin**—Set this parameter to **enabled** if you want users to be logged automatically in Superuser (administrative) mode. The default for this parameter is **disabled**.

5. Save and activate your configuration.

Persistent ACLI more Parameter

To make using the ACLI easier, the Oracle Communications Session Border Controller provides a paging feature controlled through the ACLI **cli more** command (which you can set to enabled or disabled). Disabled by default, this feature allows you to control how the Oracle Communications Session Border Controller displays information on your screen during a console or SSH session. This command sets the paging feature on a per session basis.

Customers who want to set the paging feature so that settings persist across sessions with the Oracle Communications Session Border Controller can set a configuration parameter that controls the paging feature. Enabling this parameter lets you set your preferences once rather than having to reset them each time you initiate a new session with the Oracle Communications Session Border Controller.

Persistent ACLI more Parameter Configuration

To set the persistent behavior of the ACLI more feature across sessions:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **system-config** and press Enter.

   ```
   ORACLE(system)# system-config
   ORACLE(system-config)#
   ```

   If you are adding this feature to an existing configuration, you need to select the configuration (using the ACLI **select** command) before making your changes.

4. **cli-more**—Set this parameter to **enabled** if you want the ACLI more paging feature to work persistently across console or SSH sessions with the Oracle Communications Session Border Controller. If you want to continue to set this feature on a per session basis, leave this parameter set to **disabled** (default).
5. Save and activate your configuration.

Customize the Log On Banner Message

When you want to get messaging to your Oracle Communications Session Border Controller (SBC) users, you can put your message into the optional log on banner. The log on banner is a text box that displays before the system asks users for their log on credentials.

To get your message into the log on banner, copy a text file to the log on banner field. You must name the file /code/banners/banner.txt and save it in the /code/banners directory. If that directory does not already exist on your system, the SBC creates it upon boot up.

There is no character limit. The the banner field adjusts to the quantity of text.

3
System Configuration

This chapter explains how to configure system-level functionality for the Oracle Communications Session Border Controller. Both physical and network interfaces as well as general system parameters are required to configure your Oracle Communications Session Border Controller for service. Accounting functionality, SNMP configurations, trap configurations, and host routes are optional.

The following configurations are explained in this chapter:

- General system parameters—used for operating and identification purposes. In general, the informational fields have no specific effect on services, but are important to keep populated. The default gateway parameter is included here. It requires special attention since its configuration is dependent on the type of traffic the Oracle Communications Session Border Controller is servicing.
- Physical and network interfaces—enables the Oracle Communications Session Border Controller to communicate with any network element. Interfaces are one of the most basic configurations you need to create.
- SNMP—used for monitoring system health throughout a network.
- Syslogs and Process logs—used to save a list of system events to a remote server for analysis and auditing purposes.
- Host routes—used to instruct the Oracle Communications Session Border Controller host how to reach a given network that is not directly connected to a local network interface.

Virtual SBCs

Operating the Oracle Communications Session Border Controller (SBC), as well as Oracle's other session delivery products, as a VM introduces configuration requirements that define resource utilization by the virtual machine. The applicable configuration elements allow the user to optimize resource utilization based on the application's needs and VM resource sharing. See your product and software version's Release Notes to verify your product's support for deployment as a virtual machine.

VM deployment types include:

- A standalone (not orchestrated) instance Oracle Communications Session Border Controller operating as a virtual machine running on a hypervisor
- Virtual Machine(s) deployed within private or public Cloud environments

Standalone SBC VM deployment instances supported for all platforms. Support within an orchestrated environment is dependent on orchestrator and SBC version. High Availability configurations are supported by both deployment types.

SBC configuration for VM includes settings to address:

- **media-manager** — Set media manager configuration elements to constrain bandwidth utilization, based on traffic type. See Media Manager Configuration for Virtual Machines in the Realms and Nested Realms Chapter.

- **system-config**, [*core configuration parameters*] — Set these parameters to specify CPU resources available to DoS, forwarding and transcoding processes. This configuration applies to initial deployment and tuning tasks. You may need to change the default core configuration for functionality purposes during deployment; you may decide to change core configuration for performance purposes after deployment.
- **system-config**, [**use-sibling-core-datapath**] — Enable this parameter to allow the SBC to utilize the underlying platform's CPU hyperthreading (also called SMT) capabilities for datapath cores, including Forwarding, DoS and transcoding cores. Considerations include your environment's support of the feature and its impact on your implementation. A key consideration beyond support is the ability of your platform to provide information on sibling CPUs to the SBC . The SBC supports hyperthreading of signaling cores without additional configuration.

VLAN Support

Oracle recommends that you evaluate the VLAN support of your deployment's hypervisor and interface I/O mode before implementation to ensure secure support for the transmission and receiving of VLAN-tagged traffic. Please consult your hypervisor’s vendor documentation for details.

Note that when you configure a VLAN, the SBC requires VLAN tags to be included in the packets delivered to and from the VM.

Hypervisor and cloud platform and resource requirements are version-specific. Refer to your *Release Notes* for applicable requirements, recommendations and caveats for qualified platforms.

You configure VM support for the OCSBC and the OCSR identically. This documentation refers to the OCSBC, but applies equally to the OCSR.

CPU Core Configuration

You can configure CPU core settings using **system-config** parameters. This configuration is based on the specific needs of individual implementations. These parameters allow you to set and change the number of cores you want to assign to forwarding, DoS, and transcoding functionality. The system determines which cores perform those functions automatically.

You can determine and manage your core configuration based on the services you need. The system allocates cores to signaling upon installation. You can add forwarding cores to match your needs for handling media. You can also add DoS and transcoding cores if you need those functions in your deployment. If you want to reduce the size of your SBC deployment footprint or if you do not need the maximum number of cores and amount of memory available, you can deploy the SBC virtually with fewer cores and memory requirements. For smaller scale deployments, the VNF software supports a deployment with 2 virtual cores, 2 GB RAM, 20GB storage, and 2 interfaces.

Note the following:

- By default, core 0 is always set to signaling.
- The system selects cores based on function. You cannot assign core functions.
- The system sets unassigned cores to signaling, with a maximum of 24.

> **Note:**
>
> Your hyperthreading configuration may impact these assignments.

- You must reboot the system for core configuration changes to take effect.

When you make core assignments, the (SBC) provides an error message if the system detects an issue. In addition, the system performs a check when you issue the **verify-config** command to ensure that the total number of forwarding, plus DOS, plus transcoding cores does not exceed the maximum number of physical cores. After you save and activate a configuration that includes a change to the core configuration, the system displays a prompt to remind you that a reboot is required for the changes to take place.

You can verify core configuration from the ACLI, using the **show datapath-config** command or after core configuration changes during the save and activation processes. The SBC uses the following lettering (upper- and lower-case) in the ACLI to show core assignments:

- S - Signaling
- D - DoS
- F - Forwarding
- X - Transcoding

When using hyperthreading, which divides cores into a single physical (primary) and a single logical (secondary) core, this display may differ. SBC rules for displaying cores include:

- Physical cores (no hyperthreading) in upper-case letters
- "Primary" hyperthreaded sibling cores in upper-case letters
- "Secondary" hyperthreaded sibling cores in lower-case letters
- Stale (unused) hyperthreaded cores using the lower-case letter "n"

The **system-config** element includes the following parameters for core assignment:

- **dos-cores**— Sets the number of cores the system must allocate for DOS functionality. A maximum of one core is allowed.
- **forwarding-cores**—Sets the number of cores the system must allocate for the forwarding engine.
- **transcoding-cores**—Sets the number of cores the system must allocate for transcoding. The default value is 0.
- **use-sibling-core-datapath**—Enables the SBC to utilize the platform's SMT capability, impacting how the SBC uses sibling cores.

The SBC does not have a maximum number of cores, but your deployment does, based on host resources. The system checks CPU core resources before every boot, as configuration can affect resource requirements. Examples of such resource requirement variations include:

- There are at least 2 CPUs assigned to signaling (by the system).
- If DoS is required, then there are at least 1 CPU assigned to forwarding and 1 to DoS.
- If DoS is not required, then there is at least 1 CPU assigned to forwarding.

> **Note:**
>
> Poll mode drivers, including vmxnet3, failsafe, MLX4 and Ixgbvf, only support a number of rxqueues that is a power of 2. When using these drivers, you should configure the number of forwarding cores to also be a power of 2. If there is a mismatch, the system changes the number of forwarding cores that it uses to the nearest power of 2 value. The remaining cores become stale; stale cores remain reserved by the system, but are not used.

The system performs resource utilization checks every time it boots for CPU, memory, and hard-disk to avoid configuration and resource conflicts.

Core configuration is supported by HA. For HA systems, resource utilization on the backup must be the same as the primary.

> **Note:**
>
> The hypervisor always reports the datapath CPU usage as fully utilized. This isolates a physical CPU to this work load, but may cause the hypervisor to generate a persistent alarm indicating that the VM is using an excessive amount of CPU. The alarm may trigger throttling. Oracle recommends that you configure the hypervisor monitoring appropriately, to avoid throttling.

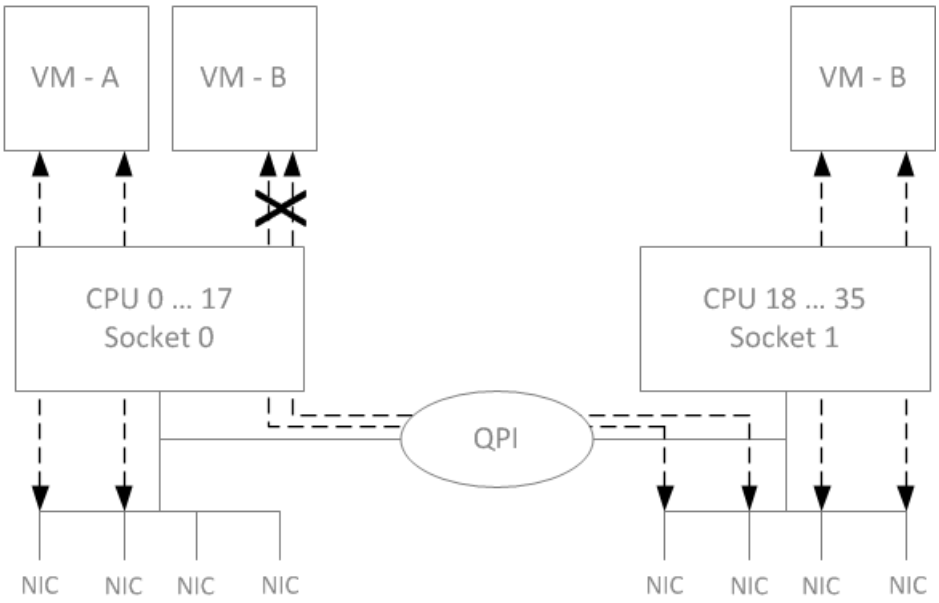
In HA environments, when the primary node's core configuration changes, the SBC raises an alarm to warn that a reboot is required. After the configuration syncs, the secondary node raises the same alarm to warn that a reboot is required.

Host Hypervisor CPU Affinity (Pinning)

Many hardware platforms have built in optimizations related to VM placement. For example, some CPU sockets may have faster local access to Peripheral Component Interconnect (PCI) resources than other CPU sockets. Users should ensure that VMs requiring high media throughput are optimally placed by the hypervisor, so that traversal of cross-domain bridges, such as QuickPath Interconnect (QPI), is avoided or minimized.

Some hypervisors implement Non-Uniform Memory Access (NUMA) topology rules to automatically enforce such placements. All hypervisors provide manual methods to perform CPU pinning, achieving the same result.

The diagram below displays two paths between the system's NICs and VM-B. Without configuring pinning, VM-B runs on Socket 0, and has to traverse the QPI to access Socket 1's NICs. The preferred path pins VM-B to Socket 1, for direct access to the local NICs, avoiding the QPI.



Oracle recommends you configure CPU affinities on the hypervisor to ensure mapping from only one virtual CPU to each physical CPU core. Learn how to configure CPU affinity and pin CPUs from your hypervisor documentation.

> **Note:**
>
> The SBC relies on multiple queues on virtual NICs to scale session capacity. Multiple queues enable the SBC to scale through multiple forwarding cores. This configuration is platform dependent: physical NIC, Hypervisor, virtual NIC, and vSwitch.

Support for Hyperthreading Datapath CPUs

You can configure the SBC to utilize hyperthreading (SMT) support for datapath cores, including forwarding, DoS and transcoding cores. This configuration allows datapath CPUs to utilize two virtual CPUs (vCPUs) as "siblings" on the same physical CPU when the platform host supports hyperthreading. Refer to your software version's Release Notes to determine platforms that support this feature.

If you do not apply this configuration, the SBC only uses one of the two logical virtual CPUs for the datapath (DPDK) cores, and marks the virtual CPU's sibling as stale. Most platforms have their own methods of determining whether hyperthreading is available; some platforms have the support, but do not expose it to the vSBC. Use of hyperthreading by vSBC datapath cores is dependent on both the availability and the visibility of the technology. A quick check to see if you are not utilizing SMT, because the host does not support SMT, does not make its CPU topology visible, or you keep the feature disabled, is that the SBC displays all core assignments in upper case.

If hyper-threading is supported and exposed by the host to the guest configuration, 8 physical cores allocated to the SBC translates to 16 logical cores. Signaling cores automatically set up as siblings. You enable this support for datapath cores using the **use-sibling-core-datapath** parameter in the **system-config** element.

Consider a use case where **use-sibling-core-datapath** remains disabled and you configure 1 forwarding core and 1 DOS core. If the host system allocates 8 vCPUs to this SBC system, the system assigns 2 cores for DPDK (or datapath) and the remaining 6 cores for signaling. This

would consume 8 physical CPUs, displayed by the **show datapath-config** command as (S-S-S-S-S-S-F-D).

By enabling hyper-threading feature in the host system's BIOS and hypervisor and the SBC, the updated core map allocation with the same datapath core configuration (1F, 1D) for 8 vCPUs in the current implementation would consume only 4 physical CPUs, displayed by the **show datapath-config** command as (S-s-S-s-F-n-D-n).

> **Note:**
>
> The Xen hypervisor displays lower-case vCPU siblings together at the end of the vCPU list. Xen pairs the first upper-case vCPU with the first lower-case vCPU, and so forth.

If you have configured CPU pinning in the hypervisor on the host, the SBC enjoys a persistent, one-to-one mapping between physical cores on the host and the vCPUs for the SBC. This can improve performance beyond what is achieved with hyperthreading alone.

> **Note:**
>
> When performing CPU pinning, neither you nor the hypervisor need to allocate cores on the Host in numerical sequence. The SBC does not require that cores be sequentially numbered.

Datapath Hyperthreading Configuration

The **use-sibling-core-datapath** parameter, within the **system-config**, supports two values, and requires that hyperthreading be both enabled and visible from the host:

- disabled (Default)— The system allocates one vCPU sibling, and marks the other as stale.
- enabled—The system allocates all vCPUs siblings.

> **Note:**
>
> When enabled, Oracle recommends you configure an even number of datapath cores for optimal performance.

Platform hosts provide more resources to a physical core on a vSBC than a hyper-threaded core. If your deployment performs Rx and Tx processing on a single core, you should consider leaving hyper-threading disabled.

The **verify-config** command notifies you about invalid configuration, including:

- You enabled the **use-sibling-core-datapath** parameter, but the CPU topology is not exposed to the vSBC. If hyper-threading is not exposed to the vSBC or enabled on the host, the **use-sibling-core-datapath** parameter is not applicable and has no impact on core allocation.
- When the number of signaling cores is less than its minimum (2)
- There is an error with CPU assignment, including improperly configured hyper-threaded sibling CPUs.

Applicable ACLI Command Output

After core configuration, you can use the **show datapath-config** and the **show platform cpu** commands to display CPU core configuration.

You can verify and troubleshoot the SBC CPU assignments using, for example, the **show datapath-config** command.

```
ORACLE# show datapath-config
     Number of cores assigned: 8
     Current core assignments: S-s-S-s-F-n-D-n
        Default hugepage size: 2 MB
     Number of 1 GB hugepages: 0
     Number of 2 MB hugepages: 980
          Total system memory: 7835 MB
 Memory reserved for datapath: 1960 MB
```

You can also use the **show platform cpu** command to see if your host provides SMT awareness.

> **Note:**
>
> This is only true for the OCSBC products.

```
ORACLE# show platform cpu
CPU count : 8
CPU speed : 2294 MHz
CPU model : Intel Core Processor ...

SMT Topology aware : True
```

Note also the CPU count output, which verifies your configuration.

Datapath CPU Hyperthreading Considerations

You need to reboot your SBC whenever you enable of disable the **use-sibling-core-datapath** parameter. You should consider whether or not to enable the feature as a means of tuning system performance. The feature does not impact or conflict with any other configuration.

You use the following criteria to decide whether or not to enable sibling datapath CPUs:

- Predictability and maintainability
- Effective utilization of all cores
- Throughput

Even if the topology is supported and known to the vSBC, you may not want to enable the new attribute. Consider the fact that the maximum number of forwarding cores is dependent on the maximum number of queue pairs supported on the network interface. An SRIOV interface with the Intel i40e driver, for example, has a limit of 4 Rx/Tx queue pairs, which means the most forwarding cores you can assign to the vSBC is 4. The result of your hyperthreading configurations are:

- Disabled: F-n-F-n-F-n-F-n—System throughput is better when disabled because the host is using 4 full physical cores. If your intent is to achieve highest concurrent session capacity, and there is no constraint on the number of cores available to the vSBC, Oracle recommends you keep this feature disabled.
- Enabled: F-f-F-f—When enabled, it only uses 2. Oracle recommends enabling the feature if your intent is to consume fewer physical cores.

Note the following guidelines when configuring hyperthreading:

- Assign the vCPUs siblings of a single physical core on the host to the same guest machine. Do not mix virtual machines on vCPU siblings.
- If hyper-threading is not supported by your platform, enabling or disabling this parameter has no impact on core allocation.
- If you enable this parameter on supported platforms, Oracle recommends that you configure the number of datapath cores for your vSBC to be divisible by 2 for optimal performance.
- If you enable Hyperthreading on an existing VM you must double-boot the SBC to accommodate the increase in the number of Signaling cores.

Supported Platforms

Of the supported hypervisors, only VMware does not expose SMT capability to the SBC. Of the supported clouds, OCI and AWS enable SMT by default and expose it to the SBC. Azure shapes that enable and expose SMT vary. Please see the Release Notes for your software version to determine which Azure Shapes apply,

System Shutdown

Use the system's **halt** command to gracefully shutdown the VNF.

```
ACMEPACKET# halt

-------------------------------------------------------
WARNING: you are about to halt this SD!
-------------------------------------------------------

Halt this SD [y/n]?:
```

See the *ACLI Reference Guide* for further information about this command.

Configuration Overview

Oracle Communications Session Border Controller Virtual Machine (VM) deployments require configuration of the VM environment and, separately, configuration of the SBC itself. VM-specific configuration on the SBC includes boot parameter configuration, enabling functionality and performance tuning.

During VM installation, you can configure vSBC boot parameters, including:

- IP address
- Host name

During VM installation, the SBC sets default functionality, assigning cores to signaling and media forwarding. If you need DoS and/or transcoding functionality, you configure the

applicable cores after installation. Applicable performance tuning configuration after deployment includes:

- Media manager traffic/bandwidth utilization tuning
- Datapath-related CPU core allocation

> **Note:**
>
> For Xen-based hypervisors, the default boot mode uses DHCP to obtain an IP address for the first management interface (wancom0) unless a static IP is provisioned. Note that DHCP on wancom0 does not support lease expiry, so the hypervisor must provide persistent IP address mapping. If persistent IP address mapping is not provided, the user must manually restart the VM whenever the wancom0 IP address changes due to a manual change or DHCP lease expiry.

Beyond installation, VM-related functional support, and VM-related tuning, you perform basic SBC configuration procedures after installation, including:

- Setting passwords
- Setup product
- Setup entitlements
- Assign Cores
- Enable hyperthreading for forwarding, DoS and transcoding cores
- Service configuration

Configure Cores

The (SBC) allows you to specify the function of the CPU cores available from the host.

Follow the steps below to set up your vSBC cores.

1. Select the **system-config**, as follows.

```
ORACLE# configuration terminal
ORACLE(configure)# system
ORACLE(system)# system-config
ORACLE(system-config)# select
```

2. Change existing core assignment settings using the **forwarding-cores**, **dos-cores** and **transcoding-cores** parameters in the preceding list. For example, to reserve a core for DoS processing:

```
ORACLE#(system-config) dos-cores 1
```

3. Type **done**, then exit, save and activate your configuration.
4. Reboot your SBC.

Configure Hyperthreading Support

The (SBC) allows you to enable the use of host hyperthreading. This parameter is applicable only when hyper-threading is supported by the platform. You can refer to the platform support list in your software version's Release Notes to identify platform applicability.

If hyper-threading is not supported by your platform, enabling or disabling this parameter has no impact on core allocation. If you enable this parameter on supported platforms, Oracle recommends that you configure the number of datapath cores for your vSBC to be divisible by 2 for optimal performance.

Follow the steps below to enable the **use-sibling-core-datapath** functionality.

1. In Superuser mode, use the following command sequence to access the **system-config**:

```
ORACLE# configuration terminal
ORACLE(configure)# system
ORACLE(system)# system-config
ORACLE(system-config)# select
```

2. Type **use-sibling-core-datapath** followed by the **enabled** value.

```
ORACLE(system-config)# use-sibling-core-datapath enabled
```

3. Type **done**, then exit, save and activate your configuration.
4. Reboot your SBC.

Session Router Session Capacity Enhancement

You can increase the Session Router's session capacity on X8-2 servers with the sip-threads option by adding it to the **system-config**. The number of sipd threads is calculated based on number of CPUs available and hence you can spawn more sip-threads with this option.

- Default: Based on the number of CPUs
- Values: Min: 1 / Max: 30

Enabling the sip-threads option

To enable this option:

```
ORACLE(system-config)# options +sip-threads=value
```

If you type the option without the plus sign, you overwrite any previously configured options. To append the new option to the options list, prepend the new option with a plus sign as shown in the previous example.

> **Note:**
>
> Contact Oracle Support for assistance with setting the sip-threads option.

General System Information

This section explains the parameters that encompass the general system information on a Oracle Communications Session Border Controller.

System Identification

Global system identification is used primarily by the Oracle Communications Session Border Controller to identify itself to other systems and for general identification purposes.

Connection Timeouts

It is important to set administrative session timeouts on the Oracle Communications Session Border Controller for security purposes. If you leave an active configuration session unattended, reconfiguration access is left open to anyone. By setting a connection timeout, only a short amount of time needs to elapse before the password is required for Oracle Communications Session Border Controller access.

Timeouts determine the specified time period that must pass before an administrative connection is terminated. Any subsequent configuration activity can only be performed after logging in again to the Oracle Communications Session Border Controller. The timeout parameter can be individually specified for SSH sessions and for console port sessions.

After the SSH timeout passes, the SSH session is disconnected. You must use your SSH program to log in to the Oracle Communications Session Border Controller once again to perform any further configuration activity.

After the console timeout passes, the console session is disconnected. The current session ends and you are returned to the login prompt on the console connection into the Oracle Communications Session Border Controller.

Cluster Member Graceful Shutdown

When it becomes necessary to temporarily remove an Oracle Communications Session Border Controller (OCSBC) from active service, and make it available only for administrative purposes, the user issues a **set-system-state offline** ACLI command. The OCSBC begins a graceful shutdown. The shutdown is graceful in that active calls and registrations are not affected, but new calls and registrations are rejected except as discussed below. When the user issues the command, the OCSBC goes into **becoming offline** mode. Once there are no active SIP sessions and no active SIP registrations in the system, the OCSBC transitions to **offline** mode. If the OCSBC is a member of a cluster, the offline status is communicated when the user issues the **set-system-state offline** command, and the OCSBC excludes the offline OCSBC in future endpoint (re)balancing algorithms.

The graceful shutdown procedure is limited only to SIP calls and registrations.

Detailed Description of Graceful Shutdowns with Active SIP Calls or Registrations

This is the procedure when active SIP calls or registrations are on an OCSBC.

When the system receives the **set-system-state offline** command, it transitions to **becoming offline** mode. It begins checking the number of SIP-INVITE-based sessions and the number of SIP registrations, and continues to check them when sessions complete or registrations expire while it is in **becoming offline** mode. When both counts reach zero, the system transitions to

offline mode. If the system is a member of a Oracle Communications Subscriber-Aware Load Balancer (OCSLB) Cluster, the OCSLB client on the OCSBC changes its cluster status to the **shutdown** state, and informs the OCSLB that it is **offline**. The OCSLB ceases to forward new end-points to the OCSBC and lists the OCSBC in a **shutdown** state on the OCSLB. The OCSBC continues to send heartbeat updates to the OCSLB as before.

Active calls continue normally when the OCSBC is in **becoming offline** mode. If SIP refresh registrations arrive for endpoints that have active calls, they are accepted. However, the expiry of these endpoints is reduced to the configurable **retry-after-upon-offline** timer value (in seconds) defined under **sip-config** on the OCSBC. This timer should be configured to be a much lower time interval than originally requested by the refresh registrations, so that endpoints refresh sooner and thus the registrations expire as closely as possible to when the active call ends. If the new timer value configured in **retry-after-upon-offline** is greater than the existing registration requested refresh value, or if its value is ‘0’ (unconfigured), the original registration refresh request is honored.

Refresh registrations for endpoints that do not have any active calls are rejected with a configurable response code defined in the **sip-config reg-reject-response-upon-offline** parameter. The default for this parameter is the **503 Service Unavailable** message. It includes a **Retry-After** header with a configurable timer set in **retry-after-upon-offline**. If the value of the configuration is 0 (unconfigured), the header is not included in the rejection message. Once these refreshes are rejected, OCSBC immediately removes such endpoints from its registration cache. It is a force remove. De-registrations are forwarded to the core. There is no local response. Removals are communicated to the OCSLB.

Any new calls that arrive for endpoints that currently have registration entries are not rejected. The same **retry-after-upon-offline** action is performed.

Any other SIP methods (like SUBSCRIBE or MESSAGE) intended for this endpoint is handled normally and are not rejected. Priority calls are processed as usual by the OCSBC, regardless of whether an active registration is present in the OCSBC as long as the OCSBC is in **becoming offline** state. When the OCSBC transitions to the **offline** state, even priority calls are rejected. If the priority calls cannot be forwarded to the endpoint, a **380 Alternative Service** response may be sent, depending on the OCSBC's configuration. However, when the OCSBC achieves offline mode, even priority calls are rejected. New non-priority calls coming for endpoints that are not currently registered are rejected with the **503 Service Unavailable** error message, as has always been done.

The OCSBC sends the endpoint removal requests to the OCSLB so that the OCSLB removes them from its endpoint table. If a REGISTER message comes in with multiple contacts, it’s possible that one of the contacts has an active call while others do not. In that scenario, the contact without active call has the Expires value in the Contact header changed to 0 and is forwarded to the core. When the response arrives from the core, the Contact with active call has its Expires parameter modified to the **retry-after-upon-offline** value or the UA expires value, whichever is lower. Any contact with no active calls is removed from the cache.

Eventually, all SIP calls end, and all registrations expire. The OCSBC transitions to the **offline** system state. The OCSBC continues to send heartbeat updates to the OCSLB.

At any time after the issuance of the **set-system-state offline** command, a **set-system-state online** command may be issued. If the OCSBC is in **becoming offline** mode, the process is aborted and the OCSBC again becomes **online**. The OCSBC state is forwarded to the OCSLB, and the OCSBC once again participates in the OCSLB's (re)balancing process.

High-level Procedure for Graceful OCSBC Shutdown

This section describes the graceful shutdown procedure. Details and exceptions to this procedure when there are active calls or registrations are discussed in later paragraphs. The

first six actions are performed regardless of whether or not the OCSBC is part of an Oracle Communications Subscriber-Aware Load Balancer (OCSLB) Cluster

- The OCSBC receives the **set-system-state offline** command.
- The OCSBC transitions to **becoming offline** mode.
- The OCSBC accepts calls and subscribes from registered endpoints.
- The OCSBC rejects calls from non-registered endpoints.
- The OCSBC rejects new registrations with a **503 Service Unavailable** error message.
- The OCSBC checks the number SIP INVITE based sessions and number of SIP registrations. When both counts are 0, the OCSBC transitions to the **offline** state.

> **Note:**
>
> Previous versions only looked at active SIP sessions (calls), without monitoring active SIP registrations.

If the OCSBC is part of an OCSLB Cluster:

- The OCSLB client on the OCSBC changes its cluster status to **shutdown** state.
- The OCSBC informs the OCSLB that it is offline.
- The OCSLB ceases to forward new end-points to the OCSBC and puts the OCSBC in a shutdown state.
- OCSLB continues to forward all messages for existing registered endpoints to the offline OCSBC.
- The OCSBC continues to send heartbeat updates the OCSLB as before.

Configuring General System Information

This section explains how to configure the general system parameters, timeouts, and the default gateway necessary to configure your Oracle Communications Session Border Controller.

To configure general system information:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# system
   ```

3. Type **system-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(system)# system-config
   ORACLE(system-config)#
   ```

The following is an example what a general system information configuration might look like. Parameters not described in this section are omitted below.

```
ORACLE(system-config)# show
system-config
        hostname                        test1
        description                     Example SD
        location                        Row 3, Rack 4, Slot 451
        default-gateway                 10.0.2.1
        console-timeout                 1000
        last-modified-date              2004-12-08 20:15:43
```

When showing a single-instance configuration element such as **system-config**, you must first use the **select** command to select the configuration element prior to viewing.

System Identification

You must specify identification parameters for this Oracle Communications Session Border Controller.

Set the following parameters to configure the system identification:

1. **hostname**—Set the primary hostname used to identify the system. This parameter is used by the software for informational purposes.
2. **description**—Enter a textual description of thesystem. This parameter is used for informational purposes.
3. **location**—Set a location description field for your system. This parameter is used for informational purposes. For example, you could include the site name and address of the location where the Oracle Communications Session Border Controller system chassis is located.
4. **default-gateway**—Set the default gateway for this Oracle Communications Session Border Controller. This is the egress gateway for traffic without an explicit destination. The application of your Oracle Communications Session Border Controller determines the configuration of this parameter.

Configuring Connection and Debug Logging Timeouts

Configure the timeouts for terminal sessions on this Oracle Communications Session Border Controller. These parameters are optional.

Set the following parameters to configure the connection timeouts:

1. **telnet-timeout**—Deprecated. Any value set here is ignored.
2. **console-timeout**—Set the console timeout to the number of seconds you want the Oracle Communications Session Border Controller to wait before it ends the console session. The default value is **0**. The valid range is:
   - Minimum—0
   - Maximum—65535
3. **debug-timeout**—Set the time in seconds you want to use for the debug timeout. This is the time allowed before the Oracle Communications Session Border Controller times out log levels for system processes set to debug using the ACLI **notify** and **debug** commands.

This command does not affect log levels set in your configuration (using parameters such as **system-config**, **process-log-level**) or those set using the ACLI **log-level** command.

The valid range is:

- Minimum—0
- Maximum—65535

Phy-Interfaces

Physical interfaces are device ports with which the user connects devices to networks. On the Oracle Communications Session Border Controller (SBC), the user configures the **phy-interface** element, within the **system** branch, for the SBC to use physical interfaces. This section provides an overview of the configuration, and variations of configuration based on platform of the **phy-interface** element.

Physical interface types include:

- Ethernet Management - Non-service interfaces, including:
  - Primary ethernet management - IP-based access to the Command Line Interface (CLI). The interface element is often referred to as wancom0 or eth0.
  - Backup ethernet management - Additional IP-based access to the CLI.
  - High Availability (HA) - Connects the active SBC to a redundant SBC; the redundant SBC immediately resumes signaling and media service if the active fails.
- Media - Interfaces designated for signaling and media service traffic.
- Serial - Direct interface to CLI, which also displays the system's boot sequence and alarm messaging.

The user configures the primary ethernet management and the serial interfaces using boot parameters. This ensures that those interfaces are available even if there is no configuration. The user configures media and backup ethernet management interface via the primary ethernet management interface, often referred to as either eth0 or wancom0, or the serial interface after the system boots.

Interface configuration is platform dependent, with consideration of the following platform types required for successful deployment:

- Acme Packet Platforms
- Virtual Machine Platforms
- Commercial Off the Shelf (COTS) Platforms

Ethernet Management Interfaces

The primary ethernet management interface does not use the **phy-interface** configuration element. The SBC does not display the primary ethernet management interface in the configuration. Instead, the **inet on ethernet** boot parameter sets this interface's IP address. Backup ethernet management and HA interfaces require **phy-interface** configuration.

Platform considerations include:

- Acme Packet platforms:
  - The system uses the **slot** and **port** configuration to identify the physical interface within the **phy-interface** element. Configuration recommendations include setting the **phy-interface**'s **name** parameter to a value that specifies the interface, such as s0p0 (slot 0 port 0).

  - The system defaults to an APIPA (RFC3927) address by default, which the user can change using the boot parameters.
- Virtual Machine platforms:
  - The user must map the primary ethernet management interface and set that interfaces IP address during installation.
  - The Hypervisor allows the user to map all the SBC management interfaces to be used during the install procedure.
- COTS platforms:
  - Primary management interface is platform dependent, using the platform's integrated management application, such as ILOM, to define access to the primary management interface. Users commonly configure a static IP address on the ILOM port, which defaults to DHCP, to simplify access to the SBC's serial port.
  - The **interface-mapping** tools allow the user to manage the mapping between the configured **phy-interface** and the platform's network interface cards on a per-MAC address basis.

Primary and backup ethernet management interfaces access the SBC's CLI by default. Uses can configure any or all ethernet management interfaces to carry other administrative traffic, including:

- SNMP
- SSH
- ACP/XML
- Logs sent from the Oracle Communications Session Border Controller
- Boot the Oracle Communications Session Border Controller from a remote file server

Media Interfaces

All media interfaces require a **phy-interface** element configuration. The **phy-interface** name is always required and is used in subsequent configuration, including **network-interface** and **realm**. Oracle recommends using the naming convention presented in the **interface-mapping** display. Further media **phy-interface** configuration is dependent on platform, including:

- Acme Packet platforms
  - The system uses the **slot** and **port** configuration to identify the physical interface within the **phy-interface** element.
  - Interface mapping management (MACTAB) is irrelevant.
  - The **phy-interface** configuration for special NICs, including the Enhanced Traffic Control and Transcoding Cards, is the same as standard cards.
- Virtual Machine platforms
  - The **interface-mapping** tools allow the user to manage the mapping between the configured **phy-interface** and the platform's network interface cards on a per-MAC address basis.
  - Hypervisor configuration and application performance may vary based on interface architecture. Applicable architecture examples include PCI Passthrough and Paravirtualized.
  - The **phy-interface**'s **name** parameter only specifies the name to be used in subsequent configuration.

  - The **slot**, **port**, **speed**, **duplex** and **autosense phy-interface** parameters are not relevant.
  - The Hypervisor allows the user to map all media interfaces to be used during the install procedure.
- COTS platforms
  - The **interface-mapping** tools allow the user to manage the mapping between the configured **phy-interface** and the platform's network interface cards on a per-MAC address basis.
  - The **phy-interface**'s **name** parameter only specifies the name to be used in subsequent configuration.
  - The **slot**, and **port phy-interface** parameters are not relevant.

Serial Interface

The serial interface provides direct access to the CLI. The user can configure the SBC's serial interface using boot parameters, which configure port output and speed. Platform-dependent detail includes:

- Acme Packet platforms - Serial access is available via one of two physical ports, depending on platform.
- Virtual Machine platforms - Virtual serial interface access is typically provided directly by the hypervisor. Boot parameters are irrelevant.
- COTS platforms - Virtual serial access is available from the integrated management application.

Refer to the High Availability chapter in this document for configuration description and procedures of HA interfaces. Refer to your release-specific *Installation and Platform Preparation Guide* for description and procedures on configuring boot parameters and using the **interface-mapping** tools.

Before You Configure

This section describes steps you should take prior to configuring **phy-interfaces**.

Before you configure a **phy-interface**:

1. Decide on the number and type of **phy-interfaces** you need.

   For example, you might have one media interface connecting to a private network and one connecting to the public network. You might also need to configure maintenance interfaces for HA functionality.
2. Depending on platform, determine the slot and port numbering you need to enter for the **phy-interfaces** you want to configure. Refer to the platform-specific graphics in the *Installation and Platform Preparation Guide* for slot and port numbering reference.
3. If you are configuring your platform for HA, refer to the HA Nodes documentation and follow the instructions there for setting special parameters in the **phy-interface** configuration.

Phy-Interface Configuration

This section describes how to configure **phy-interfaces**.

1. Access the **phy-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)#phy-interface
ORACLE(phy-interface)#
```

2. **name**—Set a name for the interface using any combination of characters entered without spaces. For example: **s0p0**.
3. **admin-state**—Leave the administrative state parameter set to **enabled** to receive and send traffic on this interface. Select **disabled** to prevent media and signaling from being received and sent. The default for this parameter is **enabled**.
4. **operation-type**—Select the type of **phy-interface** connection to use. Refer to the appropriate platform section to identify how this parameter corresponds to an external interface. The default value is **control**. The valid values are:
   - **media**—Use this value for configuring the media interfaces which carry production traffic.
   - **maintenance**—Use this value for configuring the management **phy-interfaces**, used for management protocols or HA.
   - **control**—This legacy parameter may also be used to configure the management **phy-interfaces**.
5. **slot**—Set the slot number for this **phy-interface**. Refer to the appropriate platform section to identify how this parameter corresponds to an external interface.
6. **port**—Set the port number for this **phy-interface**. Refer to the appropriate platform section to identify how this parameter corresponds to an external interface.
7. **auto-negotiation**—Leave this parameter set to **enabled** so that the Oracle Communications Session Border Controller and the device to which it is linked can automatically negotiate the duplex mode and speed for the link.

   If auto-negotiation is enabled, the Oracle Communications Session Border Controller begins to negotiate the link to the connected device at the duplex mode you configure. If auto-negotiation is disabled, then the Oracle Communications Session Border Controller will not engage in a negotiation of the link and will operate only at the duplex mode and speed you set. The default is **enabled**. The valid values are:
   - enabled | disabled

   Auto negotiation is a requirement for 1Gbit/sec speeds and higher, per the Ethernet Standard.
8. **duplex-mode**—Set the duplex mode. The default is **full**; this field is only used if the auto-negotiation field is set to disabled.

   Given an operating speed of 100 Mbps, full duplex mode lets both devices on a link send and receive packets simultaneously using a total bandwidth of 200 Mbps. Given the same operating speed, half duplex mode limits the devices to one channel with a total bandwidth of 100 Mbps. The valid values are:
   - half | full
9. **speed**—Set the speed in Mbps of the **phy-interfaces**; this field is only used if the auto-negotiation field is set to disabled. **100** is the default. The valid values are:
   - 10 | 100 | 1000

10. **virtual-mac**—Refer to Oracle Communications Session Border Controller High Availability (HA) documentation to learn how to set this parameter on an HA interface.
11. Type **done** to save your configuration.

Interface Utilization: Graceful Call Control, Monitoring, and Fault Management

When you enable this feature, the Oracle Communications Session Border Controller monitors network utilization of its media interfaces and sends alarms when configured thresholds are exceeded. You can also enable overload protection on a per-media interface basis, where the Oracle Communications Session Border Controller will prevent call initializations during high traffic but still allow established calls to continue if traffic passes the critical threshold you define.

Calculation Overview

When enabled to do so, the Oracle Communications Session Border Controller performs a network utilization calculation for each of its media ports. This calculation takes into account rates of receiving and transmitting data, the speed at which each is taking place, and the quality of data traversing the interface. The Oracle Communications Session Border Controller keeps statistics for each media port so it can compare previously- and newly-retrieved data. For heightened accuracy, calculations are performed with milliseconds (rather than with seconds).

Alarms

In the **phy-interface** configuration, you can establish up to three alarms per media interface—one each for minor, major, and critical alarm severities. These alarms do not have an impact on your system's health score. You set the threshold for an alarm as a percentage used for receiving and transmitting data.

For example, you might configure the following alarms:

- Minor, set to 50%
- Major, set to 70%
- Critical, Set to 90%

When the utilization percentage hits 50%, the system generates a minor alarm. At 70%, the system clears the minor alarm and issues a major one. And at 90%, the system clears the major alarm and issues a critical one. At that point, if you have overload protection enabled, the system will drop call initiations but allow in-progress calls to complete normally.

To prevent alarm thrashing, utilization must remain under the current alarm threshold for 10 seconds before the system clears the alarm and rechecks the state.

Alarm Configuration

This section shows you how to configure alarm thresholds and overload protection per media interface.

Configuring Utilization Thresholds for Media Interfaces

To configure utilization thresholds for media interfaces:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **system** and press Enter.

```
ORACLE(configure)# system
ORACLE(system)#
```

3. Type **phy-interface** and press Enter. **If you are adding this feature to an existing configuration, then remember you must select the configuration you want to edit.**

```
ORACLE(system)# phy-interface
ORACLE(phy-interface)#
```

4. Type **network-alarm-threshold** and press Enter.

```
ORACLE(phy-interface)# network-alarm-threshold
ORACLE(network-alarm-threshold)#
```

5. **severity**—Enter the severity for the alarm you want to fine for this interface: **minor** (default), **major**, or **critical**. Since the parameter defaults to minor, you must change the value if you want to define a major or critical alarm.
6. **value**—Enter the percentage of utilization (transmitting and receiving) for this interface that you want to trigger the alarm. For example, you might define a minor alarm with a utilization percentage of 50. Valid values are between 0 and 100, where 0 is the default.
7. Save your work.

Configuring Graceful Call Control

You can enable the Oracle Communications Session Border Controller to stop receiving session-initiating traffic on a media interface when the traffic for the interface exceeds the critical threshold you define for it.

To enable graceful call control:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **system** and press Enter.

```
ORACLE(configure)# system
ORACLE(system)#
```

3. Type **phy-interface** and press Enter. **If you are adding this feature to an existing configuration, then remember you must select the configuration you want to edit.**

```
ORACLE(system)# phy-interface
ORACLE(phy-interface)#
```

4. **overload-protection**—Change this parameter's value to enabled if you want to turn graceful call control on. Leave it set to disabled (default) if you do not want to use this feature.
5. Save your work.

Network Interfaces

The network interface element specifies a logical network interface. In order to use a network port on a network interface, you must configure both the **phy-interface** and the corresponding network interface configuration elements. If the network interface does not use VLANs tagging, ensure that the **sub-port-id** parameter is set to 0, the default value. When VLAN tags are used on a network interface, the valid **sub-port-id** value can range from 1-4096. The combination of the **name** parameter and the **sub-port-id** parameter must be unique in order to identify a discrete network interface.

IP Configuration

A Oracle Communications Session Border Controller network interface has standard parameters common to nearly all IP network interfaces. There are a few fields that are unique to the Oracle Communications Session Border Controller.

VLANs

VLANs are used to logically separate a single **phy-interface** into multiple network interfaces. There are several applications for this like MPLS VPNs (RFC 2547), MPLS LSPs, L2VPNs (IPSec, L2TP, ATM PVCs), reusing address space, segmenting traffic, and maximizing the bandwidth into a switch or router. The range of services and management capabilities you can implement with VPNs is huge.

The primary applications of VLANs on the Oracle Communications Session Border Controller are VPNs and peering. Several peering partners may terminate their connections to a Oracle Communications Session Border Controller on a single **phy-interface**. VLAN tags are used to segregate and correctly route the terminated traffic. The Oracle Communications Session Border Controller can support a maximum of 1024 VLANs per **phy-interface**. Ingress packets that do not contain the correct VLAN tag will be dropped. All packets exiting on an egress interface will have the VLAN tag appended to them.

The Oracle Communications Session Border Controller can be included in an MPLS network through its connectivity to a PE router, which maps a MPLS VPN label to an 802.1q VLAN tag. Each Oracle Communications Session Border Controller can terminate different 802.1q VLANs into separate network interfaces, each of which can represent a different customer VPN.

Overlapping Networks

Overlapping networks are when two or more private networks with the same addressing schemes terminate on one **phy-interface**. The problem this creates can easily be solved by using VLAN tagging. For example, two 10.x.x.x networks terminating on one Oracle Communications Session Border Controller network interface will obviously not work. The Oracle Communications Session Border Controller includes the IP Address, Subnet Mask, and 802.1q VLAN tag in its Network Interface determination. This allows Oracle Communications Session Border Controller to directly interface to multiple VPNs with overlapping address space.

Administrative Applications Over Media Interfaces

By default, the Oracle Communications Session Border Controller's ICMP, SNMP, and SSH services cannot be accessed via the media interfaces. In order to enable these services, you must explicitly configure access by identifying valid source addresses for the specific applications. Doing such uses the Oracle Communications Session Border Controller's host-in-path (HIP) functionality.

When traffic is received on media interfaces, it is scanned for ICMP, SNMP, or SSH packets. The configuration is set to identify the possible IP addresses where that traffic may be sourced from. When a match is made among packet type and source address, those packets are forwarded through the media interfaces to the processes running on the system's CPU.

Each media **network-interface**'s gateway should be configured so that off-subnet return traffic can be forwarded out the appropriate media interface. Also, it is advisable that no overlapping networks are configured between any media network interface and the administrative interfaces (wancom).

Configurable MTU Size

Configurable MTU on per network-interface basis enables the user to set a different MTU on each network interface. It also enables the user to set a system wide default MTU for IPv6 and IPv4 network interfaces. System wide defaults can be set in **system-config** configuration object by setting **ipv6-signaling-mtu** or **ipv4-signaling-mtu**. Defaults are 1500 for both IPv6 and IPv4.

These settings can be overwritten for each network interface by setting **signaling-mtu** in **network-interface** configuration object. Default is 0 – meaning use the system wide MTU.

This feature applies to all Signaling packets generated by the Oracle Communications Session Border Controller. All UDP packets greater than the MTU will be fragmented. For all TCP connections we advertise MSS (Maximum Segment Size) TCP option in accordance with the configured MTU. MSS option is sent in SYN and SYN/ACK packets to let the other side of the TCP connection know what your maximum segment size is. This ensures that no TCP packet is greater than the configured MTU.

1. MTU settings do not apply to media packets.
2. UDP: MTU settings apply only to packets sent by the Oracle Communications Session Border Controller. The Oracle Communications Session Border Controller will continue to process received packets even if they exceed to the configured MTU.
3. Security Phy (IPsec) hardware only; We subtract 100 bytes from the configured MTU to allow for extra headers added by security protocols. This happens even when Security Phy (IPsec) is in clear mode (no security is being applied). Due to hardware limitations of the Security Phy (IPsec) it only allows one MTU per physical port. The maximum MTU of all network interfaces on a given physical port will be used as the MTU for that physical port.
4. The Call Recording feature is where we make a copy of a packet, encapsulate it in an IP-in-IP header and send it to a configured Call Recording Server (CRS). When Call Recording is enabled, to allow space for IP-in-IP encapsulation we reduce the MTU of the original packets to be to be the lesser of the two options listed below.
   - Original Destination network MTU minus size of IP-in-IP header.
   - CRS network interface's MTU minus size of IP-in-IP header.

> **Note:**
>
> This will ensure that the traffic sent to the CRS will be within the MTU constraints of CRS' network-interface.

Disabling GARP and ND for out-of-subnet Addresses

You can configure the SBC to limit its use of Gratuitous Address Resolution Protocol (GARP) or Network Discovery (ND). Specifically, you can prevent the system from performing this function for each **sip-interface** that is not in the same subnet as the **network-interface** on which they operate. External systems typically reach these addresses through static routes or other routing configurations, making the use of GARP and ND unnecessary for them.

The SBC sends out a GARP or ND message, for IPv4 or IPv6 respectively, for every configured interface and VLAN during every interface initialization, HA switch over, and media link up event. When the number of configured interfaces and VLANs are large, the SBC may send thousands of these GARP or ND in a very short amount of time. Such GARP avalanches can overload the routers and switches connected to the SBC.

The SBC's GARP rate limiting feature helps to avoid overload to some extent. You can further limit the amount of GARP and ND traffic issued by the SBC when you enable the **disable-garp-out-of-subnet** parameter within the **system-config**. When enabled, this feature prevents the system from issuing GARP or ND messages for every **sip-interface** that is not in the same subnet as the **network-interface** over which they operate. Enabling this parameter also prevents the system from issuing GARP or ND messages to loopback interfaces.

Use the syntax below to enable this parameter.

```
ORACLE(system-config)#disable-garp-out-of-subnet enabled
```

This parameter is Real Time Configurable.

> **Note:**
>
> Although the **disable-garp-out-of-subnet** parameter is visible on the Subscriber Aware Load Balancer (SLB), it does not apply and has no effect on that product.

Reporting

You can refer to the log.l2resolver log for information about this feature. This log presents the total number of entries in the NDP table, the number of NDP entries chosen for GARP processing and the number of out-of-subnet interface IPs that the feature has filtered out.

Network Interface Configuration

This section explains how to access and configure network interface.

Special Considerations

Configuration changes to network interface parameters might have an impact on boot configuration parameters. After configuring the network interface, you might receive a message

indicating that you could be changing boot config parameters under the following circumstances:

- A **phy-interface** or network interface element matches the boot interface (for example, the physical port is the same as the boot port).
- The boot configuration parameters are modified, because the IPv4 address, netmask, or gateway is different from the corresponding boot configuration parameters.

You are asked if you want to continue. If you enter yes, the configuration will be saved and then the differing boot configuration parameters will be changed. If you enter no, then the configuration is not saved and the boot configuration parameters are not changed.

Configuring the **phy-interface** and **network interface** elements for the first management interface is optional because that interface, eth0, is implicitly created by a valid bootparam configuration that specifies the boot device, IPv4 address, subnet, and gateway.

Network Interfaces Configuration

This section describes how to configure a network interface.

- Access the **network-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-interface
ORACLE(network-interface)
```

IP Configuration and Identification

You must specify the identity and address for all network interfaces.

Set the following parameters to configure a network interface:

1. **name**—Set the name for the network interface. This must be the same name as the **phy-interface** to which it corresponds.
2. **description**—Enter a description of the network for easier identification.
3. **hostname**—Set the hostname (FQDN) of this network interface. This parameter is optional.
4. **ip-address**—Set the IP address of this network interface.
5. **netmask**—Set the netmask of this network interface in dotted decimal notation.
6. **gateway**—Set the gateway that this network interface uses to communicate with the next hop.
7. **sec-gateway**—Set an additional optional gateway for this network interface
8. **dns-ip-primary**—Set the DNS servers. You can set an additional two DNS servers by using the **dns-ip-backup1** and **dns-ip-backup2** parameters.
9. **dns-domain**—Set the default domain name.
10. **signaling-mtu**—Sets the MTU size for IPv4 or IPv6 transmission.

VLAN Configuration

One parameter is required to configure VLANs on a Oracle Communications Session Border Controller. The **sub-port-id** parameter located in the **network-interfaces** element adds and masks for a specific VLAN tag.

- **sub-port-id**—Enter the identification of a specific virtual interface in a **phy-interface** (e.g., a VLAN tab). If this network interface is not channelized, leave this field blank, and the value will correctly default to **0**. The **sub-port-id** is only required if the operation type is Media. The valid range is:
  - Minimum—0
  - Maximum—4095.

HIP Address Configuration

To configure administrative service functionality on a media interface, you must first define all source IP addresses in the media-interface's network that will exchange administrative traffic with the system. Next you will identify the type of administrative traffic each of those addresses will exchange.

You must configure the **gateway** parameter on this **network-interface** for administrative traffic to successfully be forwarded. You should also ensure that this network interface is not on an overlapping network as any of the administrative networks (wancoms).

Set the following parameters to configure HIP functionality on a network interface:

1. **add-hip-ip**—Configure all possible local IP address(es) to which a remote system can send administrative traffic. This parameter specifies addresses that can reply to requests. You must also configure them in a service list, such as **add-icmp-ip**, to specify the service to which they can reply. This parameter can accept multiple IP addresses. You can later remove this entry by typing **remove-hip-ip** followed by the appropriate IP address.
2. **add-ftp-ip**—This parameter has been deprecated.
3. **add-icmp-ip**—Set all possible local IP address(es) to which a remote system can ping the SBC and expect replies. You must also configure these addresses to the **add-hip-ip** parameter. You can later remove this entry by typing **remove-icmp-ip** followed by the appropriate IP address.

   For security, if the ICMP address and the hip-ip-list are not added for an address, the SBC hardware discards ICMP requests or responses for the address.

   > **Note:**
   >
   > IP address changes to the **add-icmp-ip** and **remove-icmp-ip** parameters during traffic hours may impact established calls

4. **add-snmp-ip**—Set the IP address(es) that will access the system's SNMP process. This lets SNMP traffic enter the SBC and reach the host. You can later remove this entry by typing **remove-snmp-ip** followed by the appropriate IP address.
5. **add-telnet-ip**—This parameter has been deprecated.
6. **add-ssh-ip**—Set the IP address(es) that can connect and access the system through SSH. You can later remove this entry by typing **remove-SSH-ip** followed by the appropriate IP address.

Configurable MTU Size

Configurable MTU on per network-interface basis enables the user to set a different MTU on each network interface. It also enables the user to set a system wide default MTU for IPv6 and IPv4 network interfaces. System wide defaults can be set in **system-config** configuration object by setting **ipv6-signaling-mtu** or **ipv4-signaling-mtu**. Defaults are 1500 for both IPv6 and IPv4.

These settings can be overwritten for each network interface by setting **signaling-mtu** in **network-interface** configuration object. Default is 0 – meaning use the system wide MTU.

This feature applies to all Signaling packets generated by the Oracle Communications Session Border Controller. All UDP packets greater than the MTU will be fragmented. For all TCP connections we advertise MSS (Maximum Segment Size) TCP option in accordance with the configured MTU. MSS option is sent in SYN and SYN/ACK packets to let the other side of the TCP connection know what your maximum segment size is. This ensures that no TCP packet is greater than the configured MTU.

1. MTU settings do not apply to media packets.
2. UDP: MTU settings apply only to packets sent by the Oracle Communications Session Border Controller. The Oracle Communications Session Border Controller will continue to process received packets even if they exceed to the configured MTU.
3. Security Phy (IPsec) hardware only; We subtract 100 bytes from the configured MTU to allow for extra headers added by security protocols. This happens even when Security Phy (IPsec) is in clear mode (no security is being applied). Due to hardware limitations of the Security Phy (IPsec) it only allows one MTU per physical port. The maximum MTU of all network interfaces on a given physical port will be used as the MTU for that physical port.
4. The Call Recording feature is where we make a copy of a packet, encapsulate it in an IP-in-IP header and send it to a configured Call Recording Server (CRS). When Call Recording is enabled, to allow space for IP-in-IP encapsulation we reduce the MTU of the original packets to be to be the lesser of the two options listed below.
   - Original Destination network MTU minus size of IP-in-IP header.
   - CRS network interface's MTU minus size of IP-in-IP header.

> **Note:**
>
> This will ensure that the traffic sent to the CRS will be within the MTU constraints of CRS' network-interface.

System Wide MTU Size

To change system wide MTU settings:

1. Access the **system-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# system-config
ORACLE(system-config)#
```

2. Type **select** to begin editing the **system-config** object.

```
ORACLE(system-config)# select
ORACLE(system-config)#
```

3. **ipv6-signaling-mtu** or **ipv4-signaling-mtu** Configure MTU in the system config and optionally in the network interface. Default will be 1500 bytes.

```
ORACLE(system-config)# ipv6-signaling-mtu 1500
ORACLE(system-config)# ipv4-signaling-mtu 1600
```

4. Type **done** to save your configuration.

Scheduled External Configuration Backup

You can configure the SBC to automatically back up its current backup configuration file dataDoc.gz, which is available at /code/gzConfig/, to an external SFTP server. This feature enhances system reliability by maintaining an off-system copy of your configuration and by making restoration processes faster.

You configure this backup process using the **schedule-backup** element in the **system-config**. The **schedule-backup** element includes parameters and sub-elements with which you configure your **config-backup** detail. This detail specifies how and when to perform the backups as well as **push-receiver** detail, which specifies the server to which you send your backup configuration.

The SBC provides several typical functions for this feature:

- The SBC names the configuration backup files using the format <SBCNODENAME>-YYYYMMDDHHMMSS where:
  - SBCNODENAME—The target name you configure in the SBC bootparam. If you have not configured a target name, the SBC uses the value you configure in the **hostname** parameter within the **system-config**.
    If both the target name in the bootparams and the hostname in the system-config are empty, the system uses the default string value “SBCNONAME” instead of SBCNODENAME.
  - YYYYMMDD—The date when the system created the backup.
  - HHMMSS—The timestamp when the system created the backup, in 24-hour format.
- If you configure more than one **push receiver**, the SBC pushes the configuration file to all of them sequentially.
- The SBC can retry pushing the backup file if it fails.
- The SBC stops attempting to push the backup file when it reaches your configured value for maximum number of retry attempts.
- The SBC generates an alarm and an SNMP trap if it fails to push the backup file to a configured **push receiver**.

To restore the backup configuration on the SBC, you:

- Copy the backup configuration from a target **push receiver** to the /code/bkups folder.
- Run the **restore-backup-config <Backup Filename>** command to restore the configuration.
- Save and Activate the new configuration.

Reporting

The SBC raises an alarm and issues a simultaneous SNMP trap to notify you each time access to a **push-receiver** fails. You can manually clear the alarm using the **clear-alarm** command. There is no associated clear-trap.

The alarm is named **APP_ALARM_SCHBKP_PUSH_FAIL**. The alarm uses the standard format and includes:

- Severity – Warning
- First occurrence timestamp
- Last occurrence timestamp
- Count
- Description – Config backup failed to upload to remote server Hostname: <hostname>, IP: <ipaddress>, Path: <Path>

You can access the SNMP trap using the applicable OID. The name is this trap is **apConfigPushReceiverFailureTrap**. You can access it from the apSip traps using the OID 1.3.6.1.4.1.9148.3.15.7.1.0.1. This trap is reserved for configuration backup push receiver failures only.

In addition, you can review the log.schbkpd file, which is available individually and within the **package-logfiles** package, for operational analysis and troubleshooting this feature.

Configure Scheduled Configuration Backups

This task explains how to establish an automatic, timed backup of your configuration and send it to a **push-receiver**.
Push receiver configurations establish an SFTP server to which the SBC pushes records. You can configure the SBC to include a copy of your backup configuration file as one of these records.

To configure scheduled configuration backups:

1. Access the **schedule-backup** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# system-config
ORACLE(system-config)# select
ORACLE(system-config)# schedule-backup
ORACLE(schedule-backup)#
```

2. **admin-state**—Enable or disable this configuration backup feature. This parameter is disabled by default.
   - **disabled**(default)
   - **enabled**
3. **config-backup**—Access the **config-backup** sub-element.

```
ORACLE(config-backup)#
```

4. **interval**—Specify the interval the system uses to determine when to push backups. This parameter is **weekly** by default.

- **daily**—24 hours from last backup
- **weekly**—7 days from last backup
- **monthly**—30 days from last backup

5. **retry-interval**—Specify the interval the system uses to determine when it tries to resend a configuration backup after an attempt fails. The range is 5 to 30 minutes and the default is 5 minutes.
6. **retry-count**—Specify the maximum number of times the system tries to resend a configuration backup after prior attempts fail. The range is 2 to 10 retries and the default is 5 retries.
7. **push-failure-alarm**—Enable or disable the generation of alarms and traps in case of any push-receiver failures. This alarm is of severity type Warning.
   - **enabled** (default)
   - **disabled**
8. **push-receiver**—Access the **push-receiver** sub-element.

   ```
   ORACLE(push-receiver)#
   ```

9. **address**—Enter the IPv4 address of the push receiver to which you want records sent.
   - Default: 0.0.0.0
10. **username**—Enter the username that the SBC uses when it sends records to this server.
11. **password**—Enter the password that the SBC uses when it sends records to this server.

    ```
    ORACLE(push-receiver)# password
    Enter password:
    Retype password:
    Password updated
    ORACLE(push-receiver)#
    ```

12. **data-store**—Enter the absolute path on the remote server where you want the collected data placed.
13. **protocol**—Enter the protocol used to push configuration data to the server.
    - **sftp** (default)

> **Note:**
>
> For SFTP to work, you must import the public key of the SFTP server into the SBC. See the "Manage SSH Keys" in the *ACLI Configuration Guide*.

IP Identification (ID) Field

By default, non-fragmented UDP packets generated by media interfaces have the ID field set to 0. You can configure the Oracle Communications Session Border Controller to populate this field with an incrementing value by adding the **increment-ip-id** option in the media manager. Every non-fragmented packet sent will have its ID increased by one from the previous packet sent.

Using a packet trace application, egress packets from the Oracle Communications Session Border Controller will have an ID field that appears to be incrementing. Enabling the ID field can help distinguish a retransmitted non-fragmented application layer packet from a packet retransmitted by the network layer in monitoring or lab situations.

IP Identification Field Configuration

To enable ID field generation in media-manager:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **media-manager** and press Enter.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. **options**—Set the options parameter by typing **options**, a Space, the option name **increment-ip-id** with a plus sign in front of it, and then press Enter.

   ```
   ORACLE(media-manager)# options + increment-ip-id
   ```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the realm configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

4. Save and activate your configuration.

SNMP

The Simple Network Management Protocol (SNMP) is a part of the Internet Protocol Suite, defined by the Internet Engineering Task Force (IETF). It allows you to monitor system and health conditions for an Oracle Communications Session Border Controller (SBC) through an external network management (northbound) system, such as the Oracle Communications Session Delivery Manager or an SNMP manager. The system supports SNMPv3, v2 or v1 to interface with a range of external NMS systems.

Detail on SNMP operation, configuration and data is documented in the *Oracle Communications Session Border Controller MIB Reference Guide*. The first chapter of the Oracle Communications SNMP Reference Guide provides a configuration overview and procedures. The rest of the guide serves as a reference for the MIB.

SNMP Configuration

SNMP configuration on the SBC typically includes defining:

- Administrative management information
- SNMP messaging, including:
  - Trap information—Sent by the SBC to the northbound system, similar to alarms.
  - System detail information—Collected by the northbound system from the SBC. This is typically referred to as read operation.

- System detail information—Configured by the northbound system on the SBC. This is typically referred to as write operation.

SNMP Data

You must understand SNMP data to determine your actions when you see it. SNMP data is organized into a hierarchical numbering scheme in the form of Object Identifiers (OIDs). OIDs are collected and presented within the context of Management Information Bases (MIBs). A text file external to the SBC system code called a miboid maintains a correlation between object numbers and text names. The system code and miboid numbers correlate each OID to a software or hardware construct that typically has a value and is of interest to the people who monitor them. A set of .mib text files contain the data presented to the human user, referenced by the object names, for each hierarchical information group. You get the applicable files from the device vendor and load them into SNMP managers

OID numbering is, to a large extent, defined and managed by the IETF. This management benefits equipment vendors by preventing information conflation and identifier overlaps. Similar to a MAC address, the IETF provides equipment vendors with numerical identities under which they can create their own hierarchical schemes and define their systems' SNMP information. An example of vendor-specific information is a configuration parameter's value. Similarly, the IETF maintains and shares standard numerical hierarchies used by all equipment vendors so they do not have to create them. An example of standard information is interface speed.

Syslog and Process Logs

Logging events is a critical part of diagnosing misconfigurations and optimizing operations. Oracle Communications Session Border Controllers can send both syslog and process log data to appropriate hosts for storage and analysis.

Overview

The Oracle Communications Session Border Controller generates two types of logs, syslogs and process logs. Syslogs conform to the standard used for logging servers and processes as defined in RFC 3164.

Process logs are Oracle proprietary logs. Process logs are generated on a per-task basis and are used mainly for debugging purposes. Because process logs are more data inclusive than syslogs, their contents usually encompass syslog log data.

Syslog and process log servers are both identified by an IPv4 address and port pair.

Process Log Messages

Process log messages are sent as UDP packets in the following format:

```
<file-name>:<log-message>
```

In this format, <filename> indicates the log filename and <log-message> indicates the full text of the log message as it would appear if it were written to the normal log file.

Syslog and Process Logs Configuration

This section describes how to configure syslog and process log servers.

To configure syslogs and process logs:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# system
   ```

3. Type **system-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(system)# system-config
   ORACLE(system-config)#
   ```

   From this point, you can set process log parameters. Skip to the following process log configuration section.

4. Type **syslog-server** and press Enter. The system prompt changes to let you know that you can begin configuring individual syslog parameters

   ORACLE(system-config)# **syslog-server**

   ORACLE(syslog-config)#

   From this point, you can set syslog parameters. The following is an example what an syslog and process log configuration might look like. Parameters not described in this section are omitted below.

   ```
   system-log-level              WARNING
   syslog-server
           address                       172.15.44.12
           port                          514
           facility                      4
   process-log-level             NOTICE
   process-log-ip-address        0.0.0.0
   process-log-port              0
   ```

Syslog Configuration

The Oracle Communications Session Border Controller supports multiple syslog servers. As the number of active syslog increases, the performance level of the Oracle Communications Session Border Controller may decrease. Therefore, we recommend configuring no more than 8 syslog servers.

Set the following parameters to configure syslog servers:

1. **address**—Set the IPv4 address of a syslog server.
2. **port**—Set the port portion of the syslog server. The default is **514**.
3. **facility**—Set an integer to identify a user-defined facility value sent in every syslog message from the Oracle Communications Session Border Controller to the syslog server. This parameter is used only for identifying the source of this syslog message as coming from the Oracle Communications Session Border Controller. It is not identifying an OS daemon or process. The default value for this parameter is **4**. RFC 3164 specifies valid facility values.

In software release versions prior to Release 1.2, the Oracle Communications Session Border Controller would send all syslog messages with a facility marker of 4.

4. **system-log-level**—Set which log severity levels write to the system log (filename: acmelog). The default is **WARNING**. Valid values are:
   - EMERGENCY | CRITICAL | MAJOR | MINOR | WARNING | NOTICE | INFO | TRACE | DEBUG | DETAIL

Configure the Process Log Server

Set the following parameters to configure the process log server:

1. **process-log-level**—Set the starting log level all processes running on the system use. Each individual process running on the system has its own process log. The default is **NOTICE**. Valid values: EMERGENCY | CRITICAL | MAJOR | MINOR | WARNING | NOTICE | INFO | TRACE | DEBUG | DETAIL
2. **process-log-ip-address**—Set the IPv4 address of the process log server. The default value is **0.0.0.0**, which causes the system to write log messages to the normal log file.
3. **process-log-port**—Set the port number associated with the process log server. The default value is **0**, which causes the system to write log messages to the normal log file. The valid range is: 1025-65535.

Host Routes

Host routes let you insert entries into the Oracle Communications Session Border Controller's routing table. These routes affect traffic that originates at the Oracle Communications Session Border Controller's host process. Host routes are used primarily for steering management traffic to the correct network.

When traffic is destined for a network that is not explicitly defined on a Oracle Communications Session Border Controller, the default gateway (located in the **system-config**) is used. If you try to route traffic to a specific destination that is not accessible through the default gateway, you need to add a host route. Host routes can be thought of as a default gateway override.

Certain SIP configurations require that the default gateway is located on a media interface. In this scenario, if management applications are located on a network connected to an administrative network, you will need to add a host route for management connectivity.

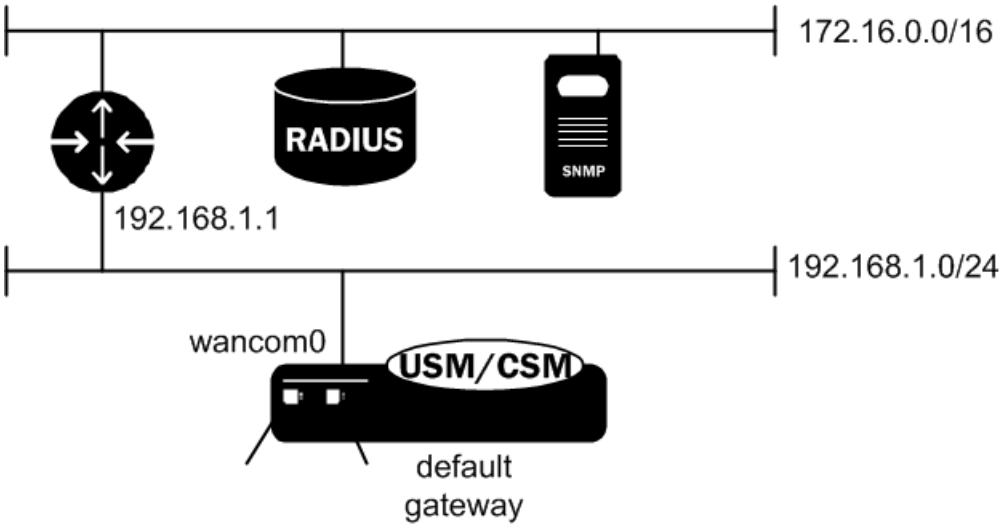
Host routes to IPv6 addresses do not support a netmask. The system uses the exact match of the dest-network parameter to target an endpoint. The system does not target IPv6 networks with a host route. For IPv4, you need to configure netmask, whereas for IPv6, SBC uses the default value set for netmask.

> **Note:**
>
> Do not configure a **host-route**, **gateway** with an address already used for any existing **network-interface**, **gateway**.

Host Routes Example

When you enable SIP signaling over media interfaces, the default gateway uses an IPv4 address assigned to a media interface. Maintenance services (SNMP and Radius) are located on a network connected to, but separate from, the 192.168.1.0/24 network on wancom0. To

route Radius or SNMP traffic to an NMS (labeled as SNMP in the following example), a host route entry must be a part of the Oracle Communications Session Border Controller configuration. The host route tells the host how to reach the 172.16.0.0/16 network. The actual configuration is shown in the example in the next section of this guide.



Host Route Configuration

To configure a host route:

1. Access the **host-route** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# host-route
ORACLE(host-route)#
```

2. **dest-network**—Set the IP address of the destination network that this host route points toward.
3. **netmask**—Set the netmask portion of the destination network for the route you are creating. The netmask is in dotted decimal notation.
4. **gateway**—Set the gateway that traffic destined for the address defined in the first two elements should use as its first hop.
5. Type **done** to save your configuration.

Setting Holidays in Local Policy

This section explains how to configure holidays on the Oracle Communications Session Border Controller.

You can define holidays that the Oracle Communications Session Border Controller recognizes. Holidays are used to identify a class of days on which a local policy is enacted. All configured holidays are referenced in the **local-policy-attributes** configuration subelement as an H in the **days-of-week** parameter. Because holidays are entered on a one-time basis per year, you must configure a new set of holidays yearly.

Holidays Configuration

To configure holidays:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-router-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# session-router-config
   ORACLE(session-router-config)#
   ```

4. Type **holidays** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router-config)# holidays
   ORACLE(session-router-holidays)#
   ```

   From this point, you can configure the holidays subelement. To view all holidays parameters, enter a **?** at the system prompt.

   ```
   holiday
                   date                            2005-01-01
                   description                     New Years Day
   ```

   To configure a holiday, add an entry for the following parameters in the holidays element:

5. **date**—Enter the holiday's date in YYYY-MM-DD format.
6. **description**—Enter a short description for the holiday you are configuring. If the description contains words separated by spaces, enter the full description surrounded by quotation marks.

Opening TCP Ports 3000 and 3001

This section explains how to open TCP ports 3000 and 3001 primarily for use with an element manager.

- TCP ports 3000 (used when notify commands are issued remotely, i.e. via an element management system) and 3001 (used for remote configuration, i.e. via an element management system), can be enabled or disabled in the system configuration

This configuration is not RTC enabled, so you must reboot your Oracle Communications Session Border Controller for changes to take effect.

Enable System to Connect to SDM

To control TCP ports 3000 and 3001 in the system configuration:

1. Access the **security-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# security
ORACLE(security)# security-config
ORACLE(security-config)#
```

2. Type **select** to begin editing the **system-config** object.

```
ORACLE(system-config)# select
ORACLE(system-config)#
```

3. The parameter controlling ports 3000 and 3001 is called remote-control, and its default is enabled. To disable the ports, set this parameter to disabled.

```
ORACLE(system-config)# remote-control disabled
```

4. Type **done** to save your configuration.
5. Reboot your Oracle Communications Session Border Controller. Type a **y** and press Enter to reboot.

```
ORACLE# reboot
----------------------------------------
WARNING: you are about to reboot this SD!
----------------------------------------
Reboot this SD [y/n]?:y
```

DNS on the OCSBC

DNS service is best known for providing resolution of internet domain names to IP addresses. Domain names are easy to remember, but connections require IP addresses. DNS deployments can also provide more comprehensive services, if required. For example, the a DNS client may need the resolution of multiple IP addresses to a single domain name, or the types of service provided by a given server. The Oracle Communications Session Border Controller (SBC) uses DNS predominantly for resolving FQDNs to IP addresses so that it can support sessions.

When configured, the SBC performs DNS client functions per RFC1034 and RFC1035. The user can define one primary DNS server and two backup DNS servers for the SBC to query a domain for NAPTR (service/port), SRV (FQDN), AAAA (IPv6), and A (IP address) information. A common example of the SBC using DNS is to locate a SIP server via server location discovery, as described in RFC 3263. An applicable context is identifying a callee so the SBC can place a call.

There are multiple reasons for the SBC to query a DNS server. In each case, the SBC follows this high level procedure:

1. The system determines the egress realm.
2. The system identifies the egress network interface.
3. From the egress network interface, the system refers to the configured DNS server(s).
4. The system issues the DNS query to the primary server, then any configured backup servers, based on the function and the initial information it has.

5. The system performs recursive lookups or subsequent queries based on, for example, information provided in NAPTR resource responses, until it has one or more resolutions for the FQDN.
6. The system continues processing using the resolved FQDN(s) or indicates it cannot reach that FQDN.

> **Note:**
>
> DNS queries may require host routes.

The SBC also has a DNS Application Layer Gateway (ALG) function that operates independently of its client function. See the DNS ALG Chapter in this document for information about using this ALG.

Closely related to DNS, ENUM service also provides a method of defining a target endpoint, translating E.164 phone numbers to FQDNs. The SBC uses configured ENUM objects for routing calls. ENUM uses Naming Authority Pointers (NAPTR) records defined in RFC 2915 in order to identify available ways or services for contacting a specific node identified through the E.164 number. See the Session Routing and Load Balancing chapter for information on ENUM services and configuration.

The SBC can cache NAPTR, SRV and A records to speed up DNS and ENUM query processes. The user configures the applicable enum-config to cache these records, providing ENUM and, when configured, DNS with applicable resolutions without having to re-query a server. These resolutions become available to all internal lookup processes that may be generated within the SBC.

DNS Configuration

DNS configuration includes procedures to the **network-interface**, **realm-config**, and **session-agent** elements.

To make DNS operational, configure addressing that is version compatible to the **network-interface** address on the network interface itself.

1. Access the **network-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-interface
ORACLE(network-interface)
```

2. **dns-ip-primary**—Set the first DNS server with which the interface conducts query procedures.
3. **dns-ip-backup1**—Set the second DNS server with which the interface conducts query procedures should the first server fail.
4. **dns-ip-backup2**—Set the third DNS server with which the interface conducts query procedures should the second server fail.

The system performs DNS query procedures with these servers every time processing encounters an FQDN for which the system needs resolution. After booting up the system, it queries **dns-ip-primary** for resolutions. It queries **dns-ip-backup1** if **dns-ip-primary** fails, and queries **dns-ip-backup2** if **dns-ip-backup1**. The system returns to using **dns-ip-primary** if the second backup fails or you reboot the system.

Review the ensuing sections and configure DNS components to refine DNS operation to your environment, including interface, realm, session agent, and ENUM operation refinement.

Retransmission Logic

The retransmission of DNS queries is controlled by three timers. These timers are derived from the configured DNS timeout value and from underlying logic that the minimum allowed retransmission interval should be 250 milliseconds; and that the Oracle Communications Session Border Controller should retransmit 3 times before timing out to give the server a chance to respond.

- Init-timer is the initial retransmission interval. If a response to a query is not received within this interval, the query is retransmitted. To safeguard from performance degradation, the minimum value allowed for this timer is 250 milliseconds.
- Max-timer is the maximum retransmission interval. The interval is doubled after every retransmission. If the resulting retransmission interval is greater than the value of max-timer, it is set to the max-timer value.
- Expire-timer: is the query expiration timer. If a response is not received for a query and its retransmissions within this interval, the server will be considered non-responsive and the next server in the list will be tried.

The following examples show different timeout values and the corresponding timers derived from them.

```
timeout >= 3 seconds
Init-timer = Timeout/11
Max-Timer = 4 * Init-timer
Expire-Timer = Timeout
timeout = 1 second
Init-Timer = 250 ms
Max-Timer = 250 ms
Expire-Timer = 1 sec
timeout = 2 seconds
Init-Timer = 250 ms
Max-Timer = 650 ms
Expire-Timer = 2sec
```

DNS Support for IPv6

The Oracle Communications Session Border Controller supports the DNS resolution of IPv6 addresses; in other words, it can request the AAAA record type (per RFC 1886) in DNS requests. In addition, the Oracle Communications Session Border Controller can make DNS requests over IPv6 transport so that it can operate in networks that host IPv6 DNS servers.

For mixed IPv4-IPv6 networks, the Oracle Communications Session Border Controller follows these rules:

- If the realm associated with the name resolution is an IPv6 realm, the Oracle Communications Session Border Controller will send the query out using the AAAA record type.
- If the realm associated with the name resolution is an IPv4 realm, the Oracle Communications Session Border Controller will send the query out using the A record type.

In addition, heterogeneous address family configuration is prevented for the **dns-ip-primary**, **dns-ip-backup1**, and **dns-ip-backup2** parameters.

DNS Transaction Timeout

This section explains how to configure the DNS transaction timeout interval on a per network-interface basis. You can currently configure the Oracle Communications Session Border Controller with a primary and two optional backup DNS servers. The Oracle Communications Session Border Controller queries the primary DNS server and upon not receiving a response within the configured number of seconds, queries the backup1 DNS server and if that times out as well, then contacts the backup2 DNS server.

DNS Transaction Timeout Configuration

To configure DNS transaction timeout:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# system
   ```

3. Type **network-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(system)# network-interface
   ORACLE(network-interface)#
   ```

   From this point, you can configure network interface parameters. To view all network interface parameters, enter a **?** at the system prompt.

4. **dns-timeout**—Enter the total time in seconds you want to elapse before a query (and its retransmissions) sent to a DNS server would timeout. The default is **11** seconds. The valid range is:

   - Minimum—1
   - Maximum—999999999.

     If a query sent to the primary DNS server times out, the backup1 DNS server is queried. If the query times out after the same period of time elapses, the query continues on to the backup2 DNS server.

5. Save and activate your configuration.

DNS Entry Maximum TTL

DNS maximum time to live (TTL) is user-configurable and complies with RFCs 1035 and 2181.

One can set the DNS maximum TTL on the Oracle Communications Session Border Controller permitting the DNS entry information to be held until that time is exceeded. One can specifiy the **dns-max-ttl** parameter per network interface and/or to support the DNS ALG feature. The default value is 86400 seconds (24 hours). When the Oracle Communications Session Border Controller configured maximum value has been exceeded, the DNS TTL value is set to the configured maximum and a log entry is written. Otherwise the Oracle Communications Session Border Controller honors the lower value in the DNS response. The Oracle Communications

Session Border Controller restricts all DNS entries minimum TTL value of 30 seconds, which the system's implementation of SIP requires.

DNS Entry Max TTL Configuration per Network Interface

Set parameter for DNS entry maximum time to live (TTL) value per network interface.

1. Access the **network-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-interface
ORACLE(network-interface)
```

2. Select the **network-interface** object to edit.

```
ORACLE(network-interface)# select
<name>:<sub-port-id>:
1: wancom0:0 ip=10.0.0.2 gw=10.0.4.1

selection: 1
ORACLE(network-interface)#
```

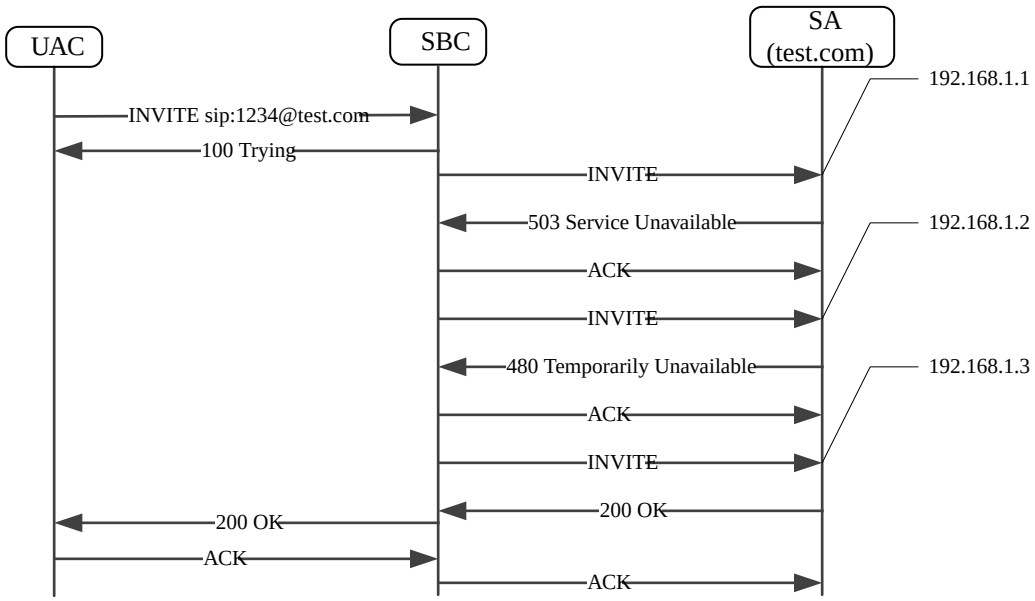
3. **dns-max-ttl**— set to the maximum time for a DNS record to remain in cache.
   - **Minimum: 30**— The lowest value to which the **dns-max-ttl** parameter can be set (in seconds)
   - **Maximum: 2073600**— The maximum value (in seconds) for which the **dns-max-ttl** parameter can be set.
   - **Default: 86400**— The value in seconds which the system uses by default.
4. Type **done** to save your configuration.

DNS-SRV Session Agent Recursion Error Handling

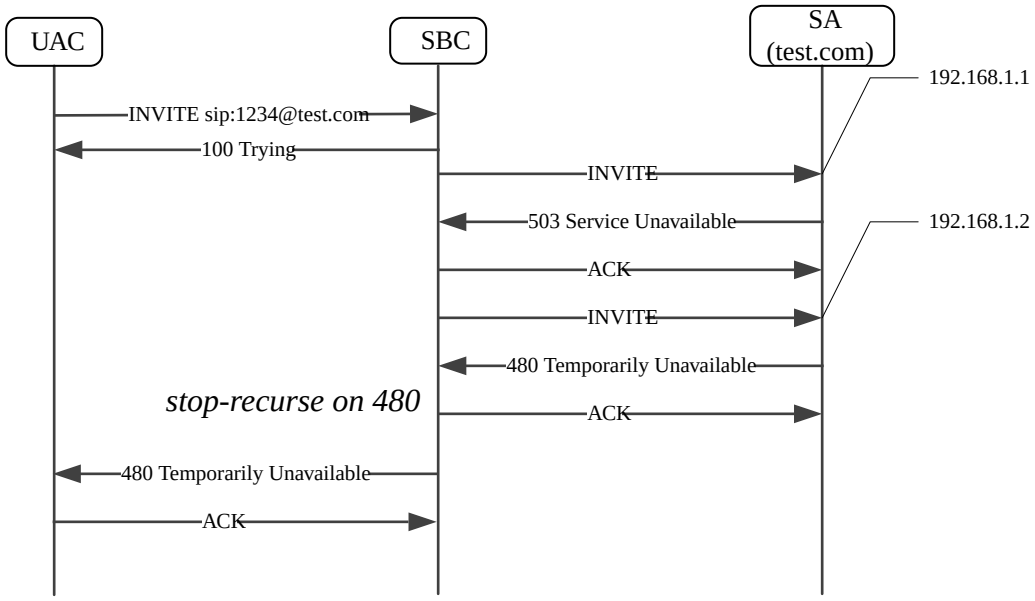
When a session request is sent from the Oracle Communications Session Border Controller to a session agent, and an error response is received (or a transport failure occurs), the Oracle Communications Session Border Controller attempts to reroute the message through the list of dynamically resolved IP addresses. The SBC can be configured to resend session requests through the list of IP addresses under more failure conditions.

This feature concerns the case when a session agent is configured with an FQDN in the hostname parameter and the **dns-load-balance** or **ping-all-addresses** option is configured. This configuration sets up the load balancing / redundancy behavior for the SBC to use all addresses returned in the SRV/A-record for that session agent. In previous versions of the SBC software, only when a 503 failure from the SA was received would the SBC resend the session request to the next dynamically resolved IP address (on the SRV/A record list).

By adding the **recurse-on-all-failures** option to a session agent, the Oracle Communications Session Border Controller will resend a session request to the next address on the list after a 4xx or 5xx failure response has been received from a session agent.



If the SBC receives a failure response from the session agent, and the number of that failure is configured in the **stop-recurse** parameter, no further session requests will be forwarded to additional addresses from the SRV/A record list. The error message will be forwarded back to the UA.



Interface and Realm Support of DNS Servers

You can configure DNS functionality on a per-network-interface, or per-realm basis. Configuring DNS servers for your realms means that you can have multiple DNS servers in connected networks. In addition, this allows you to specify which DNS server to use for a given realm because the DNS might actually be in a different realm with a different network interface.

This feature is available for SIP only.

To configure realm-specific DNS in the ACLI:

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. **dns-realm**—Enter the name of the network interface that is configured for the DNS service you want to apply in this realm. If you do not configure this parameter, then the realm will use the DNS information configured in its associated network interface.

DNS Re-query over TCP

The Oracle Communications Session Border Controller DNS supports the truncated (TC) header bit in DNS responses as defined in RFC 2181 and a re-query over TCP.

DNS queries start on UDP ports with the limit of 512 bytes. Longer responses require that the result not be cached and that the truncated (TC) header bit is set. After receiving a DNS response with the TC header set, the Oracle Communications Session Border Controller will initiate a re-query to the DNS server over TCP. The option **dns-tcp-for-truncated-response** in **realm-config** can be set to **no** to disable this behavior.

DNS Re-query over TCP Config

Enable feature to support setting the truncated header bit and initiating a DNS re-query over TCP.

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Select the **realm-config** object to edit.

```
ORACLE(realm-config)# select
identifier:
1: realm01 left-left:0 0.0.0.0

selection: 1
ORACLE(realm-config)#
```

3. **dns-tcp-for-truncated-response**— Set the options parameter by typing **options**, a Space, a plus sign (+), the option name, and queal sign (=) and then **yes** or **no** and then press Enter. The default behavior is to set the truncated header bit and initiate a DNS re-query over TCP.

```
ORACLE(realm-config)# option +dns-tcp-for-truncated-response=no
```

4. Type **done** to save your configuration.

Configurable DNS Response Size

When a realm is used for DNS queries, the Oracle Communications Session Border Controller can accept UDP DNS responses configurable up to 65535 bytes.

This functionality is useful when large numbers of SRV records will be returned in a DNS query thereby eliciting a large-sized DNS response. This behavior should be configured on the realm where the DNS servers are located.

To extend the valid DNS response size, add the **dns-max-response-size** option to the realm configuration. If this option is not configured, the Oracle Communications Session Border Controller uses the default maximum response size of 512 bytes, and information past the 512th byte will be ignored.

Do not add the **dns-max-response-size** option to realms where DNS queries are not being performed. Ensure that the realm where this option is configured is referenced in a transport realm's **dns-realm** parameter. Only the local value of the **dns-max-response-size** option is used for the realm; there is no inheritance of this value.

DNS Response Size Configuration

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Select the **realm-config** object to edit.

```
ORACLE(realm-config)# select
identifier:
1: realm01 left-left:0 0.0.0.0

selection: 1
ORACLE(realm-config)#
```

3. Add the **dns-max-response-size** option to the realm with a value between 513 — 65535.

```
ORACLE(realm-config)#options dns-max-response-size=4196
```

4. Type **done** to save your configuration.

Disabling Recursive DNS Queries for ENUM

By default, the Oracle Communications Session Border Controller (SBC) requests DNS query with recursive searches. The Telecommunication Technology Committee's Standard JJ-90.31 specifies that ENUM DNS queries be performed iteratively. The SBC complies with this requirement when remote (server) recursive searches are disabled. You can disable recursive searches on a per **enum-config** basis.

Remote recursive DNS queries instruct DNS servers to query other servers on behalf of the requester to resolve the query. Alternatively, the DNS server can return a list of other DNS servers for the requester to query itself. RFC 1035 specifies that setting the Recursive Data

(RD) bit in the DNS query to 1 requests a remote recursive DNS. Setting RD to 0 requests lists of other servers.

By default, the SBC sets the RD bit to 1. The user can disable this recursion by configuring the **enum-config** element's **remote-recursion** parameter to disabled.

This feature affects queries associated with the **enum-config**:

- Health queries
- CNAM subtype
- ENUM query

Changing this parameter's operational value does not invalidate any current DNS cache entry. The SBC uses the cached information until the cache is aged.

DNS Server Status via SNMP

The Oracle Communications Session Border Controller monitors the status of all configured DNS servers used by a SIP daemon. If a DNS server goes down, a major alarm is sent. If all DNS servers used by a SIP daemon are down, a critical alarm is sent. The apAppsDnsServerStatusChangeTrap is sent for both events.

You can poll the status of a DNS server using the apAppsDNSServerStatusTable in the ap-apps.mib.

Once the apAppsDnsServerStatusChangeTrap has been sent, a 30 second window elapses until the server status is checked again. At the 30 second timer expiration, if the server is still down, another trap and alarm are sent. If the server has been restored to service, the apAppsDnsServerStatusChangeClearTrap is sent.

Persistent Protocol Tracing

This section explains how to configure persistent protocol tracing to capture specific SIP protocol message logs and persistently send them off the Oracle Communications Session Border Controller, even after rebooting the system. This feature is not applicable to log for H.323 or IWF.

About Persistent Protocol Tracing

You can configure sending protocol message logs off of the Oracle Communications Session Border Controller, and have that persist after a reboot. You no longer have to manually issue the notify command each time you reboot.

To support persistent protocol tracing, you configure the following system-config parameters:

- **call-trace**—Enable/disable protocol message tracing (currently only sipmsg.log and alg.log) regardless of the process-log-level setting. If the process-log-level is set to trace or debug, call-trace will not disable.
- **internal-trace**—Enable/disable internal ACP message tracing for all processes, regardless of process-log-level setting. This applies to all *.log (internal ACP message exchange) files other than sipmsg.log and alg.log. If the process-log-level is set to trace or debug, call-trace will not disable.
- **log-filter**—Determine what combination of protocol traces and logs are sent to the log server defined by the process-log-ip parameter value. You can also fork the traces and logs, meaning that you keep trace and log information in local storage as well as sending it

to the server. You can set this parameter to any of the following values: none, traces, traces-fork, logs, logs, all, or all-fork.
The Oracle Communications Session Border Controller uses the value of this parameter in conjunction with the process-log-ip and process-log-port values to determine what information to send. If you have configured the proc-log-ip and proc-log-port parameters, choosing traces sends just the trace information (provided they are turned on), logs sends only process logs (log.*), and all sends everything (which is the default).

> **Note:**
>
> Set the **log-filter** to **all-fork** for the system to include TCP and TLS traces in logs.

About the Logs

When you configure persistent protocol tracing, you affect the following types of logs.

> **Note:**
>
> Enabling logs can have an impact on Oracle Communications Session Border Controller performance.

Process Logs

Events are logged to a process log flow from tasks and are specific to a single process running on the Oracle Communications Session Border Controller. By default they are placed into individual files associated with each process with the following name format:

log.<taskname>

By setting the new log-filter parameter, you can have the logs sent to a remote log server (if configured). If you set log-filter to logs or all, the logs are sent to the log server. Otherwise, the logs are still captured at the level the process-log-level parameter is set to, but the results are stored on the Oracle Communications Session Border Controller's local storage.

Communication Logs

These are the communication logs between processes and system management. The logs are usually named <name>.log, with <name> being the process name. For example, sipd.log.

This class of log is configured by the new internal-trace parameter.

Protocol Trace Logs

The only protocol trace logs included at this time are sipmsg.log for SIP. The H.323 system tracing is not included. All of the logs enabled with the call–trace parameter are sent to remote log servers, if you also set the log-filter parameter to logs or all.

Persistent Protocol Tracing Configuration

Before you configure persistent protocol tracing, ensure you have configured the process logs by setting the system configuration's **process-log-ip** parameter.

To configure persistent protocol tracing:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# system
   ```

3. Type **system-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(system)# system-config
   ORACLE(system-config)#
   ```

4. **call-trace**—Set to **enabled** to enable protocol message tracing for sipmsg.log for SIP. The default is **disabled**. The valid values are:
   - enabled | disabled
5. **internal-trace**—Set to **enabled** to enable internal ACP message tracing for all processes. The default is **disabled**. The valid values are:
   - enabled | disabled
6. **log-filter**—Choose the appropriate setting for how you want to send and/or store trace information and process logs. The valid values are:
   - **none**—No information will be sent or stored.
   - traces—Sends the trace information to both the log server; includes <name>.log files that contain information about the Oracle Communications Session Border Controller's internal communication processes (<name> is the name of the internal process)
   - **traces-fork**—Sends the trace information to both the log server and also keeps it in local storage; includes <name>.log files that contain information about the Oracle Communications Session Border Controller's internal communication processes (<name> is the name of the internal process)
   - **logs—**Sends the process logs to both the log server; includes log.* files, which are Oracle Communications Session Border Controller process logs
   - **logs-fork**—Sends the process logs to both the log server and also keeps it in local storage; includes log.* files, which are Oracle Communications Session Border Controller process logs
   - **all—**Sends all logs to the log servers that you configure
   - **all-fork**—Sends all logs to the log servers that you configure, and it also keeps the logs in local storage
7. Save and activate your configuration.

System Access Control

You can configure a system access control list (ACL) for your Oracle Communications Session Border Controller that determines what traffic the Oracle Communications Session Border Controller allows over its management interface (wancom0). By specifying who has access to the Oracle Communications Session Border Controller via the management interface, you can provide DoS protection for this interface.

Using a list of IP addresses and subnets that are allowable as packet sources, you can configure what traffic the Oracle Communications Session Border Controller accepts and what it denies. All IP packets arriving on the management interface are subject; if it does not match your configuration for system ACL, then the Oracle Communications Session Border Controller drops it.

> **Note:**
>
> All IP addresses configured in the SNMP community table are automatically permitted.

Adding an ACL for the Management Interface

The new subconfiguration **system-access-list** is now part of the system configuration, and its model is similar to host routes. For each entry, you must define an IP destination address and mask; you can specify either the individual host or a unique subnet.

If you do not configure this list, then there will be no ACL/DoS protection for the Oracle Communications Session Border Controller's management interface.

You access the **system-access-list** via system path, where you set an IP address and netmask. You can configure multiple system ACLs using this configuration.

To add an ACL for the management interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type system-access-list and press Enter.

   ```
   ORACLE(system)# system-access-list
   ORACLE(system-access-list)#
   ```

4. **source-address**—Enter the IP address representing for the source network for which you want to allow traffic over the management interface.
5. **netmask**—Enter the netmask portion of the source network for the traffic you want to allow. The netmask is in dotted decimal notation.
6. **description**—Provide a brief description of this system-access-list configuration.
7. **protocol**—Enter a specified protocol or the special value all that specifies by protocol the type of management traffic allowed to access the system. The default value (all) matches all supported transport layer protocols.

   - Default: all
   - Values: all | icmp | ssh | snmp

   An alternate means of configuring values supported by this parameter is the format IP protocol/well-known port. For example, the value 6/22 specifies protocol 6 (TCP) targeting

port 22 (ssh). In addition, you can specify multiple entries using this format. The example (6/22 1/0 17/162) configures multiple entries.

Notes on Deleting System ACLs

If you delete a system ACL from your configuration, the Oracle Communications Session Border Controller checks whether or not there are any active SFTP or SSH client was granted access when the entry was being removed. If such a client were active during ACL removal, the Oracle Communications Session Border Controller would warn you about the condition and ask you to confirm the deletion. If you confirm the deletion, then the Oracle Communications Session Border Controller's session with the active client is suspended.

The following example shows you how the warning message and confirmation appear. For this example, and ACLI has been deleted, and the user is activating the configuration that reflects the change.

```
ORACLE # activate-config
Object deleted will cause service disruption:
 system-access-list: identifier=172.30.0.24
 ** WARNING: Removal of this system-ACL entry will result
             in the lockout of a current SFTP client
Changes could affect service, continue (y/n) y
Activate-Config received, processing.
```

System TCP Keepalive Settings

You can configure the Oracle Communications Session Border Controller to control TCP connections by setting:

- The amount of time the TCP connection is idle before the Oracle Communications Session Border Controller starts sending keepalive messages to the remote peer
- The number of keepalive packets the Oracle Communications Session Border Controller sends before terminating the TCP connection

If TCP keepalive fails, then the Oracle Communications Session Border Controller will drop the call associated with that TCP connection.

In the ALCI, a configured set of network parameters appears as follows:

```
network-parameters
        tcp-keepinit-timer              75
        tcp-keepalive-count             4
        tcp-keepalive-idle-timer        400
        tcp-keepalive-interval-timer    75
        tcp-keepalive-mode              0
```

Then you apply these on a per-interface basis. For example, the H.323 interface (stack) configuration allows you to enable or disabled use of the network parameters settings.

System TCP Keepalive Configuration

TCP setting are global, and then enabled or disabled on a per-interface basis.

To configure TCP keepalive parameters on your SBC:

> **Note:**
>
> If you want to use the default values for TCP keepalive, you can simply set the TCP keepalive function in the H.323 stack configuration, and the defaults for network parameters will be applied.

1. Access the **network-parameters** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-parameters
ORACLE(network-parameters)
```

2. **tcp-keepinit-timer**—If a TCP connection cannot be established within some amount of time, TCP will time out the connect attempt. It can be used to set the initial timeout period for a given socket, and specifies the number of seconds to wait before the connect attempt is timed out. For passive connections, this value is inherited from the listening socket. The default is **75**. The valid range is:
   - Minimum — 0
   - Maximum — 999999999
3. **tcp-keepalive-count**—Enter the number of packets the SBC sends to the remote peer before it terminates the TCP connection. The default is **8**. The valid range is:
   - Minimum — 0
   - Maximum — 4294967295
4. **tcp-keepalive-idle-timer**—Enter the number of seconds of idle time before TCP keepalive messages are sent to the remote peer if the **SO-KEEPALIVE** option is set. This option is set via the **h323-stack** configuration element. The default is **7200**. The valid range is:
   - Minimum — 30
   - Maximum — 7200
5. **tcp-keepalive-interval-timer**—When the SO_KEEPALIVE option is enabled, TCP probes a connection that has been idle for some amount of time. If the remote system does not respond to a keepalive probe, TCP retransmits the probe after a set amount of time. This parameter specifies the number of seconds to wait before retransmitting a keepalive probe. The default value is **75** seconds. The valid range is:
   - Minimum — 15
   - Maximum — 75
6. **tcp-keepalive-mode**—Set the TCP keepalive response sequence number. The default is **0**. The valid values are:
   - 0—The sequence number is sent un-incremented
   - 1—The number is incremented
   - 2—No packets are sent
   - 3—Send RST (normal TCP operation)

Configurable TCP Timers

You can configure your Oracle Communications Session Border Controller to detect failed TCP connections more quickly so that data can be transmitted via an alternate connection before timers expire. Across all protocols, you can now control the following for TCP:

- Connection establishment
- Data retransmission
- Timer for idle connections

These capabilities all involve configuring an **options** parameter that appears in the network parameters configuration.

Configuring TCP Connection Establishment

To establish connections, TCP uses a three-way handshake during which two peers exchange TCP SYN messages to request and confirm the active open connection. In attempting this connection, one peer retransmits the SYN messages for a defined period of time if it does not receive acknowledgement from the terminating peer. You can configure the amount of time in seconds between the retries as well as how long (in seconds) the peer will keep retransmitting the messages.

You set two new options in the network parameters configuration to specify these amounts of time: **atcp-syn-rxmt-interval** and **atcp-syn-rxmt-maxtime**.

Note that for all configured options, any values entered outside of the valid range are silently ignored during configuration and generate a log when you enter the **activate** command.

To configure TCP connection establishment:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **network-parameters** and press Enter.

   ```
   ORACLE(system)# network-parameters
   ORACLE(network-parameters)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **atcp-syn-rxmt-interval=x** (where x is a value in seconds between 2 and 10) with a plus sign in front of it. Then press Enter. This value will be used as the interval between TCP SYN messages when the Oracle Communications Session Border Controller is trying to establish a connection with a remote peer.

   Now enter a second option to set the maximum time for trying to establish a TCP connection. Set the options parameter by typing **options**, a Space, the option name **atcp-**

syn-rxmt-maxtime=x (where x is a value in seconds between 5 and 75) with a plus sign in front of it. Then press Enter.

```
ORACLE(network-parameters)# options +atcp-syn-rxmt-interval=5
ORACLE(network-parameters)# options +atcp-syn-rxmt-maxtime=30
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

> **Note:**
>
> **atcp-syn-rxmt-maxtime=x option is equivalent to the tcp-keepinit-timer parameter, but only affects ATCP.**

5. Save and activate your configuration.

Configuring TCP Data Retransmission

TCP is considered reliable in part because it requires that entities receiving data must acknowledge transmitted segments. If data segments go unacknowledged, then they are retransmitted until they are finally acknowledged or until the maximum number of retries has been reached. You can control both the number of times the Oracle Communications Session Border Controller tries to retransmit unacknowledged segments and the periodic interval (how often) at which retransmissions occur.

You set two new options in the network parameters configuration to specify how many retransmissions are allowed and for how long: **atcp-rxmt-interval** and **atcp-rxmt-count**.

To configure TCP data retransmission:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **network-parameters** and press Enter.

   ```
   ORACLE(system)# network-parameters
   ORACLE(network-parameters)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **atcp-rxmt-interval=x** (where x is a value in seconds between 2 and 60) with a plus sign in front of it. Then press Enter. This value will be used as the interval between retransmission of TCP data segments that have not been acknowledged.

   Now enter a second option to set the number of times the Oracle Communications Session Border Controller will retransmit a data segment before it declares the connection failed. Set the options parameter by typing **options**, a Space, the option name **atcp-rxmt-**

count=x (where x is a value between 4 and 12 representing how many retransmissions you want to enable) with a plus sign in front of it. Then press Enter.

```
ORACLE(network-parameters)# options +atcp-rxmt-interval=30
ORACLE(network-parameters)# options +atcp-rxmt-count=6
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

Timer for Idle Connections

When enabled to do so, the Oracle Communications Session Border Controller monitors inbound TCP connections for inactivity. These are inbound connections that the remote peer initiated, meaning that the remote peer sent the first SYN message. You can configure a timer that sets the maximum amount of idle time for a connection before the Oracle Communications Session Border Controller consider the connection inactive. Once the timer expires and the connection is deemed inactive, the Oracle Communications Session Border Controller sends a TCP RST message to the remote peer.

To configure the timer for TCP idle connections:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **network-parameters** and press Enter.

   ```
   ORACLE(system)# network-parameters
   ORACLE(network-parameters)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **atcp-idle-timer=x** (where x is a value in seconds between 120 and 7200) with a plus sign in front of it. Then press Enter. This value will be used to measure the activity of TCP connections; when the inactivity on a TCP connection reaches this value in seconds, the Oracle Communications Session Border Controllerdeclares it inactive and drops the session.

   ```
   ORACLE(network-parameters)# options +atcp-idle-timer=900
   ```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

RTP TTL

The Oracle Communications Session Border Controller (SBC) allows you to set, on a per media-policy basis, the number of hops RTP packets can traverse before they should be dropped.

This feature uses the standard IPv4 TTL and IPv6 Hop Limit field, comprised of 8 bits in the IP header to specify time to live. The SBC supports this feature over UDP transport. The SBC sets or replaces any existing value in the TTL and Hop Limit fields with your setting before sending packets out the egress interface. The SBC knows if it has already processed any given packet. It therefore, knows to set this value only the first time it processes a packet. In addition, the SBC never decrements this value and, therefore, never discards these packets itself.

To configure, you set **rtp-ttl** in the desired **media-policy**. You also apply the **media-policy** to the desired **realm**(s). The RTP TTL value range is from 0 to 255. By default, the feature is set to zero (Disabled).

```
ORACLE# configuration terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# media-policy
ORACLE(media-policy)# rtp-ttl 30
```

Display TTL statistics using the **show datapath** command. This command's syntax is platform dependent:

- Virtual Machine, Acme Packet 1100, Acme Packet 3900, Acme Packet 3950, Acme Packet 4900 platforms
  Use **show datapath usdp ppms tos**
- Acme Packet 4600, Acme Packet 6100, Acme Packet 6300 and Acme Packet 6350 platforms
  Use **show datapath etc-stats ppm tos <slot> <port>**

This feature does not work on transcoded packets. After transcoding on Acme Packet platforms, the SBC sets the TTL value in all transcoded packets to 127.

The feature is RTC and is supported for HA deployments.

Bidirectional Forwarding Detection

The Oracle Communications Session Border Controller (SBC) supports Bidirectional Forwarding Detection (BFD) over network interfaces. BFD is a network protocol used to detect faults between two forwarding engines connected by a link. It provides low-overhead detection of faults, even on physical media that doesn't support failure detection of any kind, such as Ethernet, virtual circuits, tunnels and MPLS Label Switched Paths. You configure BFD for functions, including gateway path verification.

BFD is a simple Hello protocol, defined by RFC 5880 and related RFCs, that uses detection mechanisms similar to routing protocols to determine the availability of configured BFD peers. BFD essentially identifies network path failure by transmitting packets periodically between the two peers, and using gaps between the reception of these packets to make the assumption that something in the bidirectional path has failed.

After configuration, each BFD peer identifies itself and sets timing preferences to validate the connection between itself and its peer and establish a BFD session. Peers then negotiate

transmit intervals and 'multipliers' on an ongoing basis to fine tune their monitoring intervals, which are not symmetric. BFD peers use the exchange of BFD control packets to monitor the data path between the peers. BFD uses the "multiplier" to augment the timing intervals, which can account for traffic delays and reduce the impact of false positives. This results in network outage detection and recovery in the range of milliseconds.

The SBC uses BFD to perform two functions:

- Gateway Health Monitoring—The SBC allows the user to configure BFD sessions with applicable gateways. When a session fails, the SBC reduces its health score and raises a network interface alarm. If the session recovers, the SBC resets its health score and clears the alarm. The SBC's HA configuration is independent of this feature.
  You configure primary and secondary sessions on the SBC for this function.
- Triggering Virtual Address Re-routing—The SBC allows the user to configure a BFD session between the virtual address of each media interface and that interface's gateway. The use of BFD extends beyond the layer 2 mechanism of re-assigning a virtual address to a new physical address using, for example, GARP. Using BFD provides for this re-assignment over layer 3 networks by updating the BFD session at the gateway and triggering a dynamic routing update that reconfigures network routing tables.
  You configure Virtual IP (VIP) sessions on the SBC for this function.

Using BFD on the SBC can enable faster HA failover processes, as well as faster health score changes. Failover speed is less noticeable within back-to-back HA deployments, but it can make geographically separated (geo-redundant) HA pair deployments more effective.

> **Note:**
>
> The user may not use BFD in conjunction with the **gw-heartbeat** feature, both of which reside within the **network-interface** element. The SBC displays configuration verification errors if it finds both features configured.

When operating on the SBC, significant BFD detail includes:

- Oracle's implementation of BFD on the SBC implements certain portions of RFCs 5880, 5881, 5882 and 7419.
- The SBC supports BFD's "Asynchronous Mode", within which both endpoints periodically send **hello** packets to each other. Timing mechanisms within the protocol, including minimum receive interval, define a monitoring period within which endpoints must receive traffic. If not, they take the session down. This triggers the use of backup processes.
- The SBC supports only the mandatory components of a BFD control packet, including:
  - Packet header fields, including "Diag", which specifies the session state.
  - Session discriminator (label) used by local host
  - Session discriminator (label) used by remote host
  - Desired minimum TX interval
  - Required minimum RX interval
  - Required minimum Echo RX interval (The SBC does not implement the echo function.)
- The SBC does not support BFD's "Demand Mode".
- The SBC does not support BFD's "Echo function".
- The SBC supports BFD for both IPv4 and IPv6.

- The SBC supports BFD over UDP transport.
- The SBC reports the state of all BFD sessions through all reporting mechanisms.

Gateway Health Checking with BFD

The Oracle Communications Session Border Controller (SBC) allows you to configure Bidirectional Forwarding Detection (BFD) as a means of monitoring and reporting on gateway availability.

This gateway health checking feature monitors the gateway connectivity, and reduces a device's **health-score** when gateway connectivity is lost. For HA, you can configure it on both the active and standby node to enhance operation of OCSBCs and OCSLBs, especially when deployed in geo-redundant configurations. HA deployments use the changes to health score as a failover trigger; Standalone deployments use the feature to notify you about interface issues.

> **Note:**
>
> Gateway health checking is an alternate means of determining gateway connectivity. Do not use it simultaneously with the **gw-heartbeat** feature.

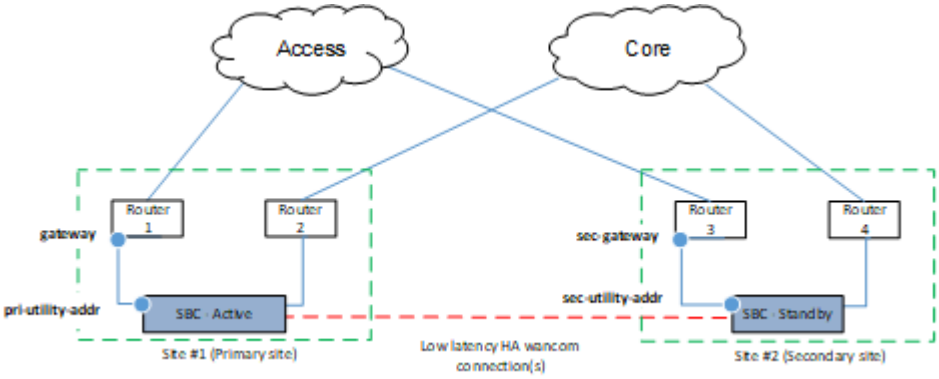
This feature does not apply to:

- Gateways configured on management interfaces (e.g., **wancom0**)
- The default gateway for the system (**system-config**, **default-gateway**)
- Default gateways for host routes (**host-route**, **gateway**)
- Standalone systems—Primary and secondary BFD sessions are not relevant on standalone systems.

For HA deployments, you can configure both **primary** and **secondary** session types, aligning them with the primary and secondary SBCs as follows:

- Configure a **primary** session type for use by the primary node, which uses the **pri-utility-addr** of the **network-interface** as the local IP address.
  These BFD sessions use the **network-interface gateway** as the remote address (i.e., the target of the BFD session).
- Configure a **secondary** session type for use by the secondary node, which uses the **sec-utility-addr** of the **network-interface** as the local IP address.
  These BFD sessions use the **sec-gateway** of the network-interface, if configured, as the remote address (i.e., the target of the BFD session). If no **sec-gateway** address is configured, then a secondary session type uses the **gateway** address for this purpose. This assumes both the primary and secondary nodes are connected to the same gateway.

The diagram below depicts a deployment wherein the primary and secondary node use different gateways.



Session Down Alarm and Trap

The SBC uses the same alarm and SNMP trap to notify you about session status as used for **gw-heartbeat** events. Upon detection of loss of connectivity to a gateway (including at system startup), the SBC raises a **GATEWAY UNREACHABLE** alarm and issues an **apSysMgmtGatewayUnreachableTrap** trap.

Upon detection of the restoration of connectivity to a gateway after loss, the SBC clears the **GATEWAY UNREACHABLE** alarm and issues an **apSysMgmtGatewayUnreachableClear** trap.

In an HA deployment, both the active and standby SBCs can raise this alarm and issue these traps.

BFD Gateway Health Checking Configuration

You configure gateway health checking sessions on the **network-interface**. Configuration includes a bfd-config and subordinate bfd-sessions. You can configure one primary and one secondary session per interface.

```
network-interface
        name                                    M05
...
        ip-address                              172.16.84.12
        pri-utility-addr                        172.16.84.13
        sec-utility-addr                        172.16.84.15
        netmask                                 255.255.0.0
        gateway                                 172.16.84.1
        sec-gateway                             172.16.84.2
        gw-heartbeat
                state                                   disabled
...
        bfd-config
                state                                   enabled
                health-score                            30
                options
                bfd-session
                        bfd-sess-type                           primary
                        admin-state                             enabled
                        admin-session-state                     up
                        min-tx-interval                         5000
                        min-rx-interval                         5000
                        detect-multiplier                       3
                        hold-down-time                          0
```

```
        local-discriminator                 102
bfd-session
        bfd-sess-type                       secondary
        admin-state                         enabled
        admin-session-state                 up
        min-tx-interval                     5000
        min-rx-interval                     5000
        detect-multiplier                   3
        hold-down-time                      0
        local-discriminator                 103
```

> **Note:**
>
> A VIP session type can operate simultaneously with **primary** and **secondary** sessions.

Using BFD To Signal Virtual Address Re-routing

The Oracle Communications Session Border Controller (SBC) allows you to configure a BFD session (or sessions) that monitor virtual address availability. During an HA switchover, this feature provides the routing network with a means of quickly reconstituting routing tables and advertising the new route to the virtual address. You enable this feature in conjunction with the SBC's GARP-based HA mechanism.

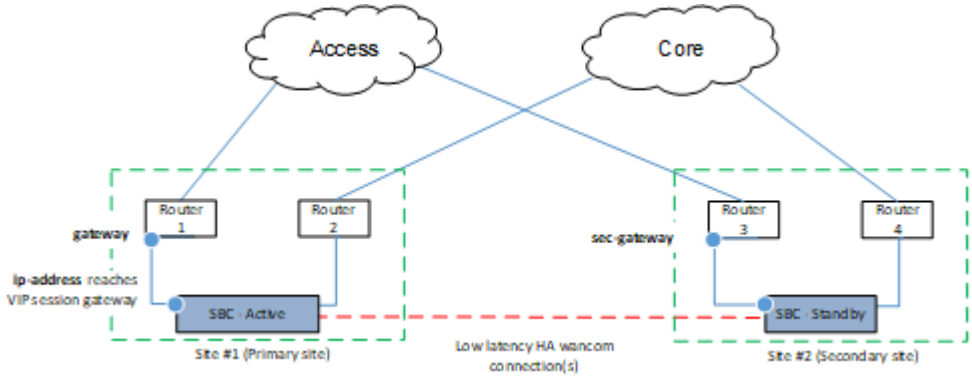
Using BFD, you configure VIP sessions between virtual addresses and the **gateway** configured on each applicable **network-interface**. HA synchronization makes this configuration applicable to the standby's interfaces in case of a fail-over. Upon fail-over, the SBC migrates virtual addresses to the new active. Simultaneously, it starts new VIP sessions between the virtual address and the new gateways on the new active. The layer 3 network, using its own mechanisms, withdraws advertisements to the virtual address over the failed VIP sessions and advertises it via the new VIP sessions.

For example:

1. A gateway device with an active VIP session between itself and an active SBC may advertise the appropriate route to the virtual address, thereby provide connectivity to the active SBC.
2. When the network detects VIP session failure with the active SBC, it may withdraw the route advertisement for the previously active node.
3. When the network detects the new VIP session with the standby SBC, it may issue new advertisements to establish the new route between the new gateway and the virtual address at the new active node.

The local and remote IP addresses for these BFD sessions hosted on the active node include:

- Local IP address: VIP (**address**) configured for the network interface
- Remote IP address, which depends on the active node, as follows:
  - If active is primary node: Configured gateway for the network interface (**gateway**)
  - If active is secondary node: Secondary gateway (**sec-gateway**) if configured, else the configured gateway (**gateway**) for the network interface



Failure of a VIP session has no effect on health score.

VIP Down Alarm

If a VIP session fails, the SBC sends out the following alarm prior to failover.

```
ID        Task  Severity First Occurred        Last Occurred
327724    117   5        2017-12-13 05:31:09   2017-12-13 05:31:09
Count   Description
1       1 VIP BFD session down !!!
```

Standalone systems support VIP sessions. When configured on a standalone, the system establishes a BFD session between the network interface address and its gateway; there are no virtual addresses on a standalone. As a result, you can use this alarm to monitor the interface status. But that is the only benefit to configuring VIP sessions on a standalone.

The SBC does not issue traps on VIP session status.

VIP Session Configuration

You configure VIP sessions on the **network-interface**. Configuration includes a **bfd-config** and a subordinate **bfd-session**. You configure one VIP session per interface. A VIP session can operate simultaneously with a **network-interface**'s gateway health check sessions.

```
network-interface
        name                                    M05
...
        ip-address                              172.16.84.100
        gateway                                 172.16.84.1
        sec-gateway                             182.16.84.2
...
        bfd-config
                state                                   enabled
                health-score                            0
                options
                bfd-session
                        bfd-sess-type                           vip
                        admin-state                             enabled
                        admin-session-state                     up
                        min-tx-interval                         5000
                        min-rx-interval                         5000
                        detect-multiplier                       3
                        hold-down-time                          0
                        local-discriminator                     101
```

Configuring a BFD Config

The Oracle Communications Session Border Controller (SBC) allows you to perform interface- and session-specific configuration for BFD sessions.

Follow the steps below to set up BFD configuration that applies to all sessions on this interface.

1. In Superuser mode, use the following command sequence to access BFD configuration mode:

   ```
   ORACLE# configuration terminal
   ORACLE(configure)# system
   ORACLE(system)# network-interface
   ORACLE(network-interface)# bfd-config
   ```

2. Type state and specify whether this network interface is enabled to use BFD sessions.

   ```
   ORACLE(bfd-config)# state enabled
   ```

3. Type health-score and specify a valid value, between 0 and 100 percent. The default of 0 specifies a deduction of zero, meaning that failed BFD sessions on this interface do not affect health score.

   ```
   ORACLE(bfd-config)# health-score 30
   ```

4. Type bfd-session to enter this subelement and configure individual BFD sessions.

   ```
   ORACLE(bfd-config)# bfd-session
   ```

   If you are adding support for the feature to a pre-existing configuration, then you must select the configuration you want to edit.

   BFD Config configurations accept two independent options:

   - **alarm_on_init**—Requests that BFD session failure alarm be raised at the time of BFD session initialization (when BFD session is enabled). When this option is not specified, the default RFC compliant behavior is to not raise a BFD session failure alarm on initialization to allow failed BFD sessions to re-connect without triggering an unnecessary failover.
   - **exclude_admin_down**—Requests that the BFD session failure alarm be cleared when transitioning to "Admin Down" state from any other state. When this option is not specified, the default behavior is that the BFD session alarm state is not changed when transitioning to "Admin Down".

Configuring BFD Sessions

The Oracle Communications Session Border Controller (SBC) allows you to perform interface- and session-specific configuration for Gateway Health Checking sessions.

Follow the steps below to configure individual sessions. Session types include Primary Gateway Health Checking, Secondary Gateway Health Checking, and VIP sessions.

1. In Superuser mode, use the following command sequence to access **bfd-session** parameters:

```
ORACLE# configuration terminal
ORACLE(configure)# system
ORACLE(system)# network-interface
ORACLE(network-interface)# bfd-config
ORACLE(bfd-config)# bfd-session
```

   If you are adding support for the feature to a pre-existing sub-element, then you must select the configuration you want to edit.

2. Use this parameter to specify this subelement's session type and press Enter. Parameters include primary and secondary, which apply to the availability of the primary and secondary gateways, and VIP, which applies within the context of HA and addresses the connection between the virtual IP address established by a working HA deployment and the applicable gateway.

```
ORACLE(bfd-session)# bfd-sess-type vip
```

3. Use this parameter to specify the admin-state of this BFD session.

```
ORACLE(bfd-session)# admin-state enabled
```

4. Use this parameter to specify the admin-session-state of this BFD session to Up or AdminDown.

```
ORACLE(bfd-session)# admin-session-state up
```

5. Specify the min-tx-interval in milleseconds. Refer to RFC 5880 for more details.

```
ORACLE(bfd-session)# min-tx-interval 5000
```

6. Specify the min-rx-interval in milleseconds. Refer to RFC 5880 for more details.

```
ORACLE(bfd-session)# min-rx-interface 5000
```

7. Specify the detect-multiplier as an integer. Refer to RFC 5880 for more details.

```
ORACLE(bfd-session)# detect-multiplier 3
```

8. Specify the hold-down-time in milleseconds. Zero is disabled. If configured, the system reports the BFD protocol state transition to Up to the application after this duration. After the state transition is eventually reported to the application, the system clears the alarm triggered by the previous BFD session failure and eliminates the corresponding health score deduction (if any).

```
ORACLE(bfd-session)# hold-down-time 0
```

9. Specify the integer used by the system to identify this session. Values range from 1 - 4294967295.

```
ORACLE(bfd-session)# local-discriminator 101
```

10. Type done, then exit, save and activate the configuration.

```
bfd-config
                state                                   enabled
                health-score                            0
                options
                bfd-session
                        bfd-sess-type                           vip
                        admin-state                             enabled
                        admin-session-state                     up
                        min-tx-interval                         5000
                        min-rx-interval                         5000
                        detect-multiplier                       3
                        hold-down-time                          0
                        local-discriminator
101
                bfd-session
                        bfd-sess-type                           primary
                        admin-state                             enabled
                        admin-session-state                     up
                        min-tx-interval                         5000
                        min-rx-interval                         5000
                        detect-multiplier                       3
                        hold-down-time                          0
                        local-discriminator                     102
                bfd-session
                        bfd-sess-type                           secondary
                        admin-state                             enabled
                        admin-session-state                     up
                        min-tx-interval                         5000
                        min-rx-interval                         5000
                        detect-multiplier                       3
                        hold-down-time                          0
                        local-discriminator                     103
```

Displaying Information on BFD Operation

The SBC provides you with commands to display status and statistics on BFD sessions for verification, validation and troubleshooting.

The **show bfd-stats** command displays global status on all active BFD sessions.

```
ORACLE# show bfd-stats
02:52:52-75
--------- -----------   ----------    -----------------  ------
Interface Type    ID    Destination   Logical Interface  State
--------- -----------   ----------    -----------------  ------
M05:0     VIP     101   172.16.84.70  172.16.84.12        Up
M05:0     Primary 102   172.16.84.71  172.16.84.13        Up
--------- -----------   -----------   -----------------
Received packet rate (total): 12 packets/sec
Sent packet rate (total)    : 11 packets/sec
--------- ----------- ----------- -------------
```

The table below provides descriptions of the column information output by the **show bfd-stats** command.

Data	Description
Interface	The Network Interface
Type	Represents the BFD session type, one of primary, secondary or VIP
ID	The configured unique local discriminator of the session
Destination	Destination address of the session
Logical Interface	Local IP address and interface [physical interface:vlan.v4/v6] (similar to network-interface specification in realm-config) of the session
State	BFD session state, one of AdminDown, Down, Init, Up (as specified in RFC 5880)
Received packet rate (total)	The received packet rate for all BFD sessions combined
Sent packet rate (total)	The sent packet rate for all BFD sessions combined

The SBC displays global statistics on BFD traffic from the **show media** command.

```
ORACLE# show media classify 0 0

Slot 0 Port 0 Fastpath Statistics
--------- Ingress Packet Counts ------------|------Egress Packet Counts-----
IPv4                  :  4120               | IPv4                  :
4111

BFD-Specific Alarm

The SBC triggers and clears a BFD-specific alarm (example below) when it detects a BFD session state change.

```
ID        Task  Severity First Occurred        Last Occurred
805372204 117   4        2018-02-22 05:36:17   2018-02-22 05:36:17
Count Description
1 gateway 192.168.17.51 unreachable on slot 0 port 1 subport 300
```

For BFD information, set **log-level** to **DEBUG** and capture **log.bfd** for analysis.

- log.bfd: This log file contains process logs and message traces.
- bfd.log: This file contains internal traces between bfd process and other processes that are not call related.

RAMdrive Log Cleaner

The RAMdrive log cleaner allows the Oracle Communications Session Border Controller to remove log files proactively and thereby avoid situations where running low on RAMdrive space is a danger. Because even a small amount of logging can consume a considerable space, you might want to enable the RAMdrive log cleaner.

The RAMdrive cleaner periodically checks the remaining free space in the RAMdrive and, depending on the configured threshold, performs a full check on the /ramdrv/logs directory. During the full check, the RAMdrive cleaner determines the total space logs files are using and deletes log files that exceed the configured maximum lifetime. In addition, if the cleaner finds that the maximum log space has been exceeded or the minimum free space is not sufficient, it deletes older log files until the thresholds are met.

Not all log files, however, are as active as others. This condition affects which log files the log cleaner deletes to create more space in RAMdrive. More active log files rotate through the system more rapidly. So, if the log cleaner were to delete the oldest of these active files, it might not delete less active logs files that could be older than the active ones. The log cleaner thus deletes files that are truly older, be they active or inactive.

Applicable Settings

In the system configuration, you establish a group of settings in the options parameter that control the log cleaner's behavior:

- **ramdrv-log-min-free**—Minimum percent of free space required when rotating log files. When the amount of free space on the RAMdrive falls below this value, the log cleaner deletes the oldest copy of the log file. The log cleaner also uses this setting when performing period cleaning.
- **ramdrv-log-max-usage**—Maximum percent of the RAMdrive the log files can use. The log cleaner removes old log files to maintain this threshold.
- **ramdrv-log-min-check**—Minimum percent of free space on the RAMdrive that triggers the log cleaner to perform a full check of log files.
- **ramdrv-min-log-check**—Minimum time (in seconds) between log cleaner checks.

- **ramdrv-max-log-check**—Maximum time (in seconds) between log cleaner checks. This value must be greater than or equal to the **ramdrv-min-log-check**.
- **ramdrv-log-lifetime**—Maximum lifetime (in days) for log files. You give logs unlimited lifetime by entering a value of 0.

Clean-Up Procedure

The log cleaner checks the amount of space remaining in the RAMdrive and performs a full check of the logs directory when:

- Free space is less than the minimum percent of the RAMdrive that triggers a full check of log files
- The amount of free space has changed by more than 5% of the RAMdrive capacity since the last full check
- A full check of the logs directory has not been performed in the last hour

When it checks the logs directory, the log cleaner inventories the collected log files. It identifies each files as one of these types:

- Process log—Files beginning with log.
- Internal trace file—A <task>.log file
- Protocol trace file—Call trace including sipmsg.log, dns.log, sipddns.log, and alg.log
- CDR file—File beginning with cdr

Next, the log cleaner determines the age of the log files using the number of seconds since the log files were created. Then it orders the files from oldest to newest. The age adjusts such that it always increases as the log file sequence number (a suffix added by file rotation) increases. The log cleaner applies an additional weighting factor to produce a weighted age that favors the preservation of protocol traces files over internal trace files, and internal trace files over process log files. The base log file and CDR files are excluded from the age list and so will not be deleted; the accounting configuration controls CDR file aging.

With the age list constructed, the log cleaner examines the list from highest weighted age to lowest. If the actual file age exceeds the RAMdrive maximum log lifetime, the log cleaner deletes it. Otherwise, the log cleaner deletes files until the maximum percent of RAMdrive that logs can use is no longer exceeded and until the minimum percent of free space required when rotating logs is available.

Clean-Up Frequency

The minimum free space that triggers a full check of log files and the maximum time between log file checks control how often the log cleaner performs the clean-up procedure. When it completes the procedure, the log cleaner determines the time interval until the next required clean-up based on the RAMdrive's state.

If a clean-up results in the deletion of one or more log files or if certain thresholds are exceeded, frequency is based on the minimum time between log cleaner checks. Otherwise, the system gradually increases the interval up to the maximum time between log cleaner checks. The system increases the interval by one-quarter of the difference between the minimum and maximum interval, but not greater than one-half the minimum interval or smaller than 10 seconds. For example, using the default values, the interval would be increased by 30 seconds.

RAMdrive Log Cleaner Configuration

You configure the log cleaner's operating parameters and thresholds in the system configuration. Note that none of these settings is RTC-supported, so you must reboot your Oracle Communications Session Border Controller in order for them to take effect. If you are using this feature on an HA node, however, you can add this feature without impact to service by activating the configuration, rebooting the standby, switching over to make the newly booted standby active, and then rebooting the newly standby system.

Unlike other values for **options** parameters, the Oracle Communications Session Border Controller validates these setting when entered using the ACLI. If any single value is invalid, they all revert to their default values.

To configure the RAMdrive log cleaner:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **system-config** and press Enter.

   ```
   ORACLE(system)# system-config
   ORACLE(system-config)#
   ```

4. **options**—Set the options parameter by typing options, a Space, **<option name>=X (where X is the value you want to use)** with a plus sign in front of it. Then press Enter.

   Remember that if any of your settings are invalid, the Oracle Communications Session Border Controller changes the entire group of these options back to their default settings.

   The following table lists and describes the supported options.

   - ramdrv-log-min-free—Minimum percent of free space required when rotating log files. When the amount of free space on the RAMdrive falls below this value, the log cleaner deletes the oldest copy of the log file. The log cleaner also uses this setting when performing period cleaning.
     - Default: 40
     - Minimum: 15
     - Maximum: 75
   - ramdrv-log-max-usage—Maximum percent of the RAMdrive the log files can use. The log cleaner removes old log files to maintain this threshold.
     - Default: 40
     - Minimum: 15
     - Maximum: 75
   - ramdrv-log-min-check—Minimum percent of free space on the RAMdrive that triggers the log cleaner to perform a full check of log files.

  - Default: 50
  - Minimum: 25
  - Maximum: 75
- ramdrv-min-log-check—Maximum time (in seconds) between log cleaner checks. This value must be greater than or equal to the ramdrv-min-log-check.
  - Default: 180
  - Minimum: 40
  - Maximum: 1800
- ramdrv-log-lifetime—Maximum lifetime (in days) for log files. You give logs unlimited lifetime by entering a value of 0.
  - Default: 30
  - Minimum: 2
  - Maximum: 9999

  Default=30; Minimum=2; Maximum=9999

```
ORACLE(system-config)# options +ramdrv-log-min-free=50
ORACLE(system-config)# options +ramdrv-log-max-usage=50
ORACLE(system-config)# options +ramdrv-log-min-check=35
ORACLE(system-config)# options +ramdrv-min-log-check=120
ORACLE(system-config)# options +ramdrv-max-log-free=1500
ORACLE(system-config)# options +ramdrv-log-lifetime=7
```

If you type **options** and then the option value for either of these entries without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Reboot your Oracle Communications Session Border Controller.

Configurable Alarm Thresholds and Traps

The Oracle Communications Session Border Controller supports user-configurable threshold crossing alarms. These configurations let you identify system conditions of varying severity which create corresponding alarms of varying severity. You configure an alarm threshold type which indicates the resource to monitor. The available types are:

- cpu — CPU utilization monitored as a percentage of total CPU capacity
- memory — memory utilization monitored as a percentage of total memory available

> **Note:**
>
> When you configure an **alarm-threshold** for **memory** with **severity** set to **critical**, the Oracle Communications Session Border Controller will stop processing traffic if that configured value is reached, regardless of how low the value is.
> When triggered this alarm issues a corresponding SNMP trap. The system checks utilization every 15 seconds after triggering the alarm and issues a the trap again if the memory utilization is still breaching the threshold. This can generate a significant number of traps sent to SNMP management systems.

- sessions — allowed utilization monitored as a percentage of session capacity
- space — remaining disk space (configured in conjunction with the volume parameter - see the Storage Expansion Module Monitoring section of the *Accounting Guide* for more information.)
- deny-allocation — denied entry utilization monitored as a percentage of reserved, denied entries.

For the alarm type you create, the Oracle Communications Session Border Controller can monitor for 1 through 3 severity levels as minor, major, and critical. Each of the severities is configured with a corresponding value that triggers that severity. For example the configuration for a CPU alarm that is enacted when CPU usage reaches 50%:

```
alarm-threshold
        type                            cpu
        severity                        minor
        value                           50
```

You may create addition CPU alarms for increasing severities. For example:

```
alarm-threshold
        type                            cpu
        severity                        critical
        value                           90
```

The alarm state is enacted when the resource defined with the type parameter exceeds the value parameter. When the resource drops below the value parameter, the alarm is cleared.

SNMP Traps

When a configured alarm threshold is reached, the Oracle Communications Session Border Controller sends an apSysMgmtGroupTrap. This trap contains the resource type and value for the alarm configured in the alarm-threshold configuration element. The trap does not contain information associated with configured severity for that value.

```
apSysMgmtGroupTrap          NOTIFICATION-TYPE
    OBJECTS         { apSysMgmtTrapType, apSysMgmtTrapValue }
    STATUS            current
    DESCRIPTION
          " The trap will generated if value of the monitoring object
```

```
        exceeds a certain threshold. "
    ::= { apSystemManagementNotifications 1 }
```

When the resource usage retreats below a configured threshold, the Oracle Communications Session Border Controller sends an apSysMgmtGroupClearTrap.

```
apSysMgmtGroupClearTrap         NOTIFICATION-TYPE
    OBJECTS        { apSysMgmtTrapType }
    STATUS           current
    DESCRIPTION
          " The trap will generated if value of the monitoring object
          returns to within a certain threshold.  This signifies that
          an alarm caused by that monitoring object has been cleared. "
    ::= { apSystemManagementNotifications 2 }
```

The alarm and corresponding traps available through the User Configurable Alarm Thresholds functionality are summarized in the following table.

Alarm	Severity	Cause	Actions
CPU	minor major	high CPU usage	apSysMgmtGroupTrap sent with apSysCPUUtil
	critical		apSysMgmtTrapValue
memory	minor major	high memory usage	apSysMgmtGroupTrap sent with apSysMemoryUtil
	critical		apSysMgmtTrapValue
sessions	minor major	high provisioned usage	apSysMgmtGroupTrap sent with apSysLicenseCapacity
	critical		apSysMgmtTrapValue
space	minor major	high HDD usage, per volume	apSysMgmtStorageSpaceAvailThresholdTrap sent with:
	critical		apSysMgmtSpaceAvailCurrent
			apSysMgmtSpaceAvailMinorThreshold
			apSysMgmtSpaceAvailMajorThreshold
			apSysMgmtSpaceAvailCriticalThreshold
			apSysMgmtPartitionPath
deny allocation	minor major	high usage of denied ACL entries	apSysMgmtGroupTrap sent with apSysCurrentEndptsDenied
	critical		apSysMgmtTrapValue

Alarm Thresholds Configuration

To configure alarm thresholds:

1. Access the **alarm-threshold** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# system-config
ORACLE(system-config)# alarm-threshold
ORACLE(alarm-threshold)#
```

2. **type** — Enter the type of resource which this alarm monitors. Valid values include:
   - cpu
   - memory
   - sessions
   - space
   - deny-allocation
3. **volume** — Enter the logical disk volume this alarm monitors (used only in conjunction when type = space).
4. **severity** — Set the severity of the threshold. Valid values include:
   - minor
   - major
   - critical
5. **value** — Enter the value from 1 to 100, indicating the percentage, which when exceeded generates an alarm.
6. Save and activate your configuration.

Alarm Synchronization

Two trap tables in the ap-smgmt.mib record trap information for any condition on the Oracle Communications Session Border Controller that triggers an alarm condition. You can poll these two tables from network management systems, OSS applications, and the Session Delivery Manager to view the fault status on one or more Oracle Communications Session Border Controller s.

The two trap tables that support alarm synchronization, and by polling them you can obtain information about the current fault condition on the Oracle Communications Session Border Controller . These tables are:

- apSysMgmtTrapTable—You can poll this table to obtain a summary of the Oracle Communications Session Border Controller ’s current fault conditions. The table records multiples of the same trap type that have occurred within a second of one another and have different information. Each table entry contains the following:
  - Trap identifier
  - System time (synchronized with an NTP server)
  - sysUpTime
  - Instance number
  - Other trap information for this trap identifier
- apSysMgmtTrapInformationTable—You can poll this table to obtain further details about the traps recorded in the apSysMgmtTrapTable table. The following information appears:
  - Data index
  - Data type
  - Data length
  - The data itself (in octets)

Trap tables do not record information about alarm severity.

The apSysMgmtTrapTable can hold up to 1000 entries, and you can configure the number of days these entries stay in the table for a maximum of seven days. If you set this parameter to 0 days, the feature is disabled. And if you change the setting to 0 days from a greater value, then the Oracle Communications Session Border Controller purges the tables.

Caveats

Note that the Oracle Communications Session Border Controller does not replicate alarm synchronization table data across HA nodes. That is, each Oracle Communications Session Border Controller in an HA node maintains its own tables.

Alarm Synchronization Configuration

You turn on alarm synchronization in the system configuration.

To use alarm synchronization:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **system-config** and press Enter.

   ```
   ORACLE(system)# system-config
   ORACLE(system-config)#
   ```

4. **trap-event-lifetime**—To enable alarm synchronization—and cause the Oracle Communications Session Border Controller to record trap information in the apSysMgmtTrapTable and the apSysMgmtTrapInformationTable—set this parameter to the number of days you want to keep the information. Leaving this parameter set to 0 (default) turns alarm synchronization off, and you can keep information in the tables for up to 7 days. 7 is the maximum value for this parameter.

Accounting Configuration

The Oracle Communications Session Border Controller offers support for RADIUS, an accounting, authentication, and authorization (AAA) system. In general, RADIUS servers are responsible for receiving user connection requests, authenticating users, and returning all configuration information necessary for the client to deliver service to the user.

You can configure your Oracle Communications Session Border Controller to send call accounting information to one or more RADIUS servers. This information can help you to see usage and QoS metrics, monitor traffic, and even troubleshoot your system.

This guide contains all RADIUS information, as well as information about:

- Accounting for SIP and H.323
- Local CDR storage on the Oracle Communications Session Border Controller , including CSV file format settings

- The ability to send CDRs via FTP to a RADIUS sever (the FTP push feature)
- Per-realm accounting control
- Configurable intermediate period
- RADIUS CDR redundancy
- RADIUS CDR content control

Stream Control Transfer Protocol Overview

The Stream Control Transmission Protocol (SCTP) was originally designed by the Signaling Transport (SIGTRAN) group of IETF for Signalling System 7 (SS7) transport over IP-based networks. It is a reliable transport protocol operating on top of an unreliable connectionless service, such as IP. It provides acknowledged, error-free, non-duplicated transfer of messages through the use of checksums, sequence numbers, and selective retransmission mechanism.

SCTP is designed to allow applications, represented as endpoints, communicate in a reliable manner, and so is similar to TCP. In fact, it has inherited much of its behavior from TCP, such as association (an SCTP peer-to-peer connection) setup, congestion control and packet-loss detection algorithms. Data delivery, however, is significantly different. SCTP delivers discrete application messages within multiple logical streams within the context of a single association. This approach to data delivery is more flexible than the single byte-stream used by TCP, as messages can be ordered, unordered or even unreliable within the same association.

SCTP Packets

SCTP packets consist of a common header and one or more chunks, each of which serves a specific purpose.

- DATA chunk — carries user data
- INIT chunk — initiates an association between SCTP endpoints
- INIT ACK chunk — acknowledges association establishment
- SACK chunk — acknowledges received DATA chunks and informs the peer endpoint of gaps in the received subsequences of DATA chunks
- HEARTBEAT chunk — tests the reachability of an SCTP endpoint
- HEARTBEAT ACK chunk — acknowledges reception of a HEARTBEAT chunk
- ABORT chunk — forces an immediate close of an association
- SHUTDOWN chunk — initiates a graceful close of an association
- SHUTDOWN ACK chunk — acknowledges reception of a SHUTDOWN chunk
- ERROR chunk — reports various error conditions
- COOKIE ECHO chunk — used during the association establishment process
- COOKIE ACK chunk — acknowledges reception of a COOKIE ECHO chunk
- SHUTDOWN COMPLETE chunk — completes a graceful association close

SCTP Terminology

This section defines some terms commonly found in SCTP standards and documentation.

SCTP Association

is a connection between SCTP endpoints. An SCTP association is uniquely identified by the transport addresses used by the endpoints in the association. An SCTP association can be represented as a pair of SCTP endpoints, for example, assoc = { [IPv4Addr : PORT1], [IPv4Addr1, IPv4Addr2: PORT2]}.

Only one association can be established between any two SCTP endpoints.

SCTP Endpoint

is a sender or receiver of SCTP packets. An SCTP endpoint may have one or more IP address but it always has one and only one SCTP port number. An SCTP endpoint can be represented as a list of SCTP transport addresses with the same port, for example, endpoint = [IPv6Addr, IPv6Addr: PORT].

An SCTP endpoint may have multiple associations.

SCTP Path

is the route taken by the SCTP packets sent by one SCTP endpoint to a specific destination transport address or its peer SCTP endpoint. Sending to different destination transport addresses does not necessarily guarantee separate routes.

SCTP Primary Path

is the default destination source address, the IPv4 or IPv6 address of the association initiator. For retransmissions however, another active path may be selected, if one is available.

SCTP Stream

is a unidirectional logical channel established between two associated SCTP endpoints. SCTP distinguishes different streams of messages within one SCTP association. SCTP makes no correlation between an inbound and outbound stream.

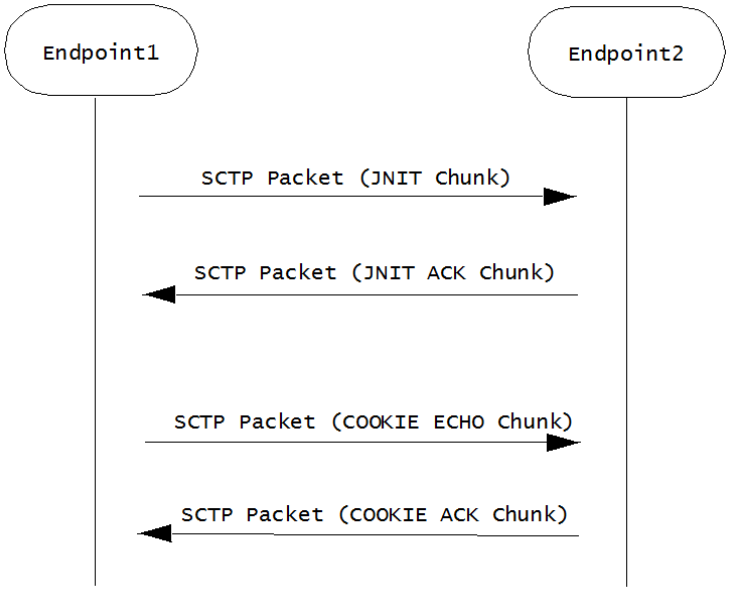
SCTP Transport Address

is the combination of an SCTP port and an IP address. For the current release, the IP address portion of an SCTP Transport Address must be a routable, unicast IPv4 or IPv6 address.

An SCTP transport address binds to a single SCTP endpoint.

SCTP Message Flow

Before peer SCTP users (commonly called endpoints) can send data to each other, an association (an SCTP connection) must be established between the endpoints. During the association establishment process a cookie mechanism is employed to provide protection against security attacks. The following figure shows a sample SCTP association establishment message flow.



Endpoint1 initiates the association by sending Endpoint2 an SCTP packet that contains an INIT chunk, which can include one or more IP addresses used by the initiating endpoint. Endpoint2 acknowledges the initiation of an SCTP association with an SCTP packet that contains an INIT_ACK chunk. This chunk can also include one or more IP addresses at used by the responding endpoint.

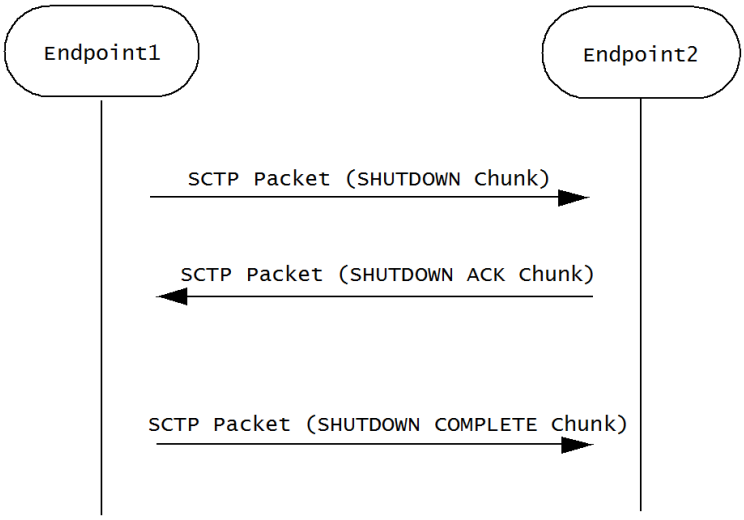
Both the INIT chuck (issued by the initiator) and INIT ACK chunk (issued by the responder) specify the number of outbound streams supported by the association, as well as the maximum inbound streams accepted from the other endpoint.

Association establishment is completed by a COOKIE ECHO/COOKIE ACK exchange that specifies a cookie value used in all subsequent DATA exchanges.

Once an association is successfully established, an SCTP endpoint can send unidirectional data streams using SCTP packets that contain DATA chunks. The recipient endpoint acknowledges with an SCTP packet containing a SACK chunk.

SCTP monitors endpoint reachability by periodically sending SCTP packets that contain HEARTBEAT chunks. The recipient endpoint acknowledges receipt, and confirms availability, with an SCTP packet containing a HEARBEAT ACK chunk.

Either SCTP endpoint can initiate a graceful association close with an SCTP packet that contains a SHUTDOWN chunk. The recipient endpoint acknowledges with an SCTP packet containing a SHUTDOWN ACK chunk. The initiating endpoint concludes the graceful close with an SCTP packet that contains a SHUTDOWN COMPLETE chunk.

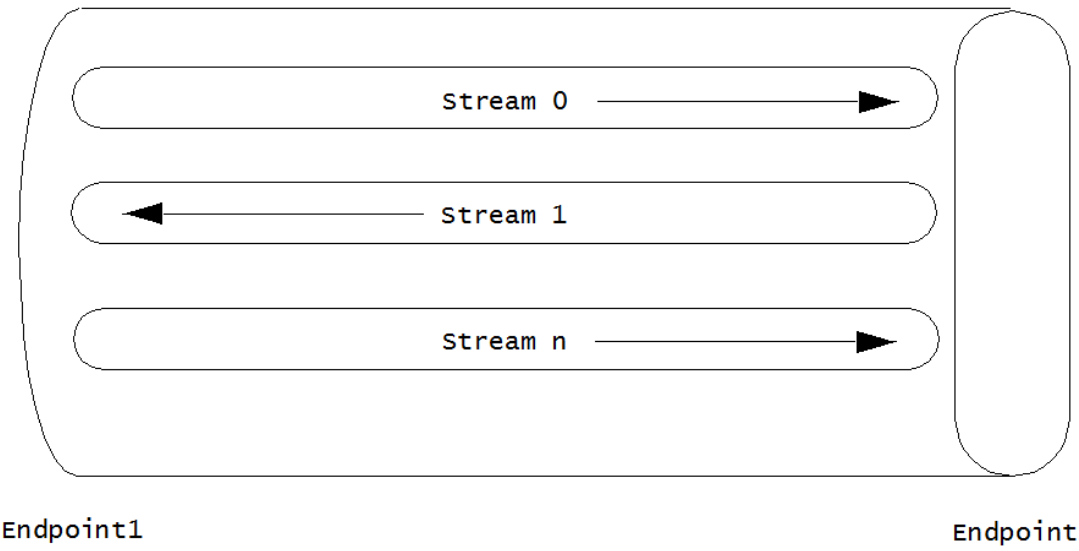


Congestion Control

SCTP congestion control mechanism is similar to that provided by TCP, and includes slow start, congestion avoidance, and fast retransmit. In SCTP, the initial congestion window (cwnd) is set to the double of the maximum transmission unit (MTU) while in TCP, it is usually set to one MTU. In SCTP, cwnd increases based on the number of acknowledged bytes, rather than the number of acknowledgements in TCP. The larger initial cwnd and the more aggressive cwnd adjustment provided by SCTP result in a larger average congestion window and, hence, better throughput performance than TCP.

Multi-Streaming

SCTP supports streams as depicted in the following figure which depicts an SCTP association that supports three streams.



The multiple stream mechanism is designed to solve the head-of-the-line blocking problem of TCP. Therefore, messages from different multiplexed flows do not block one another.

A stream can be thought of as a sub-layer between the transport layer and the upper layer. SCTP supports multiple logical streams to improve data transmission throughput. As shown in the above figure, SCTP allows multiple unidirectional streams within an association. This multiplexing/de-multiplexing capability is called multi-streaming and it is achieved by introducing a field called Stream Identifier contained in every DATA chunk) that is used to differentiate segments in different streams.

SIP transactions are mapped into SCTP streams as described in Section 5.1 of RFC 4168. In what it describes as the simplest way, the RFC suggests (keyword SHOULD) that all SIP messages be transmitted via Stream 0 with the U bit set to 1.

On the transmit side, the current SCTP implementation follows the RFC 4168 recommendation. On the receiving side, a SIP entity must be prepared to receive SIP messages over any stream.

Delivery Modes

SCTP supports two delivery modes, ordered and unordered . Delivery mode is specified by the U bit in the DATA chunk header — if the bit is clear (0), ordered delivery is specified; if the bit is set (1), unordered delivery is specified.

Within a stream, an SCTP endpoint must deliver ordered DATA chunks (received with the U bit set to 0) to the upper layer protocol according to the order of their Stream Sequence Number . Like the U bit, the Stream Sequence Number is a field within the DATA chunk header, and serves to identify the chunk's position with the message stream. If DATA chunks arrive out of order of their Stream Sequence Number, the endpoint must delay delivery to the upper layer protocol until they are reordered and complete.

Unordered DATA chunks (received with the U bit set to 1) are processed differently. When an SCTP endpoint receives an unordered DATA chunk, it must bypass the ordering mechanism and immediately deliver the data to the upper layer protocol (after reassembly if the user data is fragmented by the sender). As a consequence, the Stream Sequence Number field in an unordered DATA chunk has no significance. The sender can fill it with arbitrary value, but the receiver must ignore any value in field.

When an endpoint receives a DATA chunk with the U flag set to 1, it must bypass the ordering mechanism and immediately deliver the data to the upper layer (after reassembly if the user data is fragmented by the data sender).

Unordered delivery provides an effective way of transmitting out-of-band data in a given stream. Note also, a stream can be used as an unordered stream by simply setting the U bit to 1 in all DATA chunks sent through that stream.

Multi-Homing

Call control applications for carrier-grade service require highly reliable communication with no single point of failure. SCTP can assist carriers with its multi-homing capabilities. By providing different paths through the network over separate and diverse means, the goal of no single point of failure is more easily attained.

SCTP built-in support for multi-homed hosts allows a single SCTP association to run across multiple links or paths, hence achieving link/path redundancy. With this capability, and SCTP association can be made to achieve fast failover from one link/path to another with little interruption to the data transfer service.

Multi-homing enables an SCTP host to establish an association with another SCTP host over multiple interfaces identified by different IP addresses. With specific regard to the Oracle

Communications Session Border Controller these IP addresses need not be assigned to the same **phy-interface**, or to the same physical Network Interface Unit.

If the SCTP nodes and the according IP network are configured in such a way that traffic from one node to another travels on physically different paths if different destination IP address are used, associations become tolerant against physical network failures and other problems of that kind.

An endpoint can choose an optimal or suitable path towards a multi-homed destination. This capability increases fault tolerance. When one of the paths fails, SCTP can still choose another path to replace the previous one. Data is always sent over the primary path if it is available. If the primary path becomes unreachable, data is migrated to a different, affiliated address — thus providing a level of fault tolerance. Network failures that render one interface of a server unavailable do not necessarily result in service loss. In order to achieve real fault resilient communication between two SCTP endpoints, the maximization of the diversity of the round-trip data paths between the two endpoints is encouraged.

Multi-Homing and Path Diversity

As previously explained, when a peer is multi-homed, SCTP can automatically switch the subsequent data transmission to an alternative address. However, using multi-homed endpoints with SCTP does not automatically guarantee resilient communications. One must also design the intervening network(s) properly.

To achieve fault resilient communication between two SCTP endpoints, one of the keys is to maximize the diversity of the round-trip data paths between the two endpoints. Under an ideal situation, one can make the assumption that every destination address of the peer will result in a different, separate path towards the peer. Whether this can be achieved in practice depends entirely on a combination of factors that include path diversity, multiple connectivity, and the routing protocols that glue the network together. In a normally designed network, the paths may not be diverse, but there may be multiple connectivity between two hosts so that a single link failure will not fail an association.

In an ideal arrangement, if the data transport to one of the destination addresses (which corresponds to one particular path) fails, the data sender can migrate the data traffic to other remaining destination address(es) (that is, other paths) within the SCTP association.

Monitoring Failure Detection and Recovery

When an SCTP association is established, a single destination address is selected as the primary destination address and all new data is sent to that primary address by default. This means that the behavior of a multi-homed SCTP association when there are no network losses is similar to behavior of a TCP connection. Alternate, or secondary, destination addresses are only used for redundancy purposes, either to retransmit lost packets or when the primary destination address cannot be reached.

A failover to an alternate destination is performed when the SCTP sender cannot elicit an acknowledgement — either a SACK for a DATA chunk, or a HEARTBEAT ACK for a HEARTBEAT chunk — for a configurable consecutive number of transmissions. The SCTP sender maintains an error-counter is maintained for each destination address and if this counter exceeds a threshold (normally six), the address is marked as inactive, and taken out of service. If the primary destination address is marked as inactive, all data is then switched to a secondary address to complete the failover.

If no data has been sent to an address for a specified time, that endpoint is considered to be idle and a HEARTBEAT packet is transmitted to it. The endpoint is expected to respond to the HEARTBEAT immediately with a HEARTBEAT ACK. As well as monitoring the status of

destination addresses, the HEARTBEAT is used to obtain RTT measurements on idle paths. The primary address becomes active again if it responds to a heartbeat.

The number of events where heartbeats were not acknowledged within a certain time, or retransmission events occurred is counted on a per association basis, and if a certain limit is exceeded, the peer endpoint is considered unreachable, and the association is closed.

The threshold for detecting an endpoint failure and the threshold for detecting a failure of a specific IP addresses of the endpoint are independent of each other. Each parameter can be separately configured by the SCTP user. Careless configuration of these protocol parameters can lead the association onto the dormant state in which all the destination addresses of the peer are found unreachable while the peer still remains in the reachable state. This is because the overall retransmission counter for the peer is still below the set threshold for detecting the peer failure.

Configuring SCTP Support for SIP

RFC 4168, *The Stream Control Transfer Protocol (SCTP) as a Transport for the Session Initiation Protocol (SIP)*, specifies the requirements for SCTP usage as a layer 4 transport for SIP. Use the following steps to:

- configure SCTP as the layer 4 transport for a SIP interface
- create an SCTP-based SIP port
- associate **phy-interfaces/network interfaces** with SIP realms
- identify adjacent SIP servers that are accessible via SCTP
- set SCTP timers and counters (optional)

Configuring an SCTP SIP Port

SIP ports are created as part of the SIP Interface configuration process.

1. From superuser mode, use the following command sequence to access sip-port configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)# sip-ports
ORACLE(sip-port)#
```

2. Use the **address** parameter to provide the IPv4 or IPv6 address of the network interface that supports the SIP port.

   This is the primary address of a the local multi-homed SCTP endpoint.

```
ORACLE(sip-port)# address 172.16.10.76
ORACLE(sip-port)#
```

3. Retain the default value, 5060 (the well-known SIP port) for the **port** parameter.

```
ORACLE(sip-port)# port 5060
ORACLE(sip-port)#
```

4. Use the **transport-protocol** parameter to identify the layer 4 protocol.

Supported values are UDP, TCP, TLS, and SCTP.

Select SCTP.

```
ORACLE(sip-port)# transport-protocol sctp
ORACLE(sip-port)#
```

5. Use the **multi-homed-addrs** parameter to specify one or more local secondary addresses of the SCTP endpoint.

   Multi-homed addresses must be of the same type (IPv4 or IPv6) as that specified by the **address** parameter. Like the address parameter, these addresses identify SD network interfaces.

   To specify multiple addresses, bracket an address list with parentheses.

```
ORACLE(sip-port)# multi-homed-addrs 182.16.10.76
ORACLE(sip-port)#
ORACLE(sip-port)# multi-homed-addrs (182.16.10.76 192.16.10.76
196.15.32.108)
ORACLE(sip-port)#
```

6. Remaining parameters can be safely ignored.
7. Use **done**, **exit**, and **verify-config** to complete configuration of this SCTP-based SIP port.

```
ORACLE(sip-port)# done
ORACLE(sip-interface)# exit
ORACLE(session-router)# exit
ORACLE(configure)# exit
ORACLE# verify-config
-------------------------------------------------------------------------
Verification successful! No errors nor warnings in the configuration
ORACLE#
```

Configuring the Realm

After configuring a SIP port which identifies primary and secondary multi-homed transport addresses, you identify the network interfaces that support the primary address and secondary addresses to the realm assigned during SIP Interface configuration.

1. From superuser mode, use the following command sequence to access realm-config configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Use the **select** command to access the target realm.
3. Use the **network-interfaces** command to identify the network interfaces that support the SCTP primary and secondary addresses.

   Network interfaces are identified by their name.

Enter a list of network interface names using parentheses as list brackets. The order of interface names is not significant.

```
ORACLE(realm-config)# network-interfaces (mo1 M10)
ORACLE(realm-config)#
```

4. Use **done**, **exit**, and **verify-config** to complete realm configuration.

```
ORACLE(realm-config)# done
ORACLE(media-manager)# exit
ORACLE(configure)# exit
ORACLE# verify-config
-------------------------------------------------------------------------
Verification successful! No errors nor warnings in the configuration
ORACLE#
```

Configuring Session Agents

After configuring the realm, you identify adjacent SIP servers who will be accessed via the SCTP protocol.

1. From superuser mode, use the following command sequence to access session-agent configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

2. Use the **select** command to access the target session-agent.
3. Use the **transport-method** parameter to select the layer 4 transport protocol.

   Select staticSCTP for SCTP transport

```
ORACLE(session-agent)# transport-method staticSCTP
ORACLE(session-agent)#
```

4. Set the **reuse-connections** parameter to none.

   Select staticSCTP for SCTP transport

```
ORACLE(session-agent)# reuse-connections none
ORACLE(session-agent)#
```

5. Use **done**, **exit**, and **verify-config** to complete session agent configuration.

```
ORACLE(session-agent)# done
ORACLE(session-router)# exit
ORACLE(configure)# exit
ORACLE# verify-config
-------------------------------------------------------------------------
Verification successful! No errors nor warnings in the configuration
ORACLE#
```

6. Repeat Steps 1 through 5 as necessary to configure additional session agents who will be accessed via SCTP transport.

Setting SCTP Timers and Counters

Setting SCTP timers and counters is optional. All configurable timers and counters provide default values that conform to recommended values as specified in RFC 4960, Stream Control Transmission Protocol.

Management of Retransmission Timer, section 6.3 of RFC 4960 describes the calculation of a Retransmission Timeout (RTO) by the SCTP process. This calculation involves three SCTP protocol parameters: RTO.Initial, RTO.Min, and RTO.Max. Suggested SCTP Protocol Parameter Values section 15 of RFC 4960 lists recommended values for these parameters.

The following shows the equivalence of recommended values and ACLI defaults.

RTO.Initial = 3 seconds **sctp-rto-initial = 3000 ms (default value)**

RTO.Min = 1 second **sctp-rto-min = 1000 ms (default value)**

RTO.Max = 60 seconds **sctp-rto-max = 60000 ms (default value)**

Path Heartbeat, section 8.3 of RFC 4960 describes the calculation of a Heartbeat Interval by the SCTP process. This calculation involves the current calculated RTO and a single SCTP protocol parameter — HB.Interval.

The following shows the equivalence of recommended the value and ACLI default.

HB.Interval = 30 seconds **sctp-hb-interval = 3000 ms (default value)**

Acknowledgement on Reception of DATA Chunks, section 6.2 of RFC 4960 describes requirements for the timely processing and acknowledgement of DATA chunks. This section requires that received DATA chunks must be acknowledged within 500 milliseconds, and recommends that DATA chunks should be acknowledged with 200 milliseconds. The interval between DATA chunk reception and acknowledgement is specific by the ACLI **sctp-sack-timeout** parameter, which provides a default value of 200 milliseconds and a maximum value of 500 milliseconds.

Transmission of DATA Chunks, section 6.1 of RFC 4960 describes requirements for the transmission of DATA chunks. To avoid network congestion the RFC recommends a limitation on the volume of data transmitted at one time. The limitation is expressed in terms of DATA chunks, not in terms of SCTP packets.

The maximum number of DATA chunks that can be transmitted at one time is specified by the ACLI **sctp-max-burst** parameter, which provides a default value of 4 chunks, the limit recommended by the RFC.

Setting the RTO

An SCTP endpoint uses a retransmission timer to ensure data delivery in the absence of any feedback from its peer. RFC 4960 refers to the timer itself as T3-rtx and to the timer duration as RTO (retransmission timeout).

When an endpoint's peer is multi-homed, the endpoint calculates a separate RTO for each IP address affiliated with the peer. The calculation of RTO in SCTP is similar to the way TCP calculates its retransmission timer. RTO fluctuates over time in response to actual network conditions. To calculate the current RTO, an endpoint maintains two state variables per destination IP address — the SRTT (smoothed round-trip time) variable, and the RTTVAR (round-trip time variation) variable.

Use the following procedure to assign values used in RTO calculation.

1. From superuser mode, use the following command sequence to access network-parameters configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-parameters
ORACLE(network-parameters)#
```

2. Use the **sctp-rto-initial** parameter to assign an initial timer duration.

   Allowable values are integers within the range 0 through 4294967295 that specify the initial duration in milliseconds. In the absence of an explicitly configured integer value, **sctp-rto-initial** defaults to 3000 milliseconds (3 seconds, the recommended default value from RFC 4960).

   As described in Section 6.3 of RFC 4960, the value specified by **sctp-rto-initial** is assigned to the SCTP protocol parameter RTO.Initial, which provides a default RTO until actual calculations have derived a fluctuating duration based on network usage. The value specified by the **sctp-rto-initia**l parameter seeds these calculations.

```
ORACLE(network-parameters)# sctp-rto-initial 3000
ORACLE(network-parameters)#
```

3. Use the **sctp-rto-min** and **sctp-rto-max** parameters to assign an RTO floor and ceiling.

   Allowable values are integers within the range 0 through 4294967295 that specify the minimum and maximum durations in milliseconds. In the absence of an explicitly configured integer value, **sctp-rto-min** defaults to 1000 ms (1 second, the recommended default value from RFC 4960), and **sctp-rto-max** defaults to 60000 ms (60 seconds, the recommended default value from RFC 4960.)

   As described in Section 6.3 of RFC 4960, the values specified by **sctp-rto-min** and **sctp-rto-max** are assigned to the SCTP protocol parameters, RTO.min and RTO.max that limit RTO calculations. If a calculated RTO duration is less than RTO.min, the parameter value is used instead of the calculated value; likewise, if a calculated RTO duration is greater than RTO.max, the parameter value is used instead of the calculated value.

```
ORACLE(network-parameters)# sctp-rto-min 1000
ORACLE(network-parameters)# sctp-rto-max 60000
ORACLE(network-parameters)#
```

4. Use **done**, **exit**, and **verify-config** to complete RTO configuration.

```
ORACLE(network-parameters)# done
ORACLE(system)# exit
ORACLE(configure)# exit
ORACLE(configure)# exit
ORACLE# verify-config
-------------------------------------------------------------------------
Verification successful! No errors nor warnings in the configuration
ORACLE#
```

Setting the Heartbeat Interval

Both single-homed and multi-homed SCTP endpoints test the reachability of associates by sending periodic HEARTBEAT chunks to UNCONFIRMED or idle transport addresses.

Use the following procedure to assign values used in Heartbeat Interval calculation.

1. From superuser mode, use the following command sequence to access network-parameters configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-parameters
ORACLE(network-parameters)#
```

2. Use the **sctp-hb-interval** parameter to assign an initial Heartbeat Interval duration.

   Allowable values are integers within the range 0 through 4294967295 that specify the initial Heartbeat Interval in milliseconds. In the absence of an explicitly configured integer value, **sctp-hb-interval** defaults to 30000 milliseconds (30 seconds, the recommended default value from RFC 4960).

   As described in Section 8.3 of RFC 4960, the value specified by **sctp-hb-interval** is assigned to the SCTP protocol parameter HB.Interval, which provides a default interval until actual calculations have derived a fluctuating interval based on network usage. The value specified by the **sctp-hb-interval** parameter is used during these calculations.

```
ORACLE(network-parameters)# sctp-hb-interval 30000
ORACLE(network-parameters)#
```

3. Use **done**, **exit**, and **verify-config** to complete Heartbeat Interval configuration.

```
ORACLE(network-parameters)# done
ORACLE(system)# exit
ORACLE(configure)# exit
ORACLE(configure)# exit
ORACLE# verify-config
-------------------------------------------------------------------------
Verification successful! No errors nor warnings in the configuration
ORACLE #
```

Setting the SACK Delay Timer

An SCTP Selective Acknowledgement (SACK) is sent to the peer endpoint to acknowledge received DATA chunks and to inform the peer endpoint of gaps in the received subsequences of DATA chunks. Section 6.2 of RFC 4960 sets a specific requirement for a SACK Delay timer that specifies the maximum interval between the reception of an SCTP packet containing one or more DATA chunks and the transmission of a SACK to the packet originator.

Use the following procedure to set the SACK Delay timer.

1. From superuser mode, use the following command sequence to access network-parameters configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# system
```

```
ORACLE(system)# network-parameters
ORACLE(network-parameters)#
```

2. Use the **sctp-sack-timeout** parameter to assign a value to the SACK Delay timer.

   Allowable values are integers within the range 0 through 500 which specify the maximum delay (in milliseconds) between reception of a SCTP packet containing one or more Data chunks and the transmission of a SACK to the packet source. The value 0 indicates that a SACK is generated immediately upon DATA chunk reception

   In the absence of an explicitly configured integer value, **sctp-sack-timeout** defaults to 200 ms (the recommended default value from RFC 4960).

```
ORACLE(network-parameters)# sctp-sack-timeout 200
ORACLE(network-parameters)#
```

3. Use **done**, **exit**, and **verify-config** to complete configuration of the SACK Delay timer.

```
ORACLE(network-parameters)# done
ORACLE(system)# exit
ORACLE(configure)# exit
ORACLE(configure)# exit
ORACLE# verify-config
-------------------------------------------------------------------------
Verification successful! No errors nor warnings in the configuration
ORACLE#
```

Limiting DATA Bursts

Section 6.1 of RFC 4960 describes the SCTP protocol parameter, Max.Burst, used to limit the number of DATA chunks that are transmitted at one time.

Use the following procedure to assign a value to the SCTP protocol parameter, Max.Burst.

1. From superuser mode, use the following command sequence to access network-parameters configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-parameters
ORACLE(network-parameters)#
```

2. Use the **sctp-max-burst** parameter to assign a value to the SCTP protocol parameter, Max.Burst.

   Allowable values are integers within the range 0 through 4294967295 that specify the maximum number of DATA chunks that will be sent at one time. In the absence of an explicitly configured integer value, **sctp-max-burst** defaults to 4 (DATA chunks, the recommended default value from RFC 4960).

```
ORACLE(network-parameters)# sctp-max-burst 4
ORACLE(network-parameters)#
```

3. Use **done**, **exit**, and **verify-config** to complete configuration of DATA burst limitations.

```
ORACLE(network-parameters)# done
ORACLE(system)# exit
```

```
ORACLE(configure)# exit
ORACLE(configure)# exit
ORACLE# verify-config
-------------------------------------------------------------------------
Verification successful! No errors nor warnings in the configuration
ORACLE#
```

Setting Endpoint Failure Detection

As described in Monitoring, Failure Detection and Recovery, a single-homed SCTP endpoint maintains a count of the total number of consecutive failed (unacknowledged) retransmissions to its peer. Likewise, a multi-homed SCTP endpoint maintains a series of similar, dedicated counts for all of its destination transport addresses. If the value of these counts exceeds the limit indicated by the SCTP protocol parameter Association.Max.Retrans, the endpoint considers the peer unreachable and stops transmitting any additional data to it, causing the association to enter the CLOSED state.

The endpoint resets the counter when (1) a DATA chunk sent to that peer endpoint is acknowledged by a SACK, or (2) a HEARTBEAT ACK is received from the peer endpoint.

Use the following procedure to configure endpoint failure detection.

1. From superuser mode, use the following command sequence to access network-parameters configuration mode.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# system
   ORACLE(system)# network-parameters
   ORACLE(network-parameters)#
   ```

2. Use the **sctp-assoc-max-retrans** to assign a value to the SCTP protocol parameter Association.Max.Retrans.

   Allowable values are integers within the range 0 through 4294967295 which specify the maximum number of transmission requests. In the absence of an explicitly configured integer value, s**ctp-assoc-max-retrans** defaults to 10 (transmission re-tries, the recommended default value from RFC 4960).

   ```
   ORACLE(network-parameters)# sctp-assoc-max-retrans 10
   ORACLE(network-parameters)#
   ```

3. Use **done**, **exit**, and **verify-config** to complete endpoint failure detection configuration.

   ```
   ORACLE(network-parameters)# done
   ORACLE(system)# exit
   ORACLE(configure)# exit
   ORACLE(configure)# exit
   ORACLE# verify-config
   -------------------------------------------------------------------------
   Verification successful! No errors nor warnings in the configuration
   ORACLE#
   ```

Setting Path Failure Detection

As described in Monitoring, Failure Detection and Recovery, when its peer endpoint is multi-homed, an SCTP endpoint maintains a count for each of the peer's destination transport addresses.

Each time the T3-rtx timer expires on any address, or when a HEARTBEAT sent to an idle address is not acknowledged within an RTO, the count for that specific address is incremented. If the value of a specific address count exceeds the SCTP protocol parameter Path.Max.Retrans, the endpoint marks that destination transport address as inactive.

The endpoint resets the counter when (1) a DATA chunk sent to that peer endpoint is acknowledged by a SACK, or (2) a HEARTBEAT ACK is received from the peer endpoint.

When the primary path is marked inactive (due to excessive retransmissions, for instance), the sender can automatically transmit new packets to an alternate destination address if one exists and is active. If more than one alternate address is active when the primary path is marked inactive, a single transport address is chosen and used as the new destination transport address.

Use the following procedure to configure path failure detection.

1. From superuser mode, use the following command sequence to access network-parameters configuration mode.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# system
   ORACLE(system)# network-parameters
   ORACLE(network-parameters)#
   ```

2. Use the **sctp-path-max-retrans** parameter to assign a value to the SCTP protocol parameter Path.Max.Retrans.

   Allowable values are integers within the range 0 through 4294967295 that specify the maximum number of RTOs and unacknowledged HEARTBEATS. In the absence of an explicitly configured integer value, **sctp-path-max-retrans** defaults to 5 (RTO and/or HEARTBEAT errors per transport address, the recommended default value from RFC 4960).

   When configuring endpoint and path failure detection, ensure that the value of the **sctp-assoc-max-retrans** parameter is smaller than the sum of the **sctp-path-max-retrans** values for all the remote peer's destination addresses. Otherwise, all the destination addresses can become inactive (unable to receive traffic) while the endpoint still considers the peer endpoint reachable.

   ```
   ORACLE(network-parameters)# sctp-path-max-retrans 5
   ORACLE(network-parameters)#
   ```

3. Use **done**, **exit**, and **verify-config** to complete path failure detection configuration.

   ```
   ORACLE(network-parameters)# done
   ORACLE(system)# exit
   ORACLE(configure)# exit
   ORACLE(configure)# exit
   ORACLE# verify-config
   ----------------------------------------------------------------------
   ```

```
Verification successful! No errors nor warnings in the configuration
ORACLE#
```

Specifying the Delivery Mode

As described in Delivery Modes, SCTP support two delivery modes, ordered and unordered.

1. From superuser mode, use the following command sequence to access network-parameters configuration mode.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# system
   ORACLE(system)# network-parameters
   ORACLE(network-parameters)#
   ```

2. Use the **sctp-send-mode** parameter to select the preferred delivery mode.

   Choose ordered or unordered.

   ```
   ORACLE(network-parameters)# sctp-send-mode unordered
   ORACLE(network-parameters)#
   ```

3. Use **done**, **exit**, and **verify-config** to complete delivery mode configuration.

   ```
   ORACLE(network-parameters)# done
   ORACLE(system)# exit
   ORACLE(configure)# exit
   ORACLE(configure)# exit
   ORACLE# verify-config
   ----------------------------------------------------------------------
   Verification successful! No errors nor warnings in the configuration
   ORACLE #
   ```

Example Configurations

The following ACLI command sequences summarize required SCTP port configuration, and the configuration of required supporting elements.

- PHY interfaces
- Network interfaces
- SIP ports
- realms
- session agents

Sequences show only configuration parameters essential for SCTP operations; other parameters can retain default values, or assigned other values specific to local network requirements.

Phy Interface Configuration

The first ACLI command sequence configures a **phy-interface** named m10, that will support an SCTP primary address; the second sequence configures a **phy-interface** named m01 that will support a secondary SCTP address.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# phy-interface
ORACLE(phy-interface)# operation-type media
ORACLE(phy-interface)# port 0
ORACLE(phy-interface)# slot 1
ORACLE(phy-interface)# name m10
ORACLE(phy-interface)#
...
...
...
ORACLE(phy-interface)#
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# phy-interface
ORACLE(phy-interface)# operation-type media
ORACLE(phy-interface)# port 1
ORACLE(phy-interface)# slot 0
ORACLE(phy-interface)# name m01
ORACLE(phy-interface)#
...
...
...
ORACLE(phy-interface)#
```

Network Interface Configuration

These ACLI command sequences configure two **network-interface**s. The first sequence configures a **network-interface** named m10, thus associating the **network-interface** with the **phy-interface** of the same name. The ACLI **ip-address** command assigns the IPv4 address 172.16.10.76 to the **network-interface**. In a similar fashion, the second command sequence associates the m01 network and **phy-interfaces**, and assigns an IPv4 address of 182.16.10.76.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-interface
ORACLE(network-interface)# name m10
ORACLE(network-interface)# ip-address 172.16.10.76
...
...
...
ORACLE(network-interface)#
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(system)# network-interface
ORACLE(network-interface)# name m01
ORACLE(network-interface)# ip-address 182.16.10.76
```

```
...
...
...
ORACLE(network-interface)#
```

SIP Port Configuration

This ACLI command sequence configures a SIP port for SCTP operations. It specifies the use of SCTP as the transport layer protocol, and assigns the existing network interface address, 172.16.10.76, as the SCTP primary address. Additionally, it identifies three other existing network addresses (182.16.10.76, 192.16.10.76, and 196.15.32.108) as SCTP secondary addresses.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)# sip-ports
ORACLE(sip-port)# address 172.16.10.76
ORACLE(sip-port)# transport-protocol sctp
ORACLE(sip-port)# multi-homed-addrs (182.16.10.76 192.16.10.76 196.15.32.108)
...
...
...
ORACLE(sip-port)#
```

Realm Configuration

These ACLI command sequences configure a realm for SCTP operations. The first ACLI sequence assigns a named realm, in this example core-172, to a SIP interface during the interface configuration process. The second sequence accesses the target realm and uses the **network-interfaces** command to associate the named SCTP network interfaces with the realm.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)# realm-id core-172
...
...
...
ORACLE(sip-interface)#
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)# select
identifier: core-172
1. core-172 ...
selection: 1
ORACLE(realm-config)# network-interfaces (m01 m10 ...)
...
...
...
ORACLE(ream-config)#
```

Session Agent Configuration

The final ACLI command sequence enables an SCTP-based transport connection between the Oracle Communications Session Border Controller and an adjacent network element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# session-agent
ORACLE(session-agent)# select
<hostname>: core-172S1
1. core-172S1 ...
selection: 1
ORACLE(session-agent)#
ORACLE(session-agent)# transport-method staticSCTP
ORACLE(session-agent)# reuse-connections none
...
...
...
ORACLE(session-agent)#
```

IPv6 Address Configuration

This section calls out the configurations and parameters for which you can enter IPv6 addresses. In this first IPv6 implementation, the complete range of system configurations and their parameters are available for IPv6 use.

The Oracle Communications Session Border Controller follows RFC 3513 its definition of IPv6 address representations. Quoting from that RFC, these are the two forms supported:

- The preferred form is x:x:x:x:x:x:x:x, where the 'x's are the hexadecimal values of the eight 16-bit pieces of the address. Examples:

FEDC:BA98:7654:3210:FEDC:BA98:7654:3210

1080:0:0:0:8:800:200C:417A

Note that it is not necessary to write the leading zeros in an individual field, but there must be at least one numeral in every field (except for the case described in 2.).

- Due to some methods of allocating certain styles of IPv6 addresses, it will be common for addresses to contain long strings of zero bits. In order to make writing addresses containing zero bits easier a special syntax is available to compress the zeros. The use of "::" indicates one or more groups of 16 bits of zeros. The "::" can only appear once in an address. The "::" can also be used to compress leading or trailing zeros in an address. For example, the following addresses: 1080:0:0:0:8:800:200C:417A a unicast address FF01:0:0:0:0:0:0:101 a multicast address
  0:0:0:0:0:0:0:1 the loopback address

  0:0:0:0:0:0:0:0 the unspecified addresses

  may be represented as:

  1080::8:800:200C:417A a unicast address

  FF01::101 a multicast address

  ::1 the loopback address

  :: the unspecified addresses

> **Note:**
>
> For ACLI parameters that support only IPv4, there are many references to that version as the accepted value for a configuration parameter or other IPv4-specific languages. For IPv6 support, these references have been edited. For example, rather than providing help that refers specifically to IPv4 addresses when explaining what values are accepted in an ACLI configuration parameter, you will now see an <ipAddr> note.

Access Control

These are the IPv6-enabled parameters in the **access-control** configuration.

Parameter	Entry Format
source-address	<ip-address>[/<num-bits>][:<port>[/<port-bits>]]
destination-address	<ip-address>[/<num-bits>][:<port>[/<port-bits>]]

Host Route

These are the IPv6-enabled parameters in the **host-route** configuration.

Parameter	Entry Format
dest-network	<ipv4> | <ipv6>
netmask	<ipv4> | <ipv6>
gateway	<ipv4> | <ipv6>

Local Policy

These are the IPv6-enabled parameters in the **local-policy** configuration.

Parameter	Entry Format
from-address	<ipv4> | <ipv6> | POTS Number, E.164 Number, hostname, wildcard
to-address	<ipv4> | <ipv6> | POTS Number, E.164 Number, hostname, wildcard

Network Interface

These are the IPv6-enabled parameters in the **network-interface** configuration.

Parameter	Entry Format
hostname	<ipv4> | <ipv6> | hostname
ip-address	<ipv4> | <ipv6>
pri-utility-addr	<ipv4> | <ipv6>
sec-utility-addr	<ipv4> | <ipv6>
netmask	<ipv4> | <ipv6>
gateway	<ipv4> | <ipv6>
sec-gateway	<ipv4> | <ipv6>
dns-ip-primary	<ipv4> | <ipv6>

Parameter	Entry Format
dns-ip-backup1	<ipv4> | <ipv6>
dns-ip-backup2	<ipv4> | <ipv6>
add-hip-ip	<ipv4> | <ipv6>
remove-hip-ip	<ipv4> | <ipv6>
add-icmp-ip	<ipv4> | <ipv6>
remove-icmp-ip	<ipv4> | <ipv6>

ENUM Server

These are the IPv6-enabled parameters in the enum-config.

Parameter	Entry Format
enum-servers	[<ipv4> | <ipv6>]:port

Realm Configuration

These are the IPv6-enabled parameters in the **realm-config**.

Parameter	Entry Format
addr-prefix	[<ipv4> | <ipv6>]/prefix

Session Agent

These are the IPv6-enabled parameters in the **session-agent** configuration.

Parameter	Entry Format
hostname	<ipv4> | <ipv6>
ip-address	<ipv4> | <ipv6>

SIP Configuration

These are the IPv6-enabled parameters in the **session-config**.

Parameter	Entry Format
registrar-host	<ipv4> | <ipv6> | hostname | *

SIP Interface SIP Ports

These are the IPv6-enabled parameters in the **sip-interface>sip-ports** configuration.

Parameter	Entry Format
address	<ipv4> | <ipv6>

Steering Pool

These are the IPv6-enabled parameters in the **steering-pool** configuration.

Parameter	Entry Format
ip-address	<ipv4> | <ipv6>

System Configuration

These are the IPv6-enabled parameters in the **system-config**.

Parameter	Entry Format
default-v6-gateway	<ipv6>

Account Server

These are the IPv6-enabled parameters in the **account-server** configuration.

Parameter	Entry Format
hostname	<ip-address>[/<num-bits>][:<port>[/<port-bits>]]
dns-query-type	<none><A><AAAA>

> **Note:**
>
> When set to none, the system refers to the interface associated with the dns-realm setting in the account-config. If the interface has an IPv6 address, the system performs an AAAA query.

IPv6 Support for Management and Telemetry

Several management-oriented parameters on the Oracle Communications Session Border Controller may be configured with IPv6 addresses to be used within IPv6 networks.

The following parameters that are configured with IP addresses accept IPv6 addresses to be used within IPv6 address space.

You may configure the wancom0/eth0 physical interface in the bootparams with an IPv6 address and complementary IPv6 gateway via the following parameters:

- **bootparams**, **inet on ethernet**
- **bootparams**, **gateway inet**

You may configure a syslog server with an IPv6 destination address via the following parameter:

- **system**, **system-config**, **syslog-servers**, **address**

You may configure a system access list entry with an IPv6 source address and complementary IPv6 gateway.

- **system**, **system-access-list**, **source-address**
- **system**, **system-access-list**, **netmask**

You may configure a RADIUS server with an IPv6 destination address via the following parameter:

- **security**, **authentication**, **radius-servers**, **address**

IPv6 Default Gateway

In the system configuration, you configure a default gateway—a parameter that now has its own IPv6 equivalent.

To configure an IPv6 default gateway:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **system** and press Enter.

```
ORACLE(configure)# system
ORACLE(system)#
```

3. Type **system-config** and press Enter.

```
ORACLE(system)# system-config
ORACLE(system-config)#
```

4. **default-v6-gateway**—Set the IPv6 default gateway for this Oracle Communications Session Border Controller. This is the IPv6 egress gateway for traffic without an explicit destination. The application of your Oracle Communications Session Border Controller determines the configuration of this parameter.
5. Save your work.

IPv6 Link Local Addresses

The Oracle Communications Session Border Controller supports IPv6 Link Local addresses configured for a network interface's gateway.

An IPv6 link local address is signified by its first hextet set to FE80:. Even if a network interface's first hextet is not FE80, but the gateway is, the Oracle Communications Session Border Controller will still function as expected.

show neighbor-table

The show neighbor-table command displays the IPv6 neighbor table and validates that there is an entry for the link local address, and the gateway uses that MAC address.

```
System# show neighbor-table
LINK LEVEL NEIGHBOR TABLE
Neighbor                              Linklayer Address  Netif Expire    S
```

```

Network Interfaces and IPv6

You set many IP addresses in the network interface, one of which is the specific IP address for that network interface and others that are related to different types of management traffic. This section outlines rules you must follow for these entries.

- For the **network-interface ip-address** parameter, you can set a single IP address. When you are working with an IPv6-enabled system, however, note that all other addresses related to that network-interface IP address must be of the same version.
- Heterogeneous address family configuration is prevented for the **dns-ip-primary**, **dns-ip-backup1**, and **dns-ip-backup2** parameters.
- For HIP addresses (**add-hip-ip**), you can use either IPv4 or IPv6 entries.
- For ICMP addresses (**add-icmp-ip**), you can use either IPv4 or IPv6 entries.

IPv6 Reassembly and Fragmentation Support

As it does for IPv4, the Oracle Communications Session Border Controller supports reassembly and fragmentation for large signaling packets when you enable IPV6 on your system.

The Oracle Communications Session Border Controller takes incoming fragments and stores them until it receives the first fragment containing a Layer 4 header. With that header information, the Oracle Communications Session Border Controller performs a look-up so it can forward the packets to its application layer. Then the packets are re-assembled at the applications layer. Media fragments, however, are not reassembled and are instead forwarded to the egress interface.

On the egress side, the Oracle Communications Session Border Controller takes large signaling messages and encodes it into fragment datagrams before it transmits them.

Note that large SIP INVITE messages should be sent over TCP. If you want to modify that behavior, you can use the SIP interface's option parameter **max-udp-length=xx** for each SIP interface where you expect to receive large INVITE packets.

Other than enabling IPv6 on your Oracle Communications Session Border Controller, there is no configuration for IPv6 reassembly and fragmentation support. It is enabled automatically.

Access Control List Support

The Oracle Communications Session Border Controller supports IPv6 for access control lists in two ways:

- For static access control lists that you configure in the **access-control** configuration, your entries can follow IPv6 form. Further, this configuration supports a prefix that enables wildcarding the source IP address.
- Dynamic ACLs are also supported; the Oracle Communications Session Border Controller will create ACLs for offending IPv6 endpoints.

Data Entry

When you set the **source-address** and **destination-address** parameters in the **access-control** configuration, you will use a slightly different format for IPv6 than for IPv4.

For the **source-address**, your IPv4 entry takes the following format: <ip-address>[/<num-bits>][:<port>[/<port-bits>]]. And for the **destination-address**, your IPv4 entry takes this format: <ip-address>[:<port>[/<port-bits>]].

Since the colon (:) in the IPv4 format leads to ambiguity in IPv6, your IPv6 entries for these settings must have the address encased in brackets ([]): [7777::11]/64:5000/14.

In addition, IPv6 entries are allowed up to 128 bits for their prefix lengths.

The following is an example access control configuration set up with IPv6 addresses.

```
ORACLE(access-control)# done
access-control
        realm-id                        net7777
        description
        source-address                  7777::11/64:5060/8
        destination-address             8888::11:5060/8
        application-protocol            SIP
        transport-protocol              ALL
        access                          deny
        average-rate-limit              0
        trust-level                     none
        minimum-reserved-bandwidth      0
        invalid-signal-threshold        10
```

```
maximum-signal-threshold       0
untrusted-signal-threshold     0
deny-period                    30
```

Homogeneous Realms

IPv6 is supported for realms and for nested realms, as long as the parent chain remains within the same address family. If you try to configure realms with mixed IPv4-IPv6 addressing, your system will issue an error message when you try to save your configuration. This check saves you time because you do not have to wait to run a configuration verification (using the ACLI **verify-config** command) to find possible errors.

Parent-Child Network Interface Mismatch

Your system will issue the following error message if parent-child realms are on different network interfaces that belong to different address families:

```
ERROR: realm-config [child] and parent [net8888] are on network interfaces
that belong to different address families
```

Address Prefix-Network Interface Mismatch

If the address family and the address-prefix you configure for the realm does not match the address family of its network interface, your system will issue the following error message:

```
ERROR: realm-config [child] address prefix and network interface [1:1:0]
belong to different address families
```

RADIUS Support for IPv6

The Oracle Communications Session Border Controller's RADIUS support includes:

- RADIUS CDR generation for SIPv6-SIPv6 and SIPv6-SIPv4 calls
- IPv6-based addresses in RADIUS CDR attributes

The sixteen-byte requirement for IPv6 addresses is supported, and there is a set of attributes with the type ipv6addr. Attributes 155-170 are reserved for the IPv6 addresses.

NAS addresses use the number 95 to specify the NAS-IPV6-Address attribute. And local CDRs now contain IPv6 addresses.

Supporting RADIUS VSAs

The following VSAs have been added to the Oracle RADIUS dictionary to support IPv6.

```
Acme-Flow-In-Src-IPv6_Addr_FS1_F        155     ipv6addr      Acme
Acme-Flow-In-Dst-IPv6_Addr_FS1_F        156     ipv6addr      Acme
Acme-Flow-Out-Src-IPv6_Addr_FS1_F       157     ipv6addr      Acme
Acme-Flow-Out-Dst-IPv6_Addr_FS1_F       158     ipv6addr      Acme
Acme-Flow-In-Src-IPv6_Addr_FS1_R        159     ipv6addr      Acme
Acme-Flow-In-Dst-IPv6_Addr_FS1_R        160     ipv6addr      Acme
Acme-Flow-Out-Src-IPv6_Addr_FS1_R       161     ipv6addr      Acme
```

```
Acme-Flow-Out-Dst-IPv6_Addr_FS1_R       162     ipv6addr      Acme
Acme-Flow-In-Src-IPv6_Addr_FS2_F        163     ipv6addr      Acme
Acme-Flow-In-Dst-IPv6_Addr_FS2_F        164     ipv6addr      Acme
Acme-Flow-Out-Src-IPv6_Addr_FS2_F       165     ipv6addr      Acme
Acme-Flow-Out-Dst-IPv6_Addr_FS2_F       166     ipv6addr      Acme
Acme-Flow-In-Src-IPv6_Addr_FS2_R        167     ipv6addr      Acme
Acme-Flow-In-Dst-IPv6_Addr_FS2_R        168     ipv6addr      Acme
Acme-Flow-Out-Src-IPv6_Addr_FS2_R       169     ipv6addr      Acme
Acme-Flow-Out-Dst-IPv6_Addr_FS2_R       170     ipv6addr      Acme
```

NTP Synchronization

This section provides information about how to set and monitor NTP on your Oracle Communications Session Border Controller.

When an NTP server is unreachable or when NTP service goes down, the Oracle Communications Session Border Controller generates traps for those conditions. Likewise, the Oracle Communications Session Border Controller clears those traps when the conditions have been rectified. The Oracle Communications Session Border Controller considers a configured NTP server to be unreachable when its reach number (whether or not the NTP server could be reached at the last polling interval; successful completion augments the number) is 0. You can see this value for a server when you use the ACLI **show ntp server** command.

- The traps for when a server is unreachable and then again reachable are: **apSysMgmtNTPServerUnreachableTrap** and **apSysMgmtNTPServerUnreachableClearTrap**
- The traps for when NTP service goes down and then again returns are: **apSysMgmtNTPServiceDownTrap** and **apSysMgmtNTPServiceDownClearTrap**

> **Note:**
>
> The Oracle Communications Session Border Controller does not support NTP service over wancom0 when that interface is configured for a VLAN.

Setting NTP Synchronization

When the SBC requires time-critical processing, you can set NTP for time synchronization. Setting NTP synchronizes both the hardware and the software clocks with the reference time from an NTP server that you specify. NTP is most useful for synchronizing multiple devices located on one network, or across many networks, to a reference time standard.

To guard against NTP server failure, NTP is restarted periodically to support the dynamic recovery of an NTP server.

Note that **ntp-sync** works only by way of the management interface and only on wancom0. Do not configure **ntp-sync** by way of the media interface or any other port.

To set NTP synchronization:

1. In the ACLI's configure terminal section, type **ntp-sync** and then press Enter to access the NTP configuration.

```
ORACLE# configure terminal
ORACLE(configure)# ntp-sync
ORACLE(ntp-config)#
```

2. To add an NTP server, type **add-server**, the Space bar, then the FQDN, IPv4, or IPv6 address of the server and then press the Enter key.

   For FQDN configuration, see FQDNs for Time Servers on the SBC below.

   For example, this entry adds the NTP server at the Massachusetts Institute of Technology in Cambridge, MA:

```
ORACLE(ntp-config)# add-server 18.26.4.105
```

3. To delete an NTP server, type **delete-server**, the Space bar, and the IPv4 or IPv6 address of the server you want to delete and then press the Enter key.

```
ORACLE(ntp-config)# del-server 18.26.4.105
```

FQDNs for Time Servers on the SBC

You can configure the SBC with an FQDN for establishing communications with NTP time servers. This feature supports FQDN resolution through a DNS query over wancom or media interfaces. Having received DNS resolution for the query, the SBC uses its standard selection process for DNS results to request time synchronization from one of multiple, redundant NTP servers.

The SBC includes a DNS client that it uses for FQDN resolution purposes within several contexts, including NTP server address resolution. You set the system to use FQDN resolution for NTP servers by configuring the **add-server** parameter in the **ntp-config** with an FQDN.

The SBC includes DNS configuration on **network-interface** elements to provide resolution services for any specific realm. For NTP, you can specify the realm you want to use to access DNS services within the **ntp-config**. The system can then use the **network-interface** configuration associated with that realm to make the DNS queries.

Other elementary **ntp-config** configuration detail includes:

- You cannot configure the **add-server** parameter with both IP addresses and an FQDN.
- You cannot configure **add-server** parameter with multiple FQDNs.
- A change to a **network-interface** always requires a reboot for the change to take effect. A change to the **ntp-config**, which impacts the **network-interface**, also requires a reboot for changes to take effect.

When configured with an FQDN, the SBC:

1. Triggers the time synchronization process either after a reboot or the system's periodic NTP daemon restart.

> **Note:**
>
> This is also true when configured with an IP address.

2. Issues a DNS request out the configured realm. This DNS SRV query uses the _ntp._udp prefix to specify the resolution type.
3. Receives the SRV response from the DNS server, which includes the associated A records of IP addresses, and may or may not include priority.
4. Provides its NTP client with the addresses it receives, either ordered by priority or in the same sequence as the DNS response.
5. Issues an NTP synchronization request to the NTP server(s).
6. Receives the NTP response.
7. Synchronizes time.

Important operational detail includes the ability of the SBC to:

- Retry NTP server resolution after periodic intervals if the SRV FQDN lookup resolution fails.
- Retrieve TTL timing for each NTP resolution from the DNS response and retry this connection if and when this timer expires.
- Update the new IP List if there are any IP changes in the DNS Response.
- Apply priority provided within the DNS Response to decide the order of IP addresses it attempts to contact.
- Contact IP addresses using the sequential order presented in the DNS records if there is no priority provided.
- When a user configures NTP with an FQDN within an HA deployment, the active SBC resolves it and synchronizes the resolved IP list with the standby through NTP redundancy. After it receives the resolved IP list from the active, the standby SBC performs NTP update synchronization with the timer servers independently.

Important configuration detail includes:

- You must configure the **dns-ip-primary**, **dns-ip-backup1** and **dns-domain** parameters on the realm's **network-interface**,
- You must configure the **DNS-realm** parameter when configured for FQDN in your **ntp-config**. This realm object must be attached to the **network-interface** with your DNS server configuration, which must be attached to the applicable **phy-interface**.
- If you want to use a media interface's realm for NTP SRV FQDN Resolution, you must configure that **network-interface** for DNS, and you must configure the **ntp-config** with that realm name.
- If you want the NTP SRV FQDN resolution to use wancom0, additional configuration detail includes:
  - If you want to reach DNS servers in the same subnet range as the wancom0 address, you must configure the **phy-interface** name to begin with the “wancom0” prefix and set the **operation-type** to **maintenance**.
    For example, the name "wancom0ntp" would be correct.
  - You must create and attach a wancom0 **network-interface** to a wancom0 **phy-interface**.
  - You must configure your wancom0 **network-interface** with the same IP addressing as your boot parameters and include DNS server configuration.

Configuration

You configure this functionality using the **add-server** parameter within the **ntp-config**. Required configuration includes setting the **add-server** parameter to a text name and the **realm-id** to the realm you want to use for DNS resolution.

```
ORACLE(configuration)#ntp-sync
ORACLE(ntp-config)#add-server example.ntp.com
ORACLE(ntp-config)#realm-id wancom0realm
```

You may find it useful to create a realm specifically for this NTP FQDN resolution. Realms exclusively for NTP resolution are supported over both wancom0 or media interfaces. The following steps apply to creating an NTP resolution specific realm over wancom0.

1. Create a new **physical-interface** using the text "wancom" as the prefix to its name, and set its **operation-type** type to **maintenance**.
2. Create a **network-interface** for this **physical-interface**.
   - Configure the **network-interface** with your DNS Server configuration.
   - Configure the **network-interface** with the same IP addressing values that you use within your boot parameters.
3. Create a **realm-config** and attach it to this **network-interface**.

Resolution Process

Regardless of the interface you use to perform FQDN resolution for your NTP servers, the SBC performs the same DNS procedures to get and use the resolutions.

The SBC uses your configuration to reach DNS servers sequentially. The SBC extracts server information from the first successful DNS response and drops any subsequent responses. Information extracted for NTP purposes includes:

- IP address(es) of NTP servers—One or more addresses, based on the responding server's data.
- Priority—Each IP address can include a priority, which the SBC uses to establish a connection attempt order. The SBC uses the sequence of the resolutions in the DNS response when addresses have the same or no priority.
- Calculated minimum TTL—Each IP address includes a time to live value.

The SBC establishes the minimum value of the timer and starts it. When the timer expires, the SBC sends a new SRV-query to refresh its NTP server list. When it receives the response, the SBC stores the DNS results and rebuilds the NTP list, sorted based on priority or response sequence.

The SBC behaviors above are dependent on the DNS response:

- Single IP address received—Priority is irrelevant and the SBC simply delivers the received address to the NTP daemon.
- Multiple IP addresses received—The lowest priority value is the highest priority server. For addresses presented with the same priority, the SBC uses the DNS server list's order as the order to attempt contact with servers.
- Error/No Response—If the SBC receives an error response or no response to the SRV-query, it starts an internal DNS retry timer before it attempts to contact the servers. Also, if

it finds the primary DNS Server is down, the SBC retries using your configured backup DNS Servers.

- TTL below 30 secs—If the SBC receives TTL that is less than 30 secs for any IP address, it uses 30 seconds as the TTL. This ensures that the system does not become overloaded by an incorrect configuration.

Configuring NTP Using an FQDN - Wancom

These instructions include the specific steps that apply to configuring a wancom interface as the source for synchronizing system time with an NTP server.

Although this is an ACLI procedure, you can perform this procedure using equivalent procedures with supported management interfaces.

You must have enabled the **sip-config**.

1. Configure an applicable **phy-interface**.

   Configure your **phy-interface**, **name** using the text “wancom” as its prefix. If not, the system throws a **verify-config** error.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# system
   ORACLE(system)# phy-interface
   ORACLE(phy-interface)# name wancom_ntp
   ORACLE(phy-interface)# operation-type Maintenance
   ```

   Retain the defaults for all other parameters.

2. Configure an applicable **network-interface**.

   > **Note:**
   >
   > In a normal network interface setup, the pri-utility-addr and sec-utility-addr parameters are configured. However, for a wancom interface, you must leave these parameters unconfigured.

   Create a **network-interface** for your **phy-interface**. Configure that interface with the same **ip-address**, **netmask** and **gateway** used in your system's equivalent boot parameters. The DNS Server IP’s/IP and domain name must reachable from this network.

   ```
   ORACLE(system)# network-interface
   ORACLE(network-interface)# name wancom_ntp
   ORACLE(network-interface)# ip-address 10.196.179.2
   ORACLE(network-interface)# netmask 255.255.128.0
   ORACLE(network-interface)# gateway 10.196.128.1
   ORACLE(network-interface)# dns-ip-primary 10.196.177.83
   ORACLE(network-interface)# dns-domain ntp.com
   ```

   > **Note:**
   >
   > If your **network-interface** values are not the same as your system's boot parameters, you lose SSH connectivity.

3. Configure an applicable **realm**.

   Create a wancom **realm** and attach the **network-interface**.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)# identifier wancom_realm
ORACLE(realm-config)# network-interfaces wancom_ntp:0.4
```

4. Create an NTP Configuration.

   Create an **ntp-config** using an FQDN and attach the realm.

```
ORACLE(configure)# ntp-sync
ORACLE(ntp-config)# add-server example.ntp.com
ORACLE(ntp-config)# dns-realm wancom_realm
```

Configuring NTP Using an FQDN - Media Interfaces

These instructions include the specific steps that apply to configuring a media interface as the source for synchronizing system time with an NTP server.

You can use an existing realm if you have configured its **network-interface** with DNS parameters. Follow these steps to create a media realm dedicated to NTP services.

You must have enabled the **sip-config**.

1. Configure an applicable **phy-interface**.

   Leave the undocumented parameters at their defaults.

```
ORACLE(configure)#system-config
ORACLE(system-config)#phy-interface
ORACLE(phy-interface)#name M00
ORACLE(phy-interface)#operation-type Media
```

2. Configure an applicable **network-interface** and attach it to your **phy-interface**.

   Create a **network-interface** for your **phy-interface**. The DNS Server IP's/IP and domain name must reachable from this media interface subnet.

```
ORACLE(configure)#system-config
ORACLE(system-config)#network-interface
ORACLE(network-interface)#name M00
ORACLE(network-interface)#sub-port-id 33.4
ORACLE(network-interface)#ip-address 192.168.203.10
ORACLE(network-interface)#netmask 255.255.0.0
ORACLE(network-interface)#dns-ip-primary 192.168.203.1
ORACLE(network-interface)#dns-domain ntp.com
```

3. Configure your realm.

   Create a **realm-config** and attach the **network-interface**.

```
ORACLE(configure)#media-manager
ORACLE(media-manager)#realm-config
```

```
ORACLE(realm-config)#identifier ntp_access
ORACLE(realm-config)#network-interfaces M00:33.4
```

> **Note:**
>
> If you configure an FQDN, such as example.ntp.com, from the **add-server** parameter, the system adds the prefix _ntp._udp.example.ntp.com to the DNS request. You must also ensure that the DNS database includes the _ntp_udp prefix.

Run the command below to verify access to DNS services.

```
ORACLE# show dns query access SRV _ntp._udp.example.ntp.com
DNS Result:
Query Name -->SRV:_ntp._udp.example.ntp.com
Answers -->10.196.177.83: 5060/UDP Hl= 100
```

4. Configure an NTP configuration.

   Create an **ntp-config** using an FQDN and attach the realm.

```
ORACLE# configure terminal
ORACLE(configure)# ntp-sync
ORACLE(ntp-config)# add-server example.ntp.com
ORACLE(ntp-config)# dns-realm ntp_access
```

   Run the commands below to verify NTP synchronization and access to the DNS server the SBC selected.

```
ORACLE# show ntp status
NTP synchronized to server at: 10.196.177.83

ORACLE# show ntp server
NTP Status Tue Apr 19 10:31:34 GMT 2022MS server st poll reach LastRx
LastSample
        <LastOffset>[<ActualOffset>]+/-<Error>--
^ti 10.196.177.83 4 2 377 4 -95us[ -109us] +/- 67ms
^- 10.196.177.181 4 2 377 4 -95us[ -109us] +/- 67ms +85us[ +71us] +/- 93ms
```

Authenticated NTP

The Oracle Communications Session Border Controller can authenticate NTP server requests using MD5. The configured MD5 keys are encrypted and obscured in the ACLI. You configure an authenticated NTP server with its IP address, authentication key, and the key ID. Corresponding key and key IDs are provided by the NTP server administrator.

To configure an authenticated NTP server:

1. Access the ntp-config configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# ntp-sync
ACMEPACKET(ntp-config)#
```

2. Type select.

```
ORACLE(ntp-config)# select
```

3. Access the auth-servers configuration element

```
ORACLE(ntp-config)# auth-servers
ORACLE(auth-servers)#
```

4. ip-address — Enter the IPv4 or IPv6 address of the NTP server that supports authentication.
5. key-id — Enter the key ID of the key you enter in the next step. This value's range is 1 - 999999999.
6. key — Enter the key used to secure the NTP requests. The key is a string 1 - 31 characters in length.
7. Type **done** to save your work.
8. Type **exit** to return to the previous configuration level.
9. Type **done** to save the parent configuration element.

Monitoring NTP from the ACLI

NTP server information that you can view with the **show ntp server** command tell you about the quality of the time being used in terms of offset and delays measurements. You can also see the maximum error bounds.

When you use this command, information for all configured servers is displayed. Data appears in columns that are defined in the table below:

Display Column	Definition
server	Lists the NTP servers configured on the Oracle Communications Session Border Controller by IP address. Entries are accompanied by characters: Plus sign (+)—Symmetric active server Dash (-)—Symmetric passive server Equal sign (=)—Remote server being polled in client mode Caret (^)—Server is broadcasting to this address Tilde (~)—Remote peer is sending broadcast to * Asterisk (*)—The peer to which the server is synchronizing
st	Stratum level—Calculated from the number of computers in the NTP hierarchy to the time reference. The time reference has a fixed value of 0, and all subsequent computers in the hierarchy are n+1.
poll	Maximum interval between successive polling messages sent to the remote host, measured in seconds.

Display Column	Definition
reach	Measurement of successful queries to this server; the value is an 8-bit shift register. A new server starts at 0, and its reach augments for every successful query by shifting one in from the right: 0, 1, 3, 7, 17, 37, 77, 177, 377. A value of 377 means that there have been eight successful queries.
delay	Amount of time a reply packet takes to return to the server (in milliseconds) in response.
offset	Time difference (in milliseconds) between the client's clock and the server's.
disp	Difference between two offset samples; error-bound estimate for measuring service quality.

View Statistics

To view statistics for NTP servers:

- At the command line, type **show ntp server** and press Enter.

```
ORACLE# show ntp server
NTP Status                                      FRI APR 11:09:50 UTC 2007
 server                 st  poll  reach   delay    offset     disp
---------------------- --  ----  ------  -------  --------   ---------
*64.46.24.66             3    64     377  0.00018  0.000329   0.00255
=61.26.45.88             3    64     377  0.00017  0.002122   0.00342
```

You can the see the status of NTP on your system by using the **show ntp status** command. Depending on the status of NTP on your system, one of the following messages will appear:

- NTP not configured
- NTP Daemon synchronized to server at [the IP address of the specific server]
- NTP synchronization in process
- NTP down, all configured servers are unreachable

View Status

To view the status of NTP on your Oracle Communications Session Border Controller:

- At the command line, type **show ntp status** and press Enter.

```
ORACLE# show ntp status
```

HTTP Connection Management

By default, the SBC limits system impact caused by HTTP client behavior using the **httpclient-max-total-conn** and **httpclient-max-cpu-load** parameters in the **system-config**. These parameters allow you to change the number of TCP connections and the amount of CPU resources consumed by traffic between the SBC and all types of HTTP servers.

Use the following **system-config** parameters to adjust or disable management of the number of active HTTP clients by the SBC:

- **httpclient-max-total-conn**—Specifies the maximum number of TCP connections that the **http-client** allows open simultaneously.
  When this traffic exceeds this value, the SBC and the **http-client** begin to discard new http/https requests. When used TCP connections falls below this value, the SBC resumes accepting HTTP client TCP connections.

  Valid Values:

  – 0—Disables the function
  – Range—0 - 2147483647
  – Default—500

  You cannot configure**http-client** in real time. You must reboot the system whenever you make a change.
- **httpclient-max-cpu-load**—Specifies the maximum percentage of CPU consumed by HTTP traffic during STIR/SHAKEN operations.
  When CPU resource utilization exceeds this value, the SBC, the **http-client** begins to discard new http/https requests. When CPU utilization falls below this value, the SBC resumes accepting this traffic.

  Valid Values:

  – Range—30% - 90%
  – Default—70%

  You can configure **httpclient-max-cpu-load** in real time.
- **httpclient-cache-size-multiplier**—Specifies the multiplier used to calculate the size of the HTTP client connection cache.
  The system maintains an HTTP connection cache pool. This is a collection of previously used connections that the system keeps alive, instead of closing after use, so that subsequent transfers targeting the same host name can use them instead of creating a new connection. The size of the HTTP connection cache is based on the number of these live connections.

  The system calculates this cache size using the formula:

  client connection cache = (number of pending transactions * httpclient-cache-size-multiplier)

  Valid Values:

  – Default: 16
  – Values: 4 - 50

  You cannot configure the **http-client** in real time. You must reboot the system whenever you make a change.
- **http-clearDead-conn-timer**—Specifies the number of seconds the system waits before it closes connections to HTTP servers that are in the half closed state.
  The system maintains connections between itself and HTTP servers that is equal to the number of connections in the cache pool multiplied by the **httpclient-cache-size-multiplier** value when, for example, STIR traffic stops. The system puts these connections in half-closed state after the STIR server tries to close the connections using FIN messages. By default, these connections remain in half closed state indefinitely until STIR traffic starts again. You can set the **http-clearDead-conn-timer** parameter to a timer value, after which the system clears these connections regardless of STIR traffic status. The value specifies the regular interval the system uses to clear these half-closed STIR server connections.

  Valid Values:

- Default: 0 (disabled)
- Values: 300 - 86400

You use the **Http/s calls Dropped** field in the **show sipd errors** command to monitor dropped HTTP traffic.

Configure HTTP Connection Management

To prevent system issues caused by HTTP client traffic:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **system-config** and press Enter.

   ```
   ORACLE(system)# system-config
   ORACLE(system-config)#
   ```

   If you are adding support for this feature to a preexisting configuration, you must select (using the ACLI **select** command) the single instance **system-config** element.

4. **httpclient-max-total-conn**—Set this parameter to specify the maximum number of TCP connections that the **http-client** allows open simultaneously or disable the function. You cannot configure **httpclient-max-total-conn** in real time. You must reboot the system whenever you make a change.

   Valid Values:

   - 0—Disables the function
   - Range—0 - 2147483647
   - Default—500

   ```
   ORACLE(system-config)# httpclient-max-total-conn 1000
   ```

5. **httpclient-max-cpu-load**—Set this parameter to specify the maximum percentage of CPU consumed by HTTP traffic during STIR/SHAKEN operations. You cannot configure **httpclient-max-cpu-load** in real time.

   Valid Values:

   - Range—30% - 90%
   - Default—70%

   ```
   ORACLE(system-config)# httpclient-max-cpu-load 60
   ```

6. **httpclient-cache-size-multiplier**—Specifies the multiplier used to calculate the size of the HTTP client connection cache. The system maintains an HTTP connection cache pool. The size of the HTTP connection cache is the number of pending transactions, multiplied by this **httpclient-cache-size-multiplier**.

Valid Values:

- Default: 16
- Values: 4 - 50

```
ORACLE(system-config)# httpclient-cache-size-multiplier 20
```

7. **http-clearDead-conn-timer**—Specifies the number of seconds the system waits before it closes connections to HTTP servers that are in the half closed state.

   Valid Values:

   - Default: 0 (disabled
   - Values: 300 - 84600

```
ORACLE(system-config)# http-clearDead-conn-timer 1000
```

Telephony Fraud Protection

You can use the Oracle Communications Session Border Controller (SBC) to protect against fraudulent calls by enabling Telephony Fraud Protection and creating lists of phone numbers to block, allow, redirect, and rate limit calls. The lists reside together in a single source-file that you create and manage. The source-file can contain any combination of the list types and it can reside on either the SBC or in Session Delivery Manager (SDM) because you can manage Telephony Fraud Protection from either one. The following information explains using Telephony Fraud Protection on the SBC. See the *Oracle Communications Session Element Manager User Guide for the Enterprise Edge and Core Plug-in* for managing Telephony Fraud Protection from SDM.

> **Note:**
>
> The Session Router does not support Telephony Fraud Protection.

Fraud Protection List Types and Uses

The SBC supports the following types of lists for protecting against fraudulent calls.

Blocklist—Use the blocklist to specify a fraudulent call based on the destination phone number or URI. You can add a known fraudulent destination to the blocklist by prefix or by fixed number. When the SBC receives a call to an entry on the blocklist, the system rejects the call according to the SIP response code that you specify. When the system determines a match and blocks a call, the default response is "403 Forbidden." You can set another SIP response code from the standard list of responses defined in RFC3261 by way of the **Local Response Map** configuration and the local error **Fraud Protection Reject Call** setting.

Allowlist—Use the allowlist to manage any exception to the blocklist. Suppose you choose to block a prefix such as +49 555 123 by way of the blocklist. This action also blocks calls to individual numbers starting with this prefix, such as +49 555 123 666. If you add a prefix or individual number to the allowlist, the system allows calls to the specified prefix and number. Continuing with the example, if you add +49 555 123 6 to the allowlist, the system allows calls to +49 555 123 666, which was blocked by the blocklist entry of +49 555 123.

Redirect List—Use the redirect list to send a fraudulent call to an Interactive Voice Response (IVR) system, or to a different route. For example, you can intercept and redirect a call going to

a revenue-share fraud target in a foreign country to an end point that defeats the fraud. Or, you might want to redirect subscribers dialing a particular number and URI to an announcement to make them aware that an account is compromised and tell them what they should do.

Rate Limit List—Use rate limiting to limit the loss of money, performance, and availability that an attack might cause. While local ordinances may not allow you to completely block or suppress communication, you may want to reduce the impact of a disruption with rate limiting until a network engineer can analyze an attack and plan remediation. For example, you might want time to find the origin of an attack or to add attackers to a blocklist. Note that rate limiting may not function immediately after a High Availability switch over because the newly active system must re-calculate the call rate before it can apply rate limiting.

Configuration

The process for using Telephony Fraud Protection includes the following steps:

1. Enable Telephony Fraud Protection
2. Specify the source of fraud protection management
3. Create the file that contains the list of phone numbers to manage
4. Activate the fraud protection file

See "Configure Telephony Fraud Protection", "Fraud Protection XML Source File Example," and "Telephony Fraud Protection File Activation."

> **Note:**
>
> See the following topics in the Release Notes for important information about "Fraud Protection File Rollback Compatibility" and "Fraud Protection File Upgrade Compatibility."

You can enable and manage Telephony Fraud Protection from the ACLI command line.

Telephony Fraud Protection is included in the base license.

Administration

When you configure the SBC to manage Telephony Fraud Protection, the system applies the following behavior:

- An Administrator with privileges can Refresh, Add, and Upload an unselected file, and Edit, Download, and Delete a selected file.
- An Administrator with no privileges can only view the fraud protection file.

To view fraud protection data:

- From the ACLI, use the show commands to view fraud protection statistics. See "Telephony Fraud Protection Show Commands."

> **Note:**
>
> The Telephony Fraud Protection feature does not affect emergency calls or block any calls while you are loading entries.

High Availability

Telephony Fraud Protection supports High Availability (HA).

- After an HA switch over, use the **synchronize file <filename>** command to copy the fraud protection file to the standby.
- Note that after a switch over, rate limiting may not take effect immediately because the new Active system needs time to recalculate the call rate before it can apply rate limiting.

Whenever you refresh the telephony fraud protection file from the ACLI with the **notify fped refresh** command, this updates the runtime table by reloading the entries in the file specified in the fraud-protection configuration, only for the active SBC. To update the FPE runtime table on the standby SBC , run the **synchronize file <filename>** command on the active SBC and then run the **notify fped refresh** command on the standby SBC.

Telephony Fraud Protection Management from SDM

If you prefer to manage Telephony Fraud Protection from the Enterprise Fraud Manager in SDM, rather than from the SBC, store the fraud protection list in a file named **sbc_fpe_entries.xml** (case sensitive) in SDM. You can edit the file in SDM, which will notify the SBC afterward to download the file to its **/code/fpe** directory. When the SBC is part of an HA pair, the Active partner automatically pushes the updated file to the Standby partner. In the event of an unsuccessful download, the system raises an SNMP alarm. Should the connection to SDM ever go down, the system also raises an SNMP alarm and sends a trap. When the connection gets re-established, the alarm and trap clear, and the SBC sends a RESYNC command to SDM.

Unsupported Functions

Telephony Fraud Protection for the SBC does not support the following:

- IPv6
- H.323
- InterWorking Function (IWF)
- Comm Monitor
- Enterprise Operations Monitor

Telephony Fraud Protection Target Matching Rules

When matching a call to an entry on a telephony fraud protection list, the Oracle Communications Session Border Controller (SBC) performs the matching only on the ingress leg of the initial INVITE. If ingress realm is defined as *, then the realm takes precedence over all other entries. In the initial INVITE, the SBC uses the From, To, and User-Agent headers for matching. Because you can place a phone number on multiple types of fraud prevention lists in the same source file, the SBC uses the following evaluation hierarchy to determine which number takes precedence:

1. Longest match—The most specific entry takes precedence. For example, when 555-123-4000 is block listed and 555-123-* is allow listed, the system blocks the call from 555-123-4000 because it is the longest match.
2. Destination—When the system detects matches in both the SIP **From** header and the SIP **To** header, the match for the **To** header takes precedence.
3. URI—When the system detects matches in both the **USER** and **Host** parts of a SIP URI, the match for the **USER** part takes precedence.

4. SIP User-Agent header—Lowest priority. When nothing else matches, and there is a match for the User-Agent field, the SBC acts as instructed.
5. Multiple instances—When the system detects multiple instances of the same match length, or when the target resides in multiple lists, the system uses the following order of precedence:
   1. Allowlist—Entries on the allowlist take precedence with no restrictions. For example, when 555-123-4567 is on both the blocklist and the allowlist, the system allows this call because the number is on the allowlist.
   2. Blocklist
   3. Redirect
   4. Rate limiting

> **Note:**
>
> The telephony fraud protection feature does not affect emergency calls.

The telephony fraud protection feature uses source or destination IP, source or destination name or phone number, and caller user-agent to identify a caller. The system enforces the following rules for formatting entries on a fraud protection list:

Hostname

Format: Enter the exact IP address or FQDN.

User name

Format: Enter the exact user name. For example: joe.user or joe_user.

User-Agent-Header

The User-Agent header text in the INVITE message from the first call leg. This text usually contains the brand and firmware version of the SIP device making the call. For example, sipcli/v1.8, Asterisk PBX 1.6.026-FONCORE-r78.

Format: Enter the exact text.

Phone Number

Format: Enter the exact number or a partial number using the following characters to increase the scope of the matches.

Asterisk *	Use to indicate prefix matching, but only at the end of the pattern. For example, use 555* not *555. Do not use * in any other patterns, for example, in brackets [ ], parentheses ( ), or with an x.
Square Brackets [ ]	Use to enclose ranges in a pattern. Syntax: [min-max]. For example: 555 [0000-9999]. The system considers 8[1-20]9 and 8[01-20]9 to contain the same number of characters because the leading 0 is implied. The system strictly enforces this pattern with respect to the range and the number of characters, as follows: • 8019 matches

	• 819 does not match • 8119 matches
Character x	Use as a wild card a the end of a dial pattern to mean 0-9. For example: 555xxx means match a number starting with 555 followed by 3 digits from 0-9.
Parentheses ( )	Use to enclose optional digits in a pattern. For example: 555xx(xxxx) means match a number starting with 555 plus a minimum of 2 digits, and optionally up to 4 more digits.

Telephony Fraud Protection File Activation

After you create, edit, or upload the telephony fraud protection file, you must activate the file before the Oracle Communications Session Border Controller (SBC) can use it as the source of the fraud protection lists. The system recognizes only one file at a time as the active file.

The first time you configure the SBC to manage fraud protection, the system activates the file when you save and activate the configuration. After the initial configuration, the system does not automatically refresh the fraud protection file when you save and activate other configuration changes on the SBC. You must upload a new file or edit the existing file and activate it to update the file. The exception occurs when you specify a new file name in the fraud protection configuration and coincidentally make changes to other configurations, and then save and activate all of the changes at the same time.

After the initial configuration, use the following methods to activate the fraud protection file.

- New File—After you create or upload a new file, go to Fraud Protection configuration, enter the name of the new file, and click Save. The system prompts for activation upon a successful Save. Note that you can decline the inline activation and manually activate the file later. For example, you might want to edit an uploaded file before activation.
- Overwrite File—When you upload a file with the same name as the existing file, the system prompts for activation upon upload.
- Edit File—When you upload the edited file, the system prompts for activation.
- Refresh File—When you want to use the ACLI to refresh the fraud protection file, send the file to the SBC and use the `notify fped refresh` command. The name of the file that you refresh must match the name of the file specified in the configuration.

Telephony Fraud Protection Data Types and Formats

Use the information in the following tables when you create or edit a fraud protection list in the Add Fraud Protection Entry and Modify Fraud Protection Entry dialogs.

Data Type Descriptions

The following table describes the data types listed in the **Type** drop-down list.

from-hostname	The hostname from the SIP FROM header.
from-phone-number	The phone number from the SIP FROM header
from-username	The user name from the SIP FROM header.
to-hostname	The hostname from the SIP TO header.

to-phone-number	The phone number from the SIP TO header.
to-username	The user name from the SIP TO header.
user-agent-header	The SIP User-Agent header.

Match Value Formats

The following table describes the formats required for the data types.

hostname	Enter the exact IP address or FQDN.
username	Enter the exact user name. For example: joe.user or joe_user.
user-agent-header	Enter the exact text match to the SIP User-Agent header. For example: equipment vendor information.
phone-number	You can use the following characters for phone-number: • Asterisk *. Use to indicate prefix matching, but only at the end of the pattern. For example, use 555* not *555. Do not use * in any other patterns, for example, in brackets [ ], parentheses ( ), or with an x. • Brackets [ ]. Use to enclose ranges in a pattern. Syntax: [min-max]. For example: 555 [0000-9999]. • Parentheses. ( ) Use to enclose optional digits in a pattern. For example: 555xx(xxxx) means 555 with between 2 and 4 following digits. • Character x. Use as a wildcard a the end of a dial pattern to mean 0-9. For example: 555xxx means a number starting with 555 followed by 3 digits.

> **Caution:**
>
> The use of encoding characters is especially susceptible to creating overlapping dial pattern matches that can result in unexpected behavior.

Configure Telephony Fraud Protection

The telephony fraud protection feature requires configuration, which you can perform from the Oracle Communications Session Border Controller (SBC) ACLI by way of the **fraud-protection** configuration element under System.

- Add or upload at least one telephony fraud protection file to the SBC.
- Note the name of the fraud protection file that you want to use.

Use this procedure to enable telephony fraud protection on the SBC. You must specify the fraud protection file name and activate the configuration. You cannot specify multiple fraud protection files because the system recognizes only one file as the active source file.

1. Access the **fraud-protection** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# system
ORACLE(session-router)# fraud-protection
```

2. Type **select**, and press ENTER.
3. Type **show**, and press ENTER.
4. Do the following:

mode	Select one of the following modes: • **local**—Use the SBC as the source of the fraud protection file. • **comm-monitor**—Not currently supported. • **disabled**—Default.
file name	Enter the name of the fraud protection file. Syntax: /code/fpe/<filename>
options	Add fraud protection options. (Not supported in some releases.)
allow-remote-call-terminate	Not currently supported.

5. Save and activate the configuration.

Refresh the Telephony Fraud Protection File

You can refresh the telephony fraud protection file from the ACLI with the **notify fped refresh** command. This command updates the runtime table by reloading the entries in the file specified in the fraud-protection configuration.

- SFTP the updated file to the SBC.
- Confirm that the name of the updated file matches the name of the file specified in the configuration.

Use the following procedure apply updates to the telephony fraud protection file.

1. Log on to the ACLI.
2. Type **notify fped refresh**, and press ENTER.

   The system confirms a successful refresh.

Telephony Fraud Protection ACLI Show Commands

The Oracle Communications Session Border Controller (SBC) supports viewing and refreshing telephony fraud protection statistics by way of ACLI commands. The displayed data is read-only.

The following ACLI commands provide displays of telephony fraud protection statistics.

`show-fraud-protection <list type> <matches-only>`—Use this command to display all entries or only entries on a particular fraud prevention list, and optionally, to show only the entries on the specified list that incurred a match. Use one of the following variables for <list type>:

- all—displays all entries
- blocklist—displays only the blocklist matches
- allowlist—displays only the allowlist matches
- redirect—displays only the redirect matches

- ratelimit—displays only the rate limit matches

Command Examples:

- `show-fraud-protection all`—displays all blocklist, redirect, allowlist, and rate limit entries.
- `show-fraud-protection all matches-only`—displays only the matches for blocklist, redirect, allowlist, and rate limit entries.
- `show-fraud-protection blocklist`—displays only the blocklist, showing all entries.
- `show-fraud-protection blocklist matches-only`—displays only the matches for blocklist entries.

Display Examples

```
show fraud-protection all
17:31:09-109
-------------------------------------------------------------------------------------------------------------------
List Type   To/From     Match Value                          Ingress Realm                No. of Hits
                                                                                      Recent      Total  PerMax
-------------------------------------------------------------------------------------------------------------------
BLOCKLIST   To          1809*                                peer                         0          0       0
BLOCKLIST   To          22478300501                          access                       0          0       0

BLOCKLIST

`show-fraud-protection`—Use to display all entries with matches-only

`show fraud-protection stats`—Use to display Recent, Total, and Period Maximum statistics for the fraud protection lists: For example: STATS

```
show fraud-protection stats

Fraud Protection Engine Stats       ---- Lifetime ----
                                  Recent      Total  PerMax
Blocklisted Calls                      0          0       0
Allowlisted Calls                      0          0       0
RateLimited Calls                      0          0       0
Redirected Calls                       0          0       0
Blocklist Rejected Calls               0          0       0
RateLimit Rejected Calls               0          0       0
```

The following ACLI commands refresh displays of fraud protection entries.

`notify fped refresh`—Use to update the fraud protection lists table after you make changes. If for some reason the refresh command is unsuccessful and cannot update the list with new data, the system preserves the existing data.

`notify fped reset-stats`—Use to reset the fraud protection statistics counter to zero, for example, to begin a new data collection period.

Telephony Fraud Protection verify-config

When you run the verify-config command for Telephony Fraud Protection, the system verifies the following:

- When you set the Fraud Protection mode to local, verify-config confirms that the file specified in the Fraud Protection configuration exists in the /code/fpe directory. If the specified file is not compatible with the release version or is otherwise invalid, the system displays an error message.

Fraud Protection XML Source File Example

When you enable the Oracle Communications Session Border Controller (SBC) to protect against fraudulent calls, you must create lists of phone numbers or IP addresses to block, allow, redirect, and rate limit calls. The lists reside together in a single file that you specify as the source file in the fraud protection configuration. The source file can contain any combination of the list types, but the system limits the size of the fraud protection file to 100,000 total entries.

The following example shows an XML file created as the source file for fraud protection. The file includes a section for each type of list, which includes call-blocklist, call-allow list, call-limit, and call-redirect. The example shows the coding for adding the source-ip, destination-phone, realm, calls-per-second for rate limiting, and the target for a redirected call.

```
<?xml version='1.0' standalone='yes'?>
<oracleSbcFraudProtectionApi version="1.0">
    <call-allowlist>
         <userEntry>
             <to-phone-number>1234567[0000-9999]</to-phone-number>
             <realm>Core</realm>
         </userEntry>
         <userEntry>
             <to-phone-number>12345678901</to-phone-number>
             <realm>DefaultSP</realm>
           </userEntry>
           <userEntry>
               <from-hostname>123.45.67.8/90</from-hostname>
               <realm>*</realm>
           </userEntry>
    </call-allowlist>
    <call-blocklist>
         <userEntry>
             <to-hostname>12345678901</to-hostname>
             <realm>*</realm>
         </userEntry>
         <userEntry>
             <from-hostname>123.45.67.8/90</from-
hostname>
             <realm>*</realm>
         </userEntry>
    </call-blocklist>
    <call-redirect>
         <userEntry>
```

```
            <from-hostname>19877654321</from-hostname>
            <realm>Core</realm>
            <target>sip:support@phonesystem.com</target>
        </userEntry>
    </call-redirect>
    <call-rate-limit>
        <userEntry>
            <from-hostname>19877654321</from-
hostname>
            <realm>DefaultSP</realm>
            <calls-per-second>5</calls-per-second>
            <max-active-calls>0</max-active-calls>
        </userEntry>
    </call-rate-limit>
```

Note that the SBC enforces an order of precedence among the lists. See "Telephony Fraud Protection Target Matching Rules."

> **Note:**
>
> If you rollback to a previous version of the software, you must edit this file by changing Allowlist to Whitelist and Blocklist to Blacklist. When you return to the SCz9.1.0 or higher version of the software, revert to Allowlist and Blocklist.

4

Realms and Nested Realms

This chapter explains how to configure realms and nested realms, and specialized media-related features.

A realm is a logical definition of a network or groups of networks made up in part by devices that provide real-time communication sessions comprised of signaling messages and possibly media flows. These network devices might be call agents, softswitches, SIP proxies, H.323 gatekeepers, IP PBXs, etc., that are statically defined by IPv4 addresses. These network devices might also be IPv4 endpoints: SIP phones, IADs, MAs, media gateways, etc., that are defined by an IPv4 address prefix.

Realms support bandwidth-based call admission control and QoS marking for media. They are the basis for defining egress and ingress traffic to the Oracle Communications Session Border Controller—which supports the Oracle Communications Session Border Controller's topology hiding capabilities.

This chapter also explains how to configure media ports (steering pools). A steering pool exists within a realm and contains a range of ports that have a common address (for example, a target IPv4 address). The range of ports contained in the steering pool are used to steer media flows from one realm, through the Oracle Communications Session Border Controller, to another.

Finally, in this chapter you can learn about TOS/DiffServ functionality for realm-based packet marking by media type.

Overview

Realms are a logical distinction representing routes (or groups of routes) reachable by the Oracle Communications Session Border Controller and what kinds of resources and special functions apply to those routes. Realms are used as a basis for determining ingress and egress associations to network interfaces, which can reside in different VPNs. The ingress realm is determined by the signaling interface on which traffic arrives. The egress realm is determined by the following:

- Routing policy—Where the egress realm is determined in the session agent configuration or external address of a SIP-NAT
- Realm-bridging—As applied in the SIP-NAT configuration and H.323 stack configurations
- Third-party routing/redirect (i.e., SIP redirect or H.323 LCF)

Realms also provide configuration support for denial of service (DoS)/access control list (ACL) functionality.

Realms can also be nested in order to form nested realm groups. Nested realms consist of separate realms that are arranged within a hierarchy to support network architectures that have separate backbone networks and VPNs for signaling and media. This chapter provides detailed information about nested realms after showing you how to configure realms on your Oracle Communications Session Border Controller.

About Realms and Network Interfaces

All realms reference network interfaces on the Oracle Communications Session Border Controller. This reference is made when you configure a list of network interfaces in the realm configuration.

You configure a network interface to specify logical network interfaces that correspond existing phy-interfaces on the Oracle Communications Session Border Controller. Configuring multiple network interfaces on a single phy-interface creates a channelized phy-interface, a VLAN. VLANs, in turn, allow you to reuse address space, segment traffic, and maximize bandwidth.

In order to reach the realms you configure, you need to assign them network interfaces. The values you set for the name and port in the network interface you select then indicate where the realm can be reached.

About the SIP Home Realm

The realm configuration is also used to establish what is referred to as the SIP home realm. This is the realm where the Oracle Communications Session Border Controller's SIP proxy sits.

In peering configurations, the SIP home realm is the internal network of the SIP proxy. In backbone access configurations, the SIP home realm typically interfaces with the backbone connected network. In additions, the SIP home realm is usually exposed to the Internet in an HNT configuration.

Although you configure a SIP home realm in the realm configuration, it is specified as the home realm in the main SIP configuration by the home realm identifier parameter. Specifying the SIP home realm means that the Oracle Communications Session Border Controller's SIP proxy can be addressed directly by connected entities, but other connected network signaling receives layer 3 NAT treatment before reaching the internal SIP proxy.

About Realms and Other Functions

Realms are referenced by other configurations in order to support this functionality across the protocols the Oracle Communications Session Border Controller supports and to make routing decisions. Other configurations' parameters that point to realms are:

- SIP configuration: home realm identifier, egress realm identifier
- SIP-NAT configuration: realm identifier
- H.323 stack configuration: realm identifier
- Session agent configuration: realm identifier
- Media manager: home realm identifier
- Steering ports: realm identifier
- Static flow: in realm identifier, out realm identifier

Realms

Realm configuration is divided into the following functional areas, and the steps for configuring each are set out in this chapter: identity and IP address prefix, realm interfaces, realm service profiles, QoS measurement, QoS marking, address translation profiles, and DNS server configuration.

Before You Configure

Before you configure realms, you want to establish the phy and network interfaces with which the realm will be associated.

- Configure a phy-interface to define the physical characteristics of the signaling line.
- Configure a network-interface to define the network in which this realm is participating and optionally to create VLANs.

If you wish to use QoS, you should also determine if your Oracle Communications Session Border Controller is QoS enabled.

Remember that you will also use this realm in other configurations to accomplish the following:

- Set a signaling port or ports at which the Oracle Communications Session Border Controller listens for signaling messages.
- Configure sessions agents to point to ingress and egress signaling devices located in this realm in order to apply constraint for admission control.
- Configure session agents for defining trusted sources for accepting signaling messages.

Configure realm-config

To access the realm configuration parameters in the ACLI:

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Press **Enter**.

   The system prompt changes to let you know that you can begin configuring individual parameters. To view all realm configuration parameters, enter a **?** at the system prompt.

Identity and IP Address Prefix

The first parameters you configure for a realm are its name (a unique identifier) and an IP address prefix and subnet mask.

The IP address and subnet mask establish a set of matching criteria for the realm, and distinguishes between realms that you assign to the same network interface.

To configure a realm's identity and IP address prefix in the ACLI:

1. **identifier**—Enter the name of the realm. This parameter uniquely identifies the realm. You will use this parameter in other configurations when asked for a realm identifier value.
2. **addr-prefix**—Enter the IPv4 or IPv6 address and subnet mask combination to set the criteria the Oracle Communications Session Border Controller uses to match packets sent or received on the network interface associated with this realm. This matching determines the realm, and subsequently what resources are used for that traffic. This setting determines whether the realm is an IPv4 or IPv6 realm.

This parameter must be entered in the correct format where the IPv4 or IPv6 address comes first and is separated by a slash (/) from the subnet mask value. For example, 172.16.0.0/24.

The default for this parameter is **0.0.0.0**. When you leave this parameter set to the default, all addresses match.

Realm Interfaces

The realm points to one network interface on the Oracle Communications Session Border Controller.

> **Note:**
>
> Only one network-interface can be assigned to a single realm-config object, except for Local multi-homing SCTP deployments.

To assign interfaces to a realm:

- **network-interfaces**—Enter the physical and network interface(s) that you want this realm to reference. These are the network interfaces though which this realm can be reached by ingress traffic, and through which this traffic exits the system as egress traffic.

  Enter the name and port in the correct format where the name of the interface comes first and is separated by a colon (:) from the port number. For example, f10:0.

  The parameters you set for the network interfaces must be unique.

  Enter multiple network interfaces for this list by typing an open parenthesis, entering each field value separated by a Space, typing a closed parenthesis, and then pressing Enter.

  ```
  ORACLE(realm-config)# network-interfaces fe1:0
  ```

  You must explicitly configure a realm's network interface as either IPv4 or IPv6 when the applicable interface is either dual-stack or IPv6. You do this by appending the realm's network-interface with a **.4** or a **.6**, as shown below.

  ```
  ORACLE(realm-config)# network-interfaces fe1:0.6
  ```

  For single-stack interface configurations that do not specify this format, the Oracle Communications Session Border Controller assumes an IPv4 interface. Dual stack interface configurations fail if this IP version family suffix is not specified.

Realm Service Profile

The parameters you configure to establish the realm service profile determine how bandwidth resources are used and how media is treated in relation to the realm. Bandwidth constraints set for realm service profiles support the Oracle Communications Session Border Controller (SBC) admission control feature.

Peer-to-peer media between endpoints can be treated in one of three different ways:

- Media can be directed between sources and destinations within this realm on this specific SBC. Media travels through the SBC rather than straight between the endpoints.

- Media can be directed through the SBC between endpoints that are in different realms, but share the same subnet.
- For SIP only, media can be released between multiple SBCs.
  To enable SIP distributed media release, you must set the appropriate parameter in the realm configuration. You must also set the SIP options parameter to media-release with the appropriate header name and header parameter information. This option defines how the SBC encodes IPv4 address and port information for media streams described by, for example, SDP.

> **Note:**
>
> The **nat-traversal** parameter can establish an important media handling behavior. If you set **nat-traversal** on a **sip-interface** to **always**, this setting supersedes any multi-media configuration that would otherwise release the media. Instead, the SBC recognizes when a flow's leg is behind a NAT during the signaling, and ignores any configuration that would release the media. The SBC then sets up the end to end media flow in MBCD and performs its HNT function for that flow.

To configure realm service profile:

1. **max-bandwidth**—Enter the total bandwidth budget in kilobits per second for all flows to/from the realm defined in this element. The default is **0** which allows for unlimited bandwidth. The valid range is:
   - Minimum—0
   - Maximum—4294967295
2. **mm-in-realm**—Enable this parameter to treat media within this realm on this SBC. The default is **disabled**. Valid values are:
   - enabled | disabled
3. **mm-in-network**—Enable this parameter to treat media within realms that have the same subnet mask on this SBC. The default is **enabled**. Valid values are:
   - enabled | disabled
4. **msm-release**—Enable or disable the inclusion of multi-system (multiple SBCs) media release information in the SIP signaling request sent into the realm identified by this realm-config element. If this field is set to enabled, another SBC is allowed to decode the encoded SIP signaling request message data sent from a SIP endpoint to another SIP endpoint in the same network to restore the original SDP and subsequently allow the media to flow directly between those two SIP endpoints in the same network serviced by multiple SBCs. If this field is disabled, the media and signaling will pass through both SBCs. Remember that for this feature to work, you must also set the options parameter in the SIP configuration accordingly. The default is **disabled**. Valid values are:
   - enabled | disabled

QoS Measurement

This chapter provides detailed information about when to configure the **qos-enable** parameter. If you are not using QoS or a QoS-capable Oracle Communications Session Border Controller, then you can leave this parameter set to disabled (default).

QoS Marking

QoS marking allows you to apply a set of TOS/DiffServ mechanisms that enable you to provide better service for selected networks

You can configure a realm to perform realm-based packet marking by media type, either audio/voice or video.

The realm configuration references a set of media policies that you configure in the media policy configuration. Within these policies, you can establish TOS/DiffServ values that define an individual type (or class) of service, and then apply them on a per-realm basis. In the media profiles, you can also specify:

- One or more audio media types for SIP and/or H.323
- One or more video types for SIP and/or H.323
- Both audio and video media types for SIP and/or H.323
  To establish what media policies to use per realm in the ACLI:

- **media-policy**—Enter the name (unique identifier) of the media policy you want to apply in the realm. When the Oracle Communications Session Border Controller first sets up a SIP or H.323 media session, it identifies the egress realm of each flow and then determines the media-policy element to apply to the flow. This parameter must correspond to a valid name entry in a media policy element. If you leave this parameter empty, then QoS marking for media will not be performed for this realm.

Address Translation Profiles

If you are not using this feature, you can leave the **in-translationid** and **out-translationid** parameters blank.

Interface and Realm Support of DNS Servers

You can configure DNS functionality on a network interface or a realm.

Configuring DNS servers for your realms means that you can have multiple DNS servers in connected networks. In addition, this allows you to specify which DNS server to use for a given realm because the DNS might actually be in a different realm with a different network interface.

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. **dns-realm**—Enter the name of the network interface that is configured for the DNS service you want to apply in this realm.

   If you do not configure this parameter, then the realm will use the DNS information configured in its associated network interface.

DoS ACL Configuration

If you are not using this functionality, you can leave the parameters at their default values: **average-rate-limit**, **peak-rate-limit**, **maximum-burst-size**, **access-control-trust-level**, **invalid-signal-threshold**, and **maximum-signal-threshold**.

Enabling RTP-RTCP UDP Checksum Generation

The Oracle Communications Session Border Controller can generate a UDP checksum for RTP/ RTCP packets on a per-realm basis. This feature is useful in cases where devices performing network address translation (NAT) do not pass through packets with a zero checksum from the public Internet. These packets do not make it through the NAT, even if they have the correct to and from IP address and UDP port information. The Oracle Communications Session Border Controller calculates a checksum for these packets and thereby enables them to traverse a NAT successfully.

If a checksum is already present when the traffic arrives at the hardware, the system simply relays it.

Hiding Media Updates

The Real-Time Transport Protocol uses timestamps, sequence numbers, and synchronization source (SSRC) endpoint identifiers to identify and maintain media streams between endpoints. Unexpected changes to these can cause some VoIP terminals to drop calls. You can configure the Oracle Communications Session Border Controller (SBC) to Hide Media Update (HMU) changes from endpoints and prevent the associated media flows from failing on a per-realm basis.

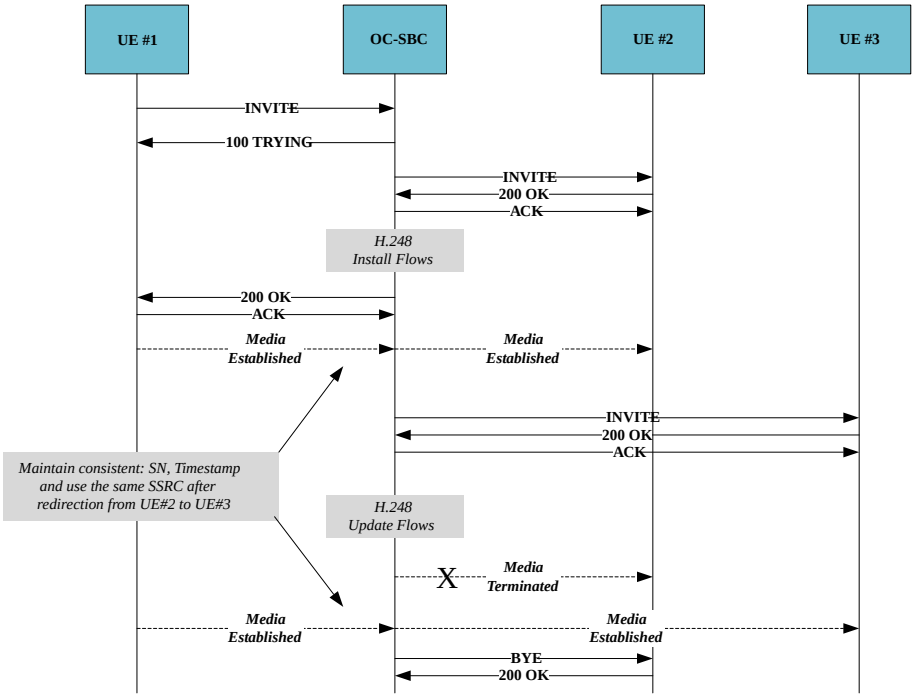
The HMU function monitors SSRC, timestamp, and sequence number data within RTP media traffic. The SBC stores this data within the context of individual NAT flows, and manages the flows internally with H.248. Changes to SSRC and sequence number trigger HMU logic. When triggered, the SBC refers to the SSRC, sequence number and timestamp stored in the flow information, calculates the preferred values for all three, calculates a new header checksum, and writes them to the egress media streams. The SBC keeps track of these events and provides you with the ability to review these changes.

The preferred values the SBC writes include:

- The original SSRC
- A new sequence number, calculated from the last sequence number
- A new timestamp, calculated from the new received timestamp and the timestamp delta

When any change to SSRC occurs, the SBC can recognize the issue and, if configured, invoke the HMU logic. Refer to the section on HMU Support for RTP to SRTP Interworking for an explanation about the use of HMU for monitoring sequence numbers.

A common cause for SSRC changes is call transfer. The diagram below depicts a transfer from UE #2 to US #3. The call transfer creates an SSRC change that the administrator has determined may not be accepted by UE #3. By configuring HMU on the egress realm, the administrator prevents these changes from causing the call to fail.



The HMU function operates on traffic at the egress realm. The SBC evaluates SSRC changes when the traffic reaches the egress interface and corrects RTP data before it egresses the SBC. You may determine that the SBC needs to hide media changes from one realm only. If you are not configuring bi-directional HMU monitoring, refer to the following table to understand where to apply your HMU configuration.

Ingress Realm HMU Enabled	Egress Realm HMU Enabled	Result
No	No	HMU not used
No	Yes	HMU applied to response RTP
Yes	No	HMU not applied to response RTP
Yes	Yes	HMU applied to response RTP

Although the feature is RTC, the system only performs HMU on new calls after configuration. In addition, HMU supports HA. The SBC maintains all established calls across a failover. Failover may cause sessions that have HMU active to have a jump in SSRC, timestamps and sequence number. This may trigger the HMU logic and generate RTP data rewrites for flows.

The SBC maintains HMU status messages whenever received RTP packets trigger the HMU logic. You can verify how many HMU transitions have occurred on interfaces using the **show media host stats** command, and the HMU index per media flow using the **show nat by-index** command.

> **Note:**
>
> HMU is not supported for RTCP or SRTCP packets. Regardless of HMU configuration, the SBC supports only up to 7 SSRC changes per SRTP session. Also, if HMU is disabled, the SBC supports only up to 7 SSRC changes per SRTP session for RTP and RTCP packets.

HMU State Machine

The SBC implements a state machine to manage HMU behavior that includes 5 states:

- INIT—For the first packet of a particular stream, The SBC stores sequence number, SSRC and timestamp in an HMU translation table identified by the index derived from the flow id.
- LEARN—For the next packet of a particular stream, HMU checks if there is change of SSRC. If the SSRC has not changed, the SBC keep the state machine in LEARN state. If there is a change, the SBC changes the state to WAIT.
- WAIT—For the next packet of the stream, HMU check if there is change on SSRC, OR if change in sequence number is not within the permissible limit, it moves the state to TRANS state. It saves the last ingress sequence number and also egress sequence number.
- TRANS—For the next packet of the stream, HMU checks if the changes observed in WAIT state are permanent; in that case it moves the state to HIDE and starts hiding the changed ingress information.
- HIDE—From here onwards, for the RTP packets received, the SBC calculates the sequence number from the latched last egress sequence number before forwarding packets.

> **Note:**
>
> The HMU state machine requires at least two consecutive packets with the same SSRC value before it begins to hide the SSRC value. This ensures that a pattern is set and there is consistency to this SSRC value, which tells the SBC it can be used for hiding other SSRC values. Also, in the case of a REINVITE, the SBC may create new flows. In these new flows, the HMU state machine restarts from its INIT state.

HMU Configuration

You can configure the Oracle Communications Session Border Controller (SBC) to Hide Media Update (HMU) changes from endpoints on a per-realm basis to prevent unsuccessful media flows due to media updates.

Use the following procedure to enable hide-media-update on a realm. By default, hide-media-update is disabled.

> **Note:**
>
> Enable hide-media-update on a realm, only. Do not enable hide-media-update in the media-sec-policy configuration.

1. In Superuser mode, use the following command sequence to access the realm-config configuration:

```
ORACLE# configuration terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

When configuring a preexisting realm, use **select** to choose the realm you want to edit.

2. **hide-egress-media-update**—Set this parameter to **enabled** to enable HMU functionality on this realm.

```
ORACLE(realm-config)# hide-egress-media-update enabled
```

3. Use done and exit to complete the configuration.

Aggregate Session Constraints Per Realm

You can set session constraints for the Oracle Communications Session Border Controller's global SIP configuration, specified session agents, and specified SIP interfaces. This forces users who have a large group of remote agents to create a large number of session agents and SIP interfaces.

With this feature implemented, however, you can group remote agents into one or more realms on which to apply session constraints.

To enable sessions constraints on a per realm basis:

- **constraint-name**—Enter the name of the constraint you want to use for this realm. You set up in the session-constraints confiuration.

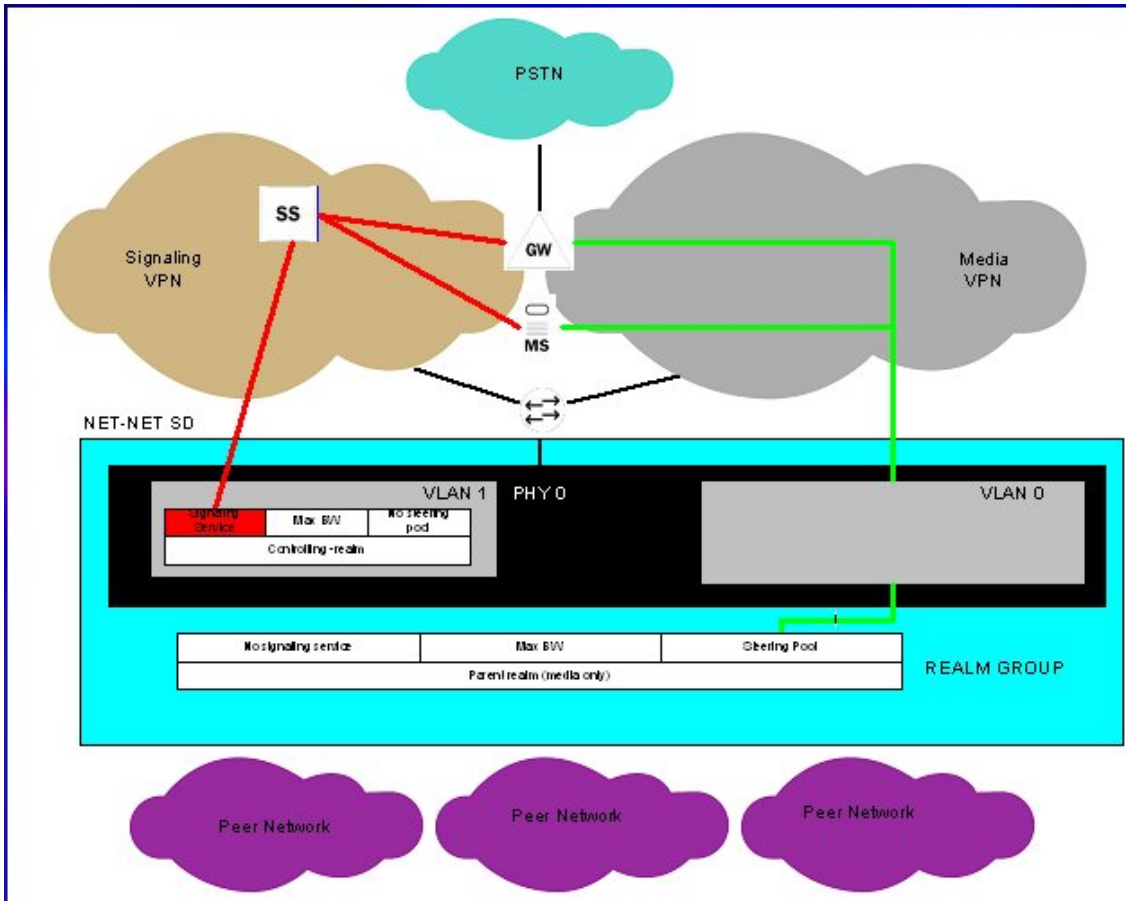
Admission Control Configuration

You can set admission control based on bandwidth for each realm by setting the **max-bandwidth** parameter for the realm configuration. Details about admission control are covered in this guide's *Admission Control and QoS* chapter.

Nested Realms

Configuring nested realms allows you to create backbone VPN separation for signaling and media. This means that you can put signaling and media on separate network interfaces, that the signaling and media VPN can have different address spaces, and that the parent realm has one media-only sub-realm.

The following figure shows the network architecture.



In addition, you can achieve enhanced scalability by using a shared service interface. A single service address is shared across many customers/peers, customer specific policies for bandwidth use and access control are preserved, and you can achieve fine-grained policy control.

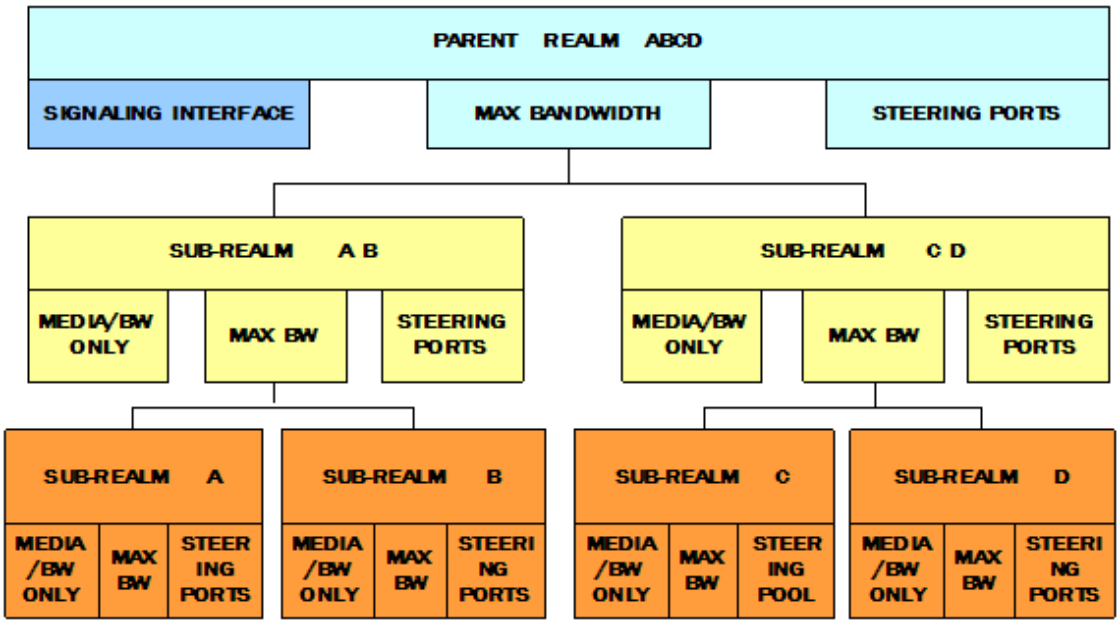
These benefits are achieved when you configure these types of realms:

- Realm group—A hierarchical nesting of realms identified by the name of the highest order realm.
- Controlling realm—A realms for which a signaling interface is configured. For example, you might configure these signaling interfaces in the following configurations: SIP-NAT, SIP port or H.323 stack. Typically, this is the highest order realm for the parent realm in a realm group.
- Parent realm—A realm that has one or more child realms. A parent realm might also be the child realm of another realm group.
- Child realm—A realm that is associated with a single higher order parent realm. A child might also be the parent realm of another realm group. Child realms inherit all signaling and steering ports from higher order realms.
- Media-only realm—A realm for which there is no configured signaling interface directly associated. Media-only realms are nested within higher order realms.

As these definitions suggest, parent and child realms can be constructed so that there are multiple nesting levels. Lower order realms inherit the traits of the realms above them, including: signaling service interfaces, session translation tables, and steering pools.

Since realms inherit the traits of the realms above them in the hierarchy, you will probably want to map what realms should be parents and children before you start configuring them. These

relationships are constructed through one parameter in the realm configuration that identifies the parent realm for the configuration. If you specify a parent realm, then the realm you are configuring becomes a child realm subject to the configured parameters you have established for that parent. And since parent realms can themselves be children of other realm, it is important that you construct these relationships with care.



Configuring Nested Realms

When you are configuring nested realms, you can separate signaling and media by setting realm parameters in the SIP interface configuration, the H.323 stack configuration, and the steering ports configuration.

- The realm identifier you set in the SIP interface configuration labels the associated realm for signaling.
- The realm identifier you set in the H.323 stack configuration labels the associated realm for signaling.
- The realm identifier you set in the steering ports configuration labels the associated realm for media.

Constructing a hierarchy of nested realms requires that you note which realms you want to handle signaling, and which you want to handle media.

In the SIP port configuration for the SIP interface and in the H.323 stack configuration, you will find an allow anonymous parameter that allows you to set certain access control measures. The table below outlines what each parameter means.

Allow Anonymous Parameter	Description
all	All anonymous connections allowed.
agents-only	Connections only allowed from configured session agents.
realm-prefix	Connections only allowed from addresses with the realm's address prefix and configured session agents.

Allow Anonymous Parameter	Description
registered	Connections allowed only from session agents and registered endpoints. (For SIP only, a REGISTER is allowed for any endpoint.)
register-prefix	Connections allowed only from session agent and registered endpoints. (For SIP only, a REGISTER is allowed for session agents and a matching realm prefix.)

Parent and Child Realm Configuration

To configure nested realms, you need to set parameters in the realm configuration.

To configure parent and child realms:

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. **parent-realm**—Enter the identifier of the realm you want to name as the parent. Configuring this parameter makes the realm you are currently configuring as the child of the parent you name. As such, the child realm is subject to the configured parameters for the parent.

Required Signaling Service Parameters

To configure nested realms, you need to set parameters in the realm configuration and in the configurations for the signaling protocols you want to use.

To configure H.323 stack parameters for nested realms:

1. Access the **h323 > h323-stacks** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# h323
ORACLE(h323)# h323-stack
ORACLE(h323-stack)# select
```

2. **allow-anonymous**—Enter the admission control of anonymous connections accepted and processed by this H.323 stack. The default is **all**. The valid values are:
   - all—Allow all anonymous connections
   - agents-only—Only requests from session agents allowed
   - realm-prefix—Session agents and address matching relam prefix

Aggregate Session Constraints Nested Realms

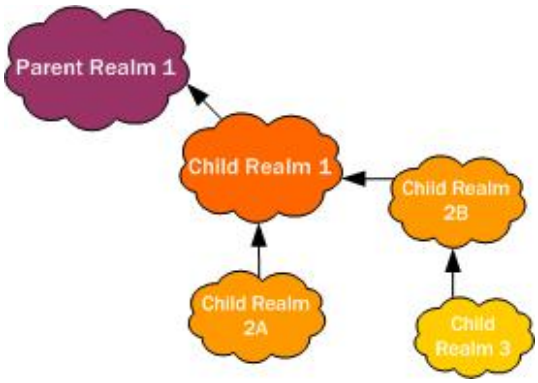
In addition to setting session constraints per realm for SIP and H.323 sessions, you can also enable the Oracle Communications Session Border Controller to apply session constraints across nested realms. When you set up session constraints for a realm, those constraints

apply only to the realm for which they are configured without consideration for its relationship either as parent or child to any other realms.

You can also, however, enable the Oracle Communications Session Border Controller to take nested realms into consideration when applying constraints. For example, if a call enters on a realm that has no constraints but its parent does, then the constraints for the parent are applied. This parameter is global and so applies to all realms on the system. For the specific realm the call uses and for all of its parents, the Oracle Communications Session Border Controller increments the counters upon successful completion of an inbound or outbound call.

In the following example, you can see one parent realm and its multiple nested, child realms. Now consider applying these realm constraints:

- Parent Realm 1—55 active sessions
- Child Realm 1—45 active sessions
- Child Realm 2A—30 active sessions
- Child Realm 2B—90 active sessions
- Child Realm 3—20 active sessions



Given the realm constraints outlined above, consider these examples of how global session constraints for realms. For example, a call enters the Oracle Communications Session Border Controller on Child Realm 2B, which has an unmet 90-session constraint set. Therefore, the Oracle Communications Session Border Controller allows the call based on Child Realm 2B. But the call also has to be within the constraints set for Child Realm 1 and Parent Realm 1. If the call fails to fall within the constraints for either of these two realms, then the Oracle Communications Session Border Controller rejects the call.

Impact to Other Session Constraints and Emergency Calls

You can set up session constraints in different places in your Oracle Communications Session Border Controller configuration. Since session agents and SIP interfaces also take session constraints, it is import to remember the order in which the Oracle Communications Session Border Controller applies them:

1. Session agent session constraints
2. Realm session constraints (including parent realms)
3. SIP interface session constraints

   Emergency and priority calls for each of these is exempt from session constraints. That is, any call coming into the Oracle Communications Session Border Controller marked priority is processed.

Session Constraints Configuration

You enabled use of session constraints for nested realms across the entire system by setting the **nested-realms-stats** parameter in the session router configuration to **enabled**.

1. Access the **session-router-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# session-router
ORACLE(session-router-config)#
```

2. **nested-realms-stats**—Change this parameter from **disabled** (default) to **enabled** if you want the Oracle Communications Session Border Controller to apply session constraints across all nested realms (realms that are children to other realms)
3. Save and activate your configuration.

Realm-Based Packet Marking

The Oracle Communications Session Border Controller supports TOS/DiffServ functions that allow you to

- Set up realm-based packet marking by media type, either audio-voice or video
- Set up realm-based packet marking for signaling, either SIP or H.323

Upstream devices use these markings to classify traffic in order to determine the priority level of treatment it will receive.

By default, the SBC does not pass DSCP codes in ingress packets to egress packets. You must configure a **media-policy** with desired TOS changes and affix those policies to the realms on which you want to define egress types of service. Without a**media-policy**, the SBC includes the default DSCP code, CS0 (Hex 0x00), as the DSCP code to all egress media packets.

TOS Passthrough Configuration

As stated above, the SBC does not passthrough received DSCP values transparently. If this is the desired behavior, no config change is required. This is the default behavior. Packets sent by SBC show DSCP value 0x00.

If passthrough support is desired, you can enable the **sip-config** option called **use-recvd-dscp-marking** which enables passthrough support. With this option enabled, the SBC passes the DSCP value which was received through to egress. To enable this option in **sip-config**, set the option as shown below.

```
ORACLE(sip-config)#options +use-recvd-dscp-marking
```

About TOS DiffServ

TOS and DiffServ are two different mechanisms used to achieve QoS in enterprise and service provider networks; they are two different ways of marking traffic to indicate its priority to upstream devices in the network.

For more information about TOS (packet) marking, refer to:

- IETF RFC 1349 (http://www.ietf.org/rfc/rfc1349.txt)

For more information about DiffServ, refer to:

- IETF RFC 2474 (http://www.ietf.org/rfc/rfc2474.txt)
- IETF RFC 2475 (http://www.ietf.org/rfc/rfc2475.txt).

ToS Byte

The TOS byte format is as follows:

The TOS byte is broken down into three components:

- **Precedence**—The most used component of the TOS byte, the precedence component is defined by three bits. There are eight possible precedence values ranging from 000 (decimal 0) through 111 (decimal 7). Generally, a precedence value of 000 refers to the lowest priority traffic, and a precedence value of 111 refers to the highest priority traffic.
- **TOS**—The TOS component is defined by four bits, although these bits are rarely used.
- **MBZ**—The must be zero (MBZ) component of the TOS byte is never used.

DiffServ Byte

Given that the TOS byte was rarely used, the IETF redefined it and in doing so created the DiffServ byte.

The DiffServ byte format is as follows:

The DiffServ codepoint value is six bits long, compared to the three-bit-long TOS byte's precedence component. Given the increased bit length, DiffServ codepoints can range from 000000 (decimal 0) to 111111 (decimal 63).

> **Note:**
>
> By default, DiffServ codepoint mappings map exactly to the precedence component priorities of the original TOS byte specification.

Packet Marking for Media

You can set the TOS/DiffServ values that define an individual type or class of service for a given realm. In addition, you can specify:

- One or more audio media types for SIP and/or H.323

- One or more video media types for SIP and/or H.323
- Both audio and video media types for SIP and/or H.323

For all incoming SIP and H.23 requests, the media type is determined by negotiation or by preferred codec. SIP media types are determined by the SDP, and H.323 media types are determined by the media specification transmitted during call setup.

Configuring Packet Marking by Media Type

This section describes how to set up the media policy configuration that you need for this feature, and then how to apply it to a realm.

These are the ACLI parameters that you set for the media policy:

```
name         media policy name
tos-settings  list of TOS settings
```

> **Note:**
>
> The **media-policy**, **tos-settings** parameter is not RTC supported and a reboot is required for these updates to take affect.

This is the ACLI parameter that you set for the realm:

```
media-policy default media policy name
```

Packet Marking Configuration

To set up a media policy configuration to mark audio-voice or video packets:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **media-policy** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# media-policy
   ORACLE(media-policy)#
   ```

   From this point, you can configure media policy parameters. To view all configuration parameters for media profiles, enter a **?** at the system prompt.

4. Type **media-policy** and press Enter.

   ```
   ORACLE(media-manager)# media-policy
   ```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration you want to edit.

5. **name**—Create a reference name for this policy and press Enter.
6. Type **tos-settings** and press Enter.

```
ORACLE(media-policy)# tos-settings
```

7. **media-type**—Enter the media type that you want to use for this group of TOS settings. You can enter any of the IANA-defined media types for this value: audio, example, image, message, model, multipart, text, and video. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

```
ORACLE(tos-settings)# media-type message
```

8. **media-sub-type**—Enter the media sub-type you want to use for the media type. This value can be any of the sub-types that IANA defines for a specific media type. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

```
ORACLE(tos-settings)# media-sub-type sip
```

9. **media-attributes**—Enter the media attribute that will match in the SDP. This parameter is a list, so you can enter more than one value. The values are case-sensitive and can be up to 255 characters in length. This parameter has no default.

   If you enter more than one media attribute value in the list, then you must enclose your entry in quotation marks ().

```
ORACLE(tos-settings)# media-attributes sendonly sendrecv
```

10. **tos-value**—Enter the TOS value you want applied for matching traffic. This value is a decimal or hexidecimal value. The valid range is:
    - 0x00 to 0xFF.

```
ORACLE(tos-settings)# tos-value 0xF0
```

11. Save and activate your configuration.

Applying a Media Policy to a Realm

To apply a media policy to a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

```
ORACLE(configure)# media-manager
```

3. Type **realm** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# realm
ORACLE(realm)#
```

4. **media-policy**—Enter the unique name of the media policy you want to apply to this realm.

Signaling Packet Marking Configuration

ToS marking for signaling requires you to configure a media policy and set the name of the media policy in the appropriate realm configuration.

This section shows you how to configure packet marking for signaling.

Configuring a Media Policy for Signaling Packet Marking

To set up a media policy configuration to mark signaling packets:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

```
ORACLE(configure)# media-manager
```

3. Type **media-policy** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# media-policy
ORACLE(media-policy)#
```

From this point, you can configure media policy parameters. To view all media policy configuration parameters, enter a **?** at the system prompt.

4. Type **media-policy** and press Enter.

```
ORACLE(media-manager)# media-policy
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration you want to edit.

5. **name**—Create a reference name for this policy and press Enter.
6. Type **tos-settings** and press Enter.

```
ORACLE(media-policy)# tos-settings
```

> **Note:**
>
> The **media-policy**, **tos-settings** parameter is not RTC supported and a reboot is required for these updates to take affect.

7. **media-type**—Enter the media type that you want to use for this group of TOS settings. You can enter any of the IANA-defined media types for this value: audio, example, image, message, model, multipart, text, and video. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

```
ORACLE(tos-settings)# media-type message
```

8. **media-sub-type**—Enter the media sub-type you want to use for the media type. This value can be any of the sub-types that IANA defines for a specific media type. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

```
ORACLE(tos-settings)# media-sub-type sip
```

9. **media-attributes**—Enter the media attribute that will match in the SDP. This parameter is a list, so you can enter more than one value. The values are case-sensitive and can be up to 255 characters in length. This parameter has no default.

   If you enter more than one media attribute value in the list, then you must enclose your entry in quotation marks ().

```
ORACLE(tos-settings)# media-attributes sendonly sendrecv
```

10. **tos-value**—Enter the TOS value you want applied for matching traffic. This value is a decimal or hexidecimal value. The valid range is:
    - 0x00 to 0xFF.

```
ORACLE(tos-settings)# tos-value 0xF0
```

11. Save and activate your configuration.

Applying a Media Policy to a Realm

To apply a media policy to a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

```
ORACLE(configure)# media-manager
```

3. Type **realm** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# realm
ORACLE(realm)#
```

4. **media-policy**—Enter the unique name of the media policy you want to apply to this realm.

Using Class Profile for Packet Marking

Class profile provides an additional means of ToS marking, but only for limited circumstances. Use class-profile only if you are marking ToS on traffic destined for a specific To address, and

when media-policy is not used on the same realm. Using media-policy for ToS marking is, by far, more common.

To configure a class profile, you prepare your desired media policy, create the class profile referencing the media policy and the To address, and set the name of the class profile in the appropriate realm configuration.

Class Profile and Class Policy Configuration

This section shows you how to configure packet marking using a class profile.

To configure the class profile and class policy:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **class-profile** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# class-profile
   ORACLE(class-profile)#
   ```

4. Type **policy** and press Enter to begin configuring the class policy.

   ```
   ORACLE(class-profile)# policy
   ```

   From this point, you can configure class policy parameters. To view all class policy configuration parameters, enter a **?** at the system prompt.

5. **profile-name**—Enter the unique name of the class policy. When you apply a class profile to a realm configuration, you use this value.
6. **to-address**—Enter a list of addresses to match to incoming traffic for marking. You can use E.164 addresses, a host domain address, or use an asterisk (*) to set all host domain addresses.
7. **media-policy**—Enter the name of the media policy you want to apply to this class policy.

Applying a Class Policy to a Realm

To apply a class policy to a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **media-policy** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# realm
ORACLE(realm)#
```

4. **class-profile**—Enter the name if the class profile to apply to this realm. This is the name you set in the **profile-name** parameter of the class-policy configuration.

Differentiated Services for DNS and ENUM

The Oracle Communications Session Border Controller can mark DNS/ENUM packets with a configurable differentiated services code point (DSCP).

Certain service providers mandate support for Differentiated Services (DS) on all traffic streams exiting any network element. This mandate requires that network elements function as a DS marker — that is as a device that sets the Distributed Services Codepoint (DSCP) in the Differentiated Services field of the IP header.

Previous software releases provided the capabilities to mark standard SIP and Real-Time Protocol (RTP) messages. Release S-CX6.4.0M3 adds the capability to mark DNS and ENUM queries.

For basic information about DS, refer to:

- The *ACLI Configuration Guide* Realm-Based Packet Marking topic in the Realms and Nested Realms chapter, which provides information on currently supported DS marking of SIP and RTP packets
- *IETF RFC 2474, Definition of the Differentiated Services Field (DS Field) in the IPv4 and IPv6 Headers* (http://www.ietf.org/rfc/rfc2474.txt)
- *IETF RFC 2475, An Architecture for Differentiated Services* (http://www.ietf.org/rfc/rfc2475.txt).

DS provides a mechanism to define and deliver multiple and unique service classifications that can be offered by a service provider. Specific service classifications are identified by a DSCP, essentially a numeric index. The DSCP maps to a per-hop-behavior (PHB) that defines an associated service class. PHBs are generally defined in terms of call admission controls, packet drop criteria, and queue admission algorithms. In theory, DS supports 64 distinct classifications. In practice, however, network offerings generally consist of a much smaller suite, which typically includes:

- Default PHB - required best effort service — defined in RFC 2474
- Expedited Forwarding (EF) PHB - low-loss, low-latency — defined in RFC 3246, An Expedited Forwarding PHB
- Assured Forwarding (AF) PHB - assured delivery within subscriber limits — defined in *RFC 2597, Assured Forwarding PHB Group*, and *RFC 3260, New Terminology and Clarifications for Diffserv*
- Class Selector PHBs - maintain compatibility with previous TOS (type of service) precedence usage — defined in RFC 2474

Marking of DNS and ENUM queries requires the creation of a Differentiated Services media policy, and the assignment of such a policy to a specific realm.

Differentiated Services for DNS and ENUM Configuration

To create a Differentiated Services media policy:

1. From Superuser mode, use the following ACLI command sequence to move to media-policy configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# media-policy
ORACLE(media-policy)#
```

2. Use the required **name** parameter to provide a unique identifier for this media-policy instance.

```
ORACLE(media-policy)# name diffServeDnsEnum
ORACLE(media-policy)#
```

3. Use the tos-settings command to move to tos-settings configuration mode.

```
ORACLE(media-policy)# tos-settings
ORACLE(tos-settings)#
```

> **Note:**
>
> The **media-policy**, **tos-settings** parameter is not RTC supported and a reboot is required for these updates to take affect.

4. Use the required media-type parameter to identify the packet-type subject to Diffentiated Services marking.

   For DNS/ENUM packets, use message/dns.

```
ORACLE(tos-settings)# media-type message/dns
ORACLE(tos-settings)#
```

5. Use the required tos-value parameter to specify the 6-bit DSCP to be included in the Differentiated Services field of the IP header.

   Specify the DSCP as an integer (within the range from 0 to 63). The DSCP can be expressed in either decimal or hexadecimal format.

```
ORACLE(tos-settings)# tos-value 0x30
ORACLE(tos-settings)#
```

6. Other displayed parameters, media-attributes and media-sub-type, can be safely ignored.
7. Use the done and exit commands to complete Differentiated Services media policy configuration and return to media-policy configuration-mode.

```
ORACLE(tos-settings)# done
tos-settings
        media-type                  message/dns
        media-sub-type
```

```
        tos-value                0x30
        media-attributes
ORACLE(tos-settings)# exit
ORACLE(media-policy)#
```

8. If necessary, repeat steps 2 through 7 to create additional Differentiated Services media policies.
9. Assign this media policy to the target realm via the **media-policy** parameter in a **realm-config** object.

SIP-SDP DCSP Marking ToS Bit Manipulation

Used to indicate priority and type of requested service to devices in the network, type of service (TOS) information is included as a set of four-bit flags in the IP header. Each bit has a different purpose, and only one bit at a time can be set: There can be no combinations. Available network services are:

- Minimum delay—Used when latency is most important
- Maximum throughput—Used when the volume of transmitted data in any period of time is important
- Maximum reliability—Used when it is important to assure that data arrives at its destination without requiring retransmission
- Minimum cost—Used when it is most important to minimize data transmission costs

The Oracle Communications Session Border Controller's support for type of service (TOS allows you to base classification on the media type as well as the media subtype. In prior releases, you can configure the Oracle Communications Session Border Controller to mark TOS bits on outgoing packets using a media policy. Supported media types include audio, video, application, data, image, text, and message; supported protocol types are H.225, H.245, and SIP. Note that, although H.225 and H.245 are not part of any IANA types, they are special cases (special subtypes) of message for the Oracle Communications Session Border Controller. When these criteria are met for an outgoing packet, the Oracle Communications Session Border Controller applies the TOS settings to the IP header. The augmented application of TOS takes matching on media type or protocol and expands it to match on media type, media-sub-type, and media attributes.

The new flexibility of this feature resolves issues when, for example, a customer needs to differentiate between TV-phone and video streaming. While both TV-phone and video streaming have the attribute "media=video," TV-phone streaming has "direction=sendrcv" prioritized at a high level and video has direction=sendonly or recvonly with middle level priority. The Oracle Communications Session Border Controller can provide the appropriate marking required to differentiate the types of traffic.

In the media policy, the **tos-values** parameter accepts values that allow you to create any media type combination allowed by IANA standards. This is a dynamic process because theOracle Communications Session Border Controller generates matching criteria directly from messages.

The new configuration takes a media type value of any of these: audio, example, image, message, model, multipart, text, and video. It also takes a media sub-type of any value specified for the media type by IANA; however, support for T.38 must be entered exactly as **t.38** (rather than t38). Using these values, the Oracle Communications Session Border Controller creates a value Based on a combination of these values, the Oracle Communications Session Border Controller applies TOS settings.

You also configure the TOS value to be applied, and the media attributes you want to match.

You can have multiple groups of TOS settings for a media policy.

ToS Bit Manipulation Configuration

This section provides instructions for how to configure TOS bit manipulation on your Oracle Communications Session Border Controller.

To configure TOS bit manipulation:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **media-policy** and press Enter.

   ```
   ORACLE(media-manager)# media-policy
   ```

   If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration you want to edit.

4. **name**—Create a reference name for this policy and press Enter.
5. Type **tos-settings** and press Enter.

   ```
   ORACLE(media-policy)# tos-settings
   ```

   > **Note:**
   >
   > The **media-policy**, **tos-settings** parameter is not RTC supported and a reboot is required for these updates to take affect.

6. **media-type**—Enter the media type that you want to use for this group of TOS settings. You can enter any of the IANA-defined media types for this value: audio, example, image, message, model, multipart, text, and video. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

   ```
   ORACLE(tos-settings)# media-type message
   ```

7. **media-sub-type**—Enter the media sub-type you want to use for the media type. This value can be any of the sub-types that IANA defines for a specific media type. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

   ```
   ORACLE(tos-settings)# media-sub-type sip
   ```

8. **media-attributes**—Enter the media attribute that will match in the SDP. This parameter is a list, so you can enter more than one value. The values are case-sensitive and can be up to 255 characters in length. This parameter has no default.

If you enter more than one media attribute value in the list, then you must enclose your entry in quotation marks ().

```
ORACLE(tos-settings)# media-attributes sendonly sendrecv
```

9. **tos-value**—Enter the TOS value you want applied for matching traffic. This value is a decimal or hexidecimal value. The valid range is:
   - 0x00 to 0xFF.

   ```
   ORACLE(tos-settings)# tos-value 0xF0
   ```

10. Save and activate your configuration.

DSCP Marking for MSRP and Media Over TCP

The Oracle Communications Session Border Controller supports Differentiated Services Code Point (DSCP) marking of MSRP and Media over TCP traffic. This feature may be used for MSRP traffic in both B2BUA and non-B2BUA modes.

In order to configure the Oracle Communications Session Border Controller to mark MSRP or media over TCP packets with a value in the IP header's DSCP field, create a **media-manager**, **media-policy**, **tos-settings** configuration element and set the **media-type** parameter to **message**. This has the effect of marking all traffic described by prior SDP with m=message with this DSCP value.

Note that setting **media-type** to **message** can potentially mark a large range of traffic. For other common traffic to remain marked differently than marked MSRP, you need to create additional **tos-settings** configuration elements with valid **media-sub-type** configurations. The following values may be provisioned in the **media-sub-type** parameter to mark these other types of traffic differently (with an accompanying **tos-value**).

- sip
- li
- dns

PAI Header and FQDN Manipulation

You can configure the SBC to manipulate the content of egress messages using realm parameters instead of HMR. By setting these parameters, you cause the SBC to perform these manipulations on specific SIP methods that egress the realm.
Realm-based content manipulation that applies to surrogate agent operation includes:

- P-Asserted Identity (PAI) content
- Fully Qualified Domain Name (FQDN) content

PAI Header Manipulation

You can configure the **realm-config** element with PAI manipulation behavior that applies to the realm's egress traffic.
You set the **P-Asserted-Identity** parameter in conjunction with the **P-Asserted-Identity-For** parameter to insert PAI headers into that realm's egress traffic. You specify the methods that you want to include by configuring the **P-Asserted-Identity-For** parameter for any or all of the following methods:

- INVITE
- ACK
- BYE
- REGISTER

You enable the behavior by configuring the **P-Asserted-Identity** parameter with the PAI value you want to insert. If you do not set both of these parameters, the SBC does not insert the headers. This manipulation deals with the selected headers for egress INVITE and REGISTER flows, and does not interfere with PRACK INVITE flows.

If the originating message does not include any PAI headers, the SBC inserts the headers per configuration. If PAI headers are already present, inserted by an upstream device, the SBC:

- Adds any **P-Asserted-Identity** parameter headers to the top of the header list.
- Replaces any existing sip:PAI headers with the sip:PAI headers you configure with the **P-Asserted-Identity** parameter.
- Replaces any existing tel:PAI headers with the tel:PAI headers you configure with the **P-Asserted-Identity** parameter.
- The SBC retains any existing tel:PAI headers or sip:PAI headers at the bottom of the PAI list that are not replaced by **P-Asserted-Identity** tel:PAI or sip:PAI values, as above.

Example configuration syntax includes:

```
ORACLE(realm-config)# P-Asserted-Identity sip:MyPai

ORACLE(realm-config)# P-Asserted-Identity-For (INVITE BYE)
```

Examples

Example 1—When you configure the **P-Asserted-Identity** as a TEL URI and there is a tel URI PAI header in the incoming message, the SBC replaces the incoming TEL URI with the PAI header configured in the **P-Asserted-Identity** parameter in the egress messages specified in the **P-Asserted-Identity-For** parameter.

- Incoming PAI: tel:56789
- P-Asserted-Identity configured: tel:12345
- P-Asserted-Identity-For: INVITE
- Output: Egress PAI: tel:12345

Example 2—When you configure the **P-Asserted-Identity** parameter as a TEL URI and there is a SIP URI in the incoming message, the SBC inserts the SIP URI with the PAI header configured in the **p-asserted-identity** parameter in the egress messages specified in the **P-Asserted-Identity-For** parameter.

- Incoming PAI headers: sip:123@oracle.com
- P-Asserted-Identity configured: tel:12345
- P-Asserted-Identity-For: INVITE
- Output Egress PAI: tel:12345 sip:123@oracle.com

FQDN Hostname Manipulation

Additional configuration allows you to modify the hostname used in SBC response headers. Some deployments need you to specify a hostname value in specific headers. You can configure the SBC to make these changes using two **realm-config** parameters. You can configure the system to apply your hostname to the following SIP headers:

- FROM
- TO
- CONTACT
- RUI

You specify a desired hostname value by configuring in the **fqdn-hostname** parameter with the desired hostname. Furthermore, you specify the headers you want to change using the **fqdn-hostname-in-header** parameter. If either of these parameters are empty, the SBC does not set this hostname in any headers.

Example settings for these parameter include:

```
ORACLEORACLE(realm-config)# fqdn-hostname MyHostName

ORACLEORACLE(realm-config)# fqdn-hostname-in-header FROM, TO
```

Configure Manipulation Attributes on a Realm

In the SBC ACLI, you can access manipulation parameters applicable to surrogate agent operation using the path **media-manager**, **realm-config**.

To configure targeted manipulation parameter on the SBC:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type media-manager and press Enter to access the media manager-related objects.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type realm-config and press Enter.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Create or select the realm-config on which the softswitch resides.
5. P-Asserted-Identity — Enter the string you want to use to set the identity within PAI headers for traffic egressing this realm.

   ```
   ORACLE(realm-config)# P-Asserted-Identity MyPAI
   ```

6. P-Asserted-Identity-For — List the methods for which the SBC includes a PAI header using the PAI identity you set in this realm's p-asserted-identity parameter. Separate multiple values with a comma.
   - INVITE
   - BYE
   - ACK
   - REGISTER

   ```
   (realm-config)# P-Asserted-Identity-For (INVITE BYE)
   ```

7. fqdn-hostname — Enter the hostname you want to in include in the selected headers for this realm's egress traffic.

   ```
   ORACLE(realm-config)# fqdn-hostname MyHostName
   ```

8. fqdn-hostname-in-header — List the headers for which the SBC inlcudes the hostname that you configured in the fqdn-host-name parameter. Separate multiple values with a comma.
   - FROM
   - TO
   - CONTACT
   - RURI

   ```
   (realm-config)# fqdn-hostname-in-header FROM, TO
   ```

9. Type done to save changes to this realm-config.
10. Save and activate your configuration.

Configure the applicable **local-policy**. This configuration includes setting the **auth-user-lookup** parameter in the applicable **local-policy-attribute** with the same value as the **auth-user-lookup** above.

SDP Alternate Connectivity

The Oracle Communications Session Border Controller can create an egress-side SDP offer containing both IPv4 and IPv6 media addresses via a mechanism which allows multiple IP addresses, of different address families (i.e., IPv4 & IPv6) in the same SDP offer. Our implementation is based on the RFC draft "draft-boucadair-mmusic-altc-09".

Each realm on the Oracle Communications Session Border Controller can be configured with an alternate family realm on which to receive media in the alt family realm parameter in the realm config. As deployed, one realm will be IPv4, and the alternate will be IPv6. The Oracle Communications Session Border Controller creates the outbound INVITE with IPv4 and IPv6 addresses to accept the media, each in an a=altc: line and each in its own realm. The IP addresses inserted into the a=altc: line are from the egress realm’s and alt-realm-family realm’s steering pools. Observe in the image how the red lines indicate the complementary, alternate realms.

You can configure the order in which the a=altc: lines appear in the SDP in the pref-address-type parameter in the realm-config. This parameter can be set to

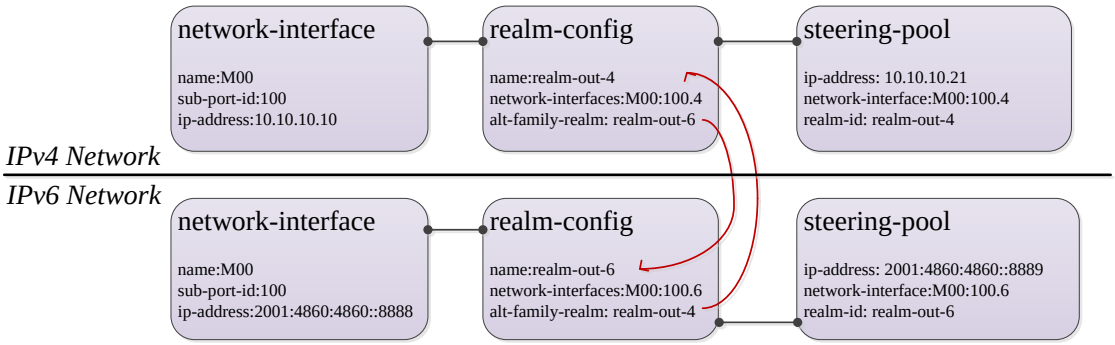
- IPv4 - SDP contains the IPv4 address first

- IPv6 - SDP contains the IPv6 address first
- NONE - SDP contains the native address family of the egress realm first

In the 200OK to the INVITE, the callee chooses either the IPv6 or IPv4 address to use for the call's media transport between itself and Oracle Communications Session Border Controller. After the Oracle Communications Session Border Controller receives the 200OK, the chosen flow is installed, and the unused socket is discarded.

For two realms from different address families to share the same phy-interface and vlan, you use a .4 or .6 tag in the network-interface reference. When IPv4 and IPv6 realms share the same network-interface and VLAN, you identify them by realm name and network-interface configured as:

- IPv4 - <phy-interface>:<vlan>.4
- IPv6 - <phy-interface>:<vlan>.6



If the INVITE's egress realm is IPv6, pref-address-type = NONE, the outbound SDP has these a=altc: lines:

```
a=altc:1 IPv6 2001:4860:4860::8889 20001
a=altc:2 IPv4 10.10.10.21 20001
```

If the INVITE's egress realm is IPv6, pref-address-type = IPv4, the outbound SDP has these a=altc: lines:

```
a=altc:1 IPv4 10.10.10.21 20001
a=altc:2 IPv6 2001:4860:4860::8889 20001
```

SDP Alternate connectivity supports B2B and hairpin call scenarios. SDP Alternate connectivity also supports singleterm, B2B, and hairpin call scenarios.

When providing SDP alternate connectivity for SRTP traffic, in the security policy configuration element, the network-interface parameter's value must be configured with a .4 or .6 suffix to indicate IPv4 or IPv6 network, respectively.

SDP Alternate Connectivity Configuration

To configure SDP alternate connectivity:

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Select the **realm-config** object to edit.

```
ORACLE(realm-config)# select
identifier:
1: realm01 left-left:0 0.0.0.0

selection: 1
ORACLE(realm-config)#
```

3. **alt-realm-family** — Enter the realm name of the alternate realm, from which to use an IP address in the other address family. If this parameter is within an IPv4 realm configuration, you will enter an IPv6 realm name.
4. **pref-address-type** — Set the order in which the a=altc: lines suggest preference. Valid values are:
   - none — address family type of egress realm signaling
   - ipv4 — IPv4 realm/address first
   - ipv6 — IPv6 realm/address first
5. Type **done** to save your configuration.

Steering Pools

Steering pools define sets of ports that are used for steering media flows through the Oracle Communications Session Border Controller. These selected ports are used to modify the SDP to cause receiving session agents to direct their media toward this system. Media can be sent along the best quality path using these addresses and ports instead of traversing the shortest path or the BGP-4 path.

For example, when the Oracle Communications Session Border Controller is communicating with a SIP device in a specific realm defined by a steering pool, it uses the IP address and port number from the steering pool's range of ports to direct the media. The port the Oracle Communications Session Border Controller chooses to use is identified in the SDP part of the message.

> **Note:**
>
> The values entered in the steering pool are used when the system provides NAT, PAT, and VLAN translation.

Configuration Overview

To plan steering pool ranges, take into account the total sessions available on the box, determine how many ports these sessions will use per media stream, and assign that number of ports to all of the steering pools on your Oracle Communications Session Border Controller.

For example, if your Oracle Communications Session Border Controller can accommodate 500 sessions and each session typically uses 2 ports, you would assign 1000 ports to each steering pool. This strategy provides for a maximum number of ports for potential use, without using extra resources on ports your Oracle Communications Session Border Controller will never use.

The following lists the steering pool parameters you must configure:

- IP address—IP address of the steering pool.
- start port—Port number that begins the range of ports available to the steering pool. You must define this port to enable the system to perform media steering and NAT operations.
- end port—Port number that ends the range of ports available to the steering pool. You must define this port to enable the system to perform media steering and NAT operations.
- realm id—Identifies the steering pool's realm. The steering pool is restricted to only the flows that originate from this realm.

> **Note:**
>
> The combination of entries for IP address, start port, and realm ID must be unique in each steering pool. You cannot use the same values for multiple steering pools.

Each bidirectional media stream in a session uses two steering ports, one in each realm (with the exception of audio/video calls that consume four ports). You can configure the start and end port values to provide admission control. If all of the ports in all of the steering pools defined for a given realm are in use, no additional flows/sessions can be established to/from the realm of the steering pool.

> **Note:**
>
> If your signaling interface and **steering-pool** use the same IP address over TCP, you must ensure the **steering-pool** port range does not include the signaling interface's port number. If it does, the system cannot properly process signaling traffic on that interface.

Allocation Strategies for Steering Pools

You can configure the SBC with three types of steering pools to allocate network ports for specific types of network traffic. These pool types include audio/video, MSRP and mixed media types. Establishing these pool types provides more efficient use of media ports. The SBC provides you with a means of monitoring port usage by type to troubleshoot and refine these configurations.

By default, the SBC does not allocate steering pool ports based on media type. These default allocations can establish scenarios, including sequential allocation and port release, wherein port usage is inefficient. By configuring or monitoring your realms for traffic type use, you can plan for and adjust configuration based on expected port usage:

- Audio/Video sessions—Consume 4 ports, including two audio ports supporting the two traffic directions and two additional ports for RTP and RTCP
- MSRP sessions—Consume 2 ports supporting the two traffic directions

- Hairpin Audio sessions—Consume 8 ports, including four audio flows supporting the two traffic directions, two for RTP, and two for RTCP

Per recommendation in RFC 3550, the SBC allocates RTP and RTCP ports for audio calls sequentially. This behavior can reduce the number of ports you have configured for a **steering-pool**.

For example, if you have configured 100 ports on a realm and it receives 100 MSRP calls, the SBC allocates the 100 ports for the MSRP call flows. When the users terminate these sessions, those terminations happen randomly, leaving multiple non-sequential ports open.

If the users terminate 20 random sessions, the number of ports that become available are not likely to support 5 A/V calls. This is because the SBC may not be able to find open, sequential ports to support RTP and RTCP. This can cause calls to fail, with the system reporting no ports available as the reason.

This feature provides you with a means of establishing multiple **steering-pool** objects for a realm that use your configured allocation strategy as a means of determining pool affinity based on traffic type. The SBC recognizes the traffic type and chooses the appropriate **steering-pool** based on **port-allocation-strategy** and current pool capacity:

- **mixed**—(Default) Supports all types of sessions
- **single**—Recommended for MSRP sessions
- **pair**—Recommended for audio and video sessions

The SBC tracks pool utilization and, assuming the **port-allocation-strategy** is appropriate, allocates traffic preferred for an empty pool to use ports from a pool that is not empty rather than reject the call. In addition, the system supports the use of steering pool ports from a parent realm by flows in a child realm. This adds an additional option for establishing allocation flexibility.

Consider a realm with three steering pools, including a **mixed**, a **single** and a **pair**. System port allocation behavior would include:

- The SBC directs MSRP sessions to the **single** pool. If the **single** pool runs out of ports, the SBC directs MSRP sessions to the **mixed** pool. If both of these pools are exhausted, the SBC drops new MSRP sessions and increments the 'no ports' counter.
- The SBC directs audio sessions to the **pair** pool. If the **pair** runs out of ports, the SBC directs audio sessions to the **mixed** pool. If both of these pools are exhausted, the SBC drops new audio sessions and increments the 'no ports' counter.

Notice that the SBC restricts traffic types when using the **single** and **pair** allocation strategies. The **mixed** pool, however, supports both traffic types.

To mitigate against the lack of consecutive ports described above, you could configure two **steering-pool** objects for same realm, one set to **pair** and the other to **single**. This configuration also restricts port utilization to specific pools by not including any **steering-pool** set to **mixed**.

Ultimately, you evaluate and monitor your deployment's needs for pool allocation and configure pools to suit those needs.

Configuration

You configure this functionality using the **port-allocation-strategy** parameter within **steering-pool** elements. The default is **mixed**.

```
ORACLE(steering-pool)#port-allocation-strategy single
```

Important configuration detail includes:

- Do not overlap port ranges configured on the same interface regardless of allocation strategy. The system throws a **verify-config** error identifying any overlapping **steering-pool** port range configuration, but it does not prevent you from saving and activating the configuration.
- The **port-allocation-strategy** parameter is real time configurable, allowing you to change an allocation strategy during operation. Established calls using this pool's strategy persist until the users terminate them. Ensuing calls use your updated strategy.
- The SBC selects ports from a child realm's pools when sessions start on that child realm. If a child realm's ports are exhausted, the SBC can allocate ports from the parent realm as long as the strategy is appropriate.

Steering Pool Allocation Examples

When determining the best port allocation strategies for your deployment, consider the examples in this section.

Basic Example

This example presents a realm with 3 **steering-pool** elements configured to the following strategies:

- SP1—**mixed**
- SP2—**single**
- SP3— **pair**

When MSRP calls arrive at this realm, the system allocates ports from SP2. If SP2 becomes exhausted, the system allocates ports for new MSRP calls from SP1. If both SP2 and SP1 become exhausted, the system rejects MSRP calls to this realm.

Similarly, when audio calls arrive at this realm, the system allocates ports from SP3. If SP3 becomes exhausted, the system allocates ports for new audio calls from SP1. If both SP3 and SP1 become exhausted, the system rejects audio calls to this realm.

Configuration Change Example

When a call is established with a steering pool port, configuration changes do not affect that call. After a configuration change, however, the system uses that port's updated strategy for ensuing allocations.

This example presents a realm with 3 **steering-pool** elements configured to the following strategies:

- SP1—**mixed**
- SP2—**single**
- SP3— **mixed**

> **Note:**
>
> Port allocation to pools of the same type depends on the port range available. When it begins allocating ports from a pool, the system chooses the lowest port available. But calls terminate randomly, so the system picks the topmost port available in a pool on ensuing calls, which may not be the lowest port number available.

When MSRP calls arrive at this realm, the system allocates ports from SP2. If SP2 becomes exhausted, the system allocates ports for new MSRP calls from SP1 and SP3. If both SP1 and SP3 become exhausted, the system rejects MSRP calls to this realm and increments the no ports counter.

Similarly, when audio calls arrive at this realm, the system allocates ports from SP1 and SP3. If SP3 becomes exhausted, the system allocates ports for new audio calls from SP1. If both SP3 and SP1 become exhausted, the system rejects audio calls to this realm.

If you change the **port-allocation-strategy** of SP2 from **single** to **pair**, then perform the **save-config** and **activate config** commands, the system begins to allocate audio calls to SP2. With this new configuration, the system is able to assign audio calls to all three pools. If SP1, SP2 and SP3 become exhausted, the system rejects audio calls to this realm.

If MSRP calls arrive at this realm, the system allocates ports for these calls using SP1 and SP3. If SP1 and SP3 become exhausted, the system rejects MSRP calls to this realm

Parent/Child Realm Allocation Example 1

Note that the following example presents a typical port utilization scenario. The difference here is that the system is using the parent realm's ports. In this example, either the child realm has no steering pools, or all of the child realm's applicable ports are in use.

Case 1—Assume the parent realm has 3 steering-pools:

- SP1—**mixed**
- SP2—**single**
- SP3— **pair**

In this case, an MSRP call arriving at the child realm uses the parent realm's SP2. If SP2 runs out of ports, the system tries to use SP1. Audio calls to the child realm use the parent realm's SP3. If SP3 runs out of ports, the system again tries to use SP1.

Case 2—In this case, all of the parent realm pools are **mixed**. Here, both MSRP and audio calls to the child realm can use SP1, SP2 and SP3.

Parent/Child Realm Allocation Example 2

Similar to Parent/Child Realm Allocation Example 1, the system here uses a child realm's steering pool ports first, then begins to use the parent realm's ports when the child realm's ports are in use. Utilization detail still uses the mixed, single, pair strategy rules.

- Case 1—Assume a child realm has:
  - SP4—**mixed**
  - SP5—**mixed**

  If you have configured 200 ports, the system uses all of those ports before using parent realm ports.
  - Sub Case 1—Assume the parent realm has:

        * SP1—**mixed**
        * SP2—**single**
        * SP3—**pair**

        The system receives MSRP calls to the child realm, which then uses SP2 in the parent realm. If parent realm SP2 becomes exhausted, the system starts using SP1. Audio calls to the child realm use the parent realm's SP3 and then SP1 when SP3 is exhausted.

    – Sub Case 2—Assume all of the parent realm's pool strategies are **mixed**. In this case, all MSRP and audio calls to the child realm can use SP1, SP2 and SP3.

- Case 2—In this case, assume the parent realm uses the same allocation for Case 1, Sub-case 1 and the child realm has:
    – SP4—**mixed** - 100 ports
    – SP5—**single** - 80 ports
    – SP6—**pair** - 60 ports

    Consider the results when there are 180 MSRP calls to the child realm. The system handles the first 80 using SP5 ports and the next 100 using SP4 ports. When MSRP call number 181 arrives, the system uses the parents realm's SPs, not the child realm's SPs. Similarly, when all 60 **pair** ports are used, the system uses any available **mixed** ports from SP4, and then uses the parent realm SPs.

    The following cases assume the child realm's ports are all used.

    – Sub Case 1—Incoming MSRP calls to child realm use SP2, in the parent realm, for port allocation. If SP2 ports are used, the system uses SP1. Audio calls to child realm use SP3, in the parent realm, for port allocation. If SP3 ports are used, the system uses SP1.
    – Sub Case 2—If the parent realm's pools are all **mixed**, all calls to child realm can use SP1, SP2 and SP3.
    – Sub Case 3—If the parent realm's pools are all **single**, the system terminates all audio calls to the child realm, and indicates that no ports are available.
    – Sub Case 4—If the parent realm's pools are all **pair**, the system terminates all MSRP calls to the child realm, and indicates that no ports are available.

Monitoring Port Allocation

You can troubleshoot your port allocation configuration and report on port usage, including the number of audio, MSRP calls and ports assigned using following commands:

- show sipd
- show mbcd
- show mbcd realms
- show mbcd realms <identifier>
- show mbcd realms <identifier> detailed

You can see status on **steering-pool** ports using the **show mbcd realm <identifier> detailed** command. On a per-realm basis, this command displays used and free ports for each steering pool whether configured as **mixed**, **single** or **pair**. This command also displays the 'no ports'

counter. This command allows you to monitor port utilization on a realm and adjust your allocation configuration based on your traffic.

```
ORACLE#show mbcd realm Realm172 detailed

Steering Pool Configuration

To configure a steering pool:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **steering-pool** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# steering-pool
   ORACLE(steering-pool)#
   ```

4. **ip-address**—Enter the target IP address of the steering pool in IP address format. For example:

   ```
   192.168.0.11
   ```

5. **start-port**—Enter the start port value that begins the range of ports available to this steering pool. The default is **0**. The valid range is:
   - Minimum—1
   - Maximum—65535
     You must enter a valid port number or the steering pool will not function properly.
6. **end-port**—Enter the end port value that ends the range of ports available to this steering pool. The default is **0**. The valid range is:
   - Minimum—1
   - Maximum—65535
     You must enter a valid port number or the steering pool will not function properly.
7. **realm-id**—Enter the realm ID to identify the steering pool's realm, following the name format. The value you enter here must correspond to the value you entered as the identifier (name of the realm) when you configured the realm. For example:

   ```
   peer-1
   ```

   This steering pool is restricted to flows that originate from this realm.
8. **network-interface** —Enter the name of network interface this steering pool directs its media toward. A valid value for this parameter must match a configured name parameter in the network-interface configuration element. This parameter applies only to realms with multiple interfaces.
9. **port-allocation-strategy** —Select the appropriate strategy for this steering pool based on media type support in this realm. You can create multiple steering pools using different strategies to support multiple media types, per your deployment. Settings include:
   - mixed—(Default)
   - pair—The system only allocates these ports for calls that require multiple ports
   - single—The system only allocates these ports for calls that require a single port

   The following example shows the configuration of a steering pool.

   ```
   steering-pool
           ip-address                      192.168.0.11
           start-port                      20000
           end-port                        21000
           realm-id                        peer-1
           network-interface
           port-allocation-strategy        mixed

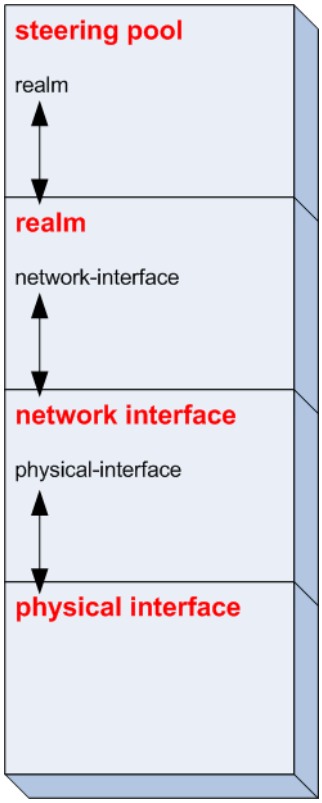
Multiple Interface Realms

The multi-interface realm feature lets you group multiple network interfaces to aggregate their bandwidth for media flows. In effect, this feature lets you use the total throughput of the available phy-interfaces on your Oracle Communications Session Border Controller for a single realm. Multi-interface realms are implemented by creating multiple steering pools, each on an individual network interface, that all reference a single realm.

> **Note:**
>
> Labels that read 'physical interface' in the diagrams below should be understood to reference the **phy-interface** configuration element.

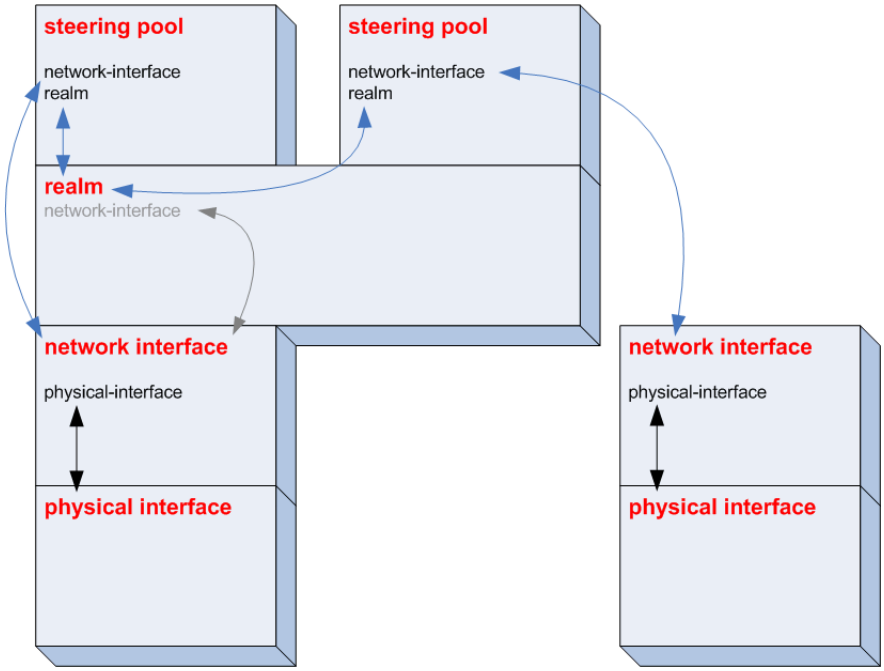
Of course, you can not to use this feature and configure your Oracle Communications Session Border Controller to create a standard one-realm to one-network interface configuration.

Without using multiple interface realms, the basic hierarchical configuration of the Oracle Communications Session Border Controller from the phy-interface through the media steering pool looks like this:

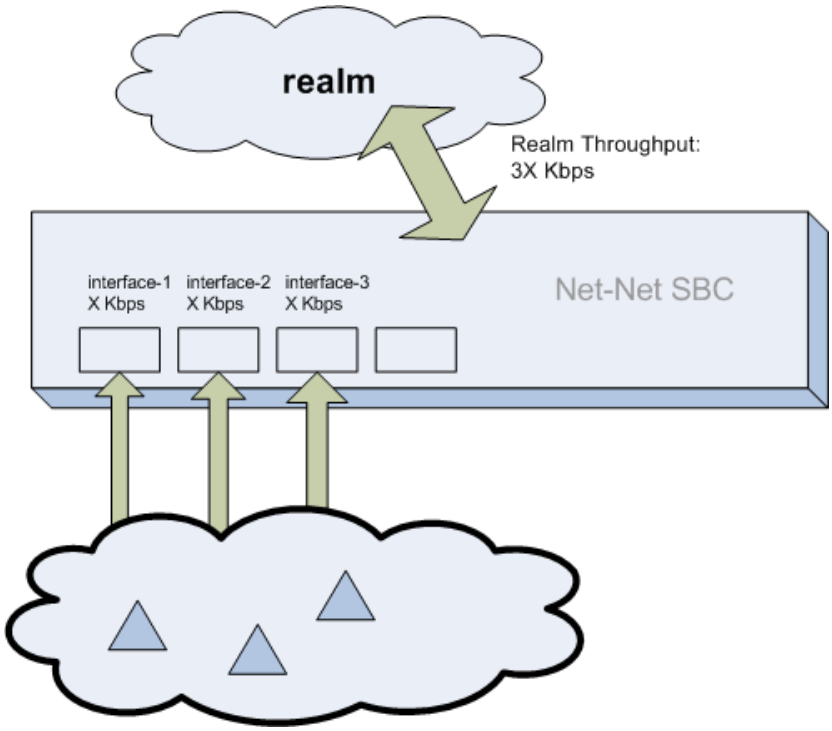


In this model, one (non-channelized) network interface exists on a phy-interface. One realm exists on one network interface. One or more steering pools can exist on one realm. Within each higher level configuration element exists a parameter that references a lower level configuration element in the Oracle Communications Session Border Controller's logical network model.

The multi-interface realm feature directs media traffic entering and exiting multiple network interfaces in and out of a single realm. Since all the steering pools belong to the same realm, their assigned network interfaces all feed into the same realm as well. The following diagram shows the relationship in the new logical model:



The advantage of using multi-interface realms is the ability to aggregate the bandwidth available to multiple network interfaces for a larger-than-previously-available total bandwidth for a realm. In the illustration below, three phy-interfaces each have X Kbps of bandwidth. The total bandwidth available to the realm with multiple network interfaces is now 3X the bandwidth. (In practical usage, interface-1 only contributes X - VoIP Signaling to the total media bandwidth available into the realm.)



Steering Pool Port Allocation

Every steering pool you create includes its own range of ports for media flows. The total number of ports in all the steering pools that feed into one realm are available for calls in and out of the realm.

Steering pool ports for a given realm are assigned to media flows sequentially. When the first call enters the Oracle Communications Session Border Controller after start-up, it is assigned the first ports on the first steering pool that you configured. New calls are assigned to ports sequentially in the first steering pool. When all ports from the first steering pool are exhausted, the Oracle Communications Session Border Controller uses ports from the next configured steering pool. This continues until the last port on the last configured steering pool is used.

After the final port is used for the first time, the next port chosen is the one first returned as empty from the full list of ports in all the steering pools. As media flows are terminated, the ports they used are returned to the realm's full steering pool. In this way, after initially exhausting all ports, the realm takes new, returned, ports from the pool in a least last used manner.

When a call enters the Oracle Communications Session Border Controller, the signaling application allocates a port from all of the eligible steering pools that will be used for the call. Once a port is chosen, the Oracle Communications Session Border Controller checks if the steering pool that the port is from has a defined network interface. If it does, the call is set up on the corresponding network interface. If a network interface is not defined for that steering pool, the network interface defined for the realm is used.

Network Interface Configuration

This section explains how to configure your Oracle Communications Session Border Controller to use multiple interface realms.

You must first configure multiple phy-interfaces and multiple network interfaces on your Oracle Communications Session Border Controller.

To configure the realm configuration for multi-interface realms.

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-manager path.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm-config** and press Enter. The system prompt changes.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

   From this point, you can configure a realm that will span multiple network interfaces.

4. **network-interfaces**—Enter the name of the network interface where the signaling traffic for this realm will be received.

Creating Steering Pools for Multiple Interface Realms

To configure steering pools for multi-interface realms:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-manager path.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **steering-pool** and press Enter. The system prompt changes.

   ```
   ORACLE(media-manager)# steering-pool
   ORACLE(steering-pool)#
   ```

   From this point, you can configure steering pools which collectively bridge the multiple network interfaces they are connected to.

4. **ip-address**—Enter the IP address of the first steering pool on the first network interface.

   This IP address must correspond to an IP address within the subnet of a network interface you have already configured.

   This IP can not exist on a network interface other than the one you configure in the **network-interface** parameter.

5. **start-port**—Enter the beginning port number of the port range for this steering pool. The default is **0**. The valid range is:

   - Minimum—0
   - Maximum—65535

6. **end-port**—Enter the ending port number of the port range for this steering pool. The default is **0**. The valid range is:

   - Minimum—0
   - Maximum—65535

7. **realm-id**—Enter the name of the realm which this steering pool directs its media traffic toward.

8. **network-interface**—Enter the name of the network interface you want this steering pool to direct its media toward. This parameter will match a **name** parameter in the network-interface configuration element. If you do not configure this parameter, you can only assign a realm to a single network interface, as the behavior was in all Oracle Communications Session Border Controller Software releases pre- 2.1.

9. Create additional steering pools on this and on other network interfaces as needed. Remember to type **done** when you are finished configuring each new steering pool.

Media over TCP

The Oracle Communications Session Border Controller now supports RFC 4145 (TCP-Based Media Transport in the SDP), also called TCP Bearer support. Media over TCP can be used to support applications that use TCP for bearer path transport.

RFC 4145 adds two new attributes, setup and connection, to SDP messages. The setup attribute indicates which end of the TCP connection should initiate the connection. The connection attribute indicates whether an existing TCP connection should be used or if a new TCP connection should be setup during re-negotiation. RFC 4145 follows the offer/answer model specified in RFC3264. An example of the SDP offer message from the end point 192.0.2.2 as per RFC4145 is as given below:

```
m=image 54111 TCP t38
c=IN IP4 192.0.2.2
a=setup:passive
a=connection:new
```

This offer message indicates the availability of t38 fax session at port 54111 which runs over TCP. Oracle Communications Session Border Controller does not take an active part in the application-layer communication between each endpoint.

The Oracle Communications Session Border Controller provides the means to set up the end-to-end TCP flow by creating the TCP/IP path based on the information learned in the SDP offer/answer process.

TCP Bearer Conditions

The following conditions are applicable to the Oracle Communications Session Border Controller's support of RFC 4145.

1. The Oracle Communications Session Border Controller can not provide media-over-TCP for HNT scenarios (endpoints behind a NAT).
2. When media is released into the network, the TCP packets do not traverse the Oracle Communications Session Border Controller because nNo TCP bearer connection is created.
3. The Oracle Communications Session Border Controller does not inspect the setup and connection attributes in the SDP message since the TCP packets transparently pass through the Oracle Communications Session Border Controller. These SDP attributes are forwarded to the other endpoint. It is the other endpoint's responsibility to act accordingly.
4. After the Oracle Communications Session Border Controllerreceives a SYN packet, it acts as a pure pass through for that TCP connection and ignores all further TCP handshake messages including FIN and RST. The flow will only be torn down in the following instances:
   - The TCP initial guard timer, TCP subsequent guard timer, or the TCP flow time limit timer expire for that flow.
   - The whole SIP session is torn down.

TCP Port Selection

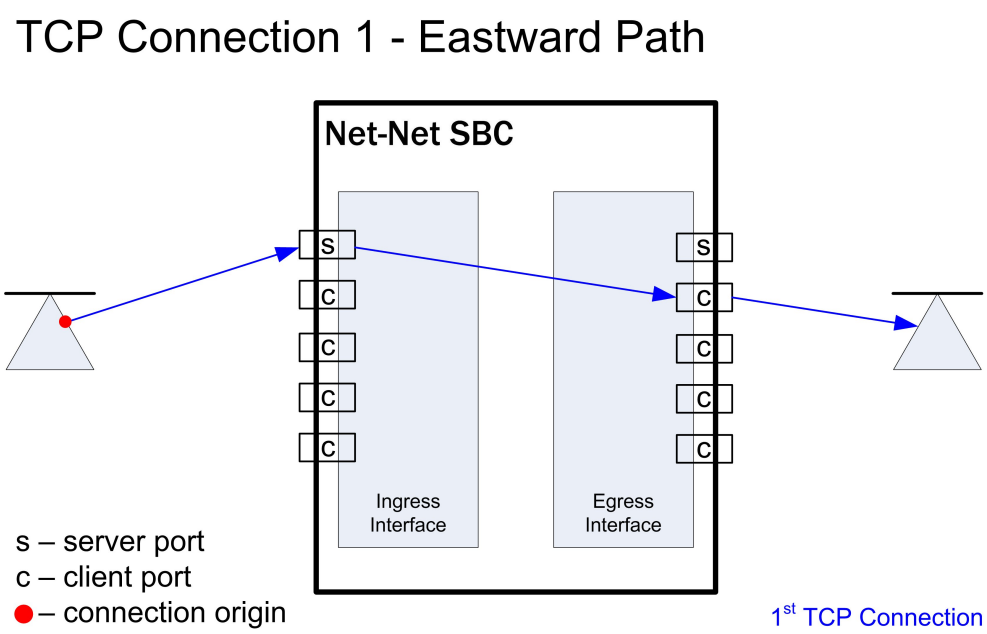
When a call is first set up, the Oracle Communications Session Border Controller inspects the SDP message's m-line to see if any media will be transported via TCP. If the SDP message indicates that some content will use TCP, the Oracle Communications Session Border Controller allocates a configured number of steering ports for the media-over-TCP traffic. These TCP media ports are taken from the each realm's steering pool.

Each endpoint can initiate up to four end-to-end TCP flows between itself and the other endpoint. The Oracle Communications Session Border Controller assigns one port to receive the initial TCP packet (server port), and one to four ports assigned to send TCP traffic (client

ports) to the receiving side of the TCP flow. The number of TCP flows for each call is configured globally.

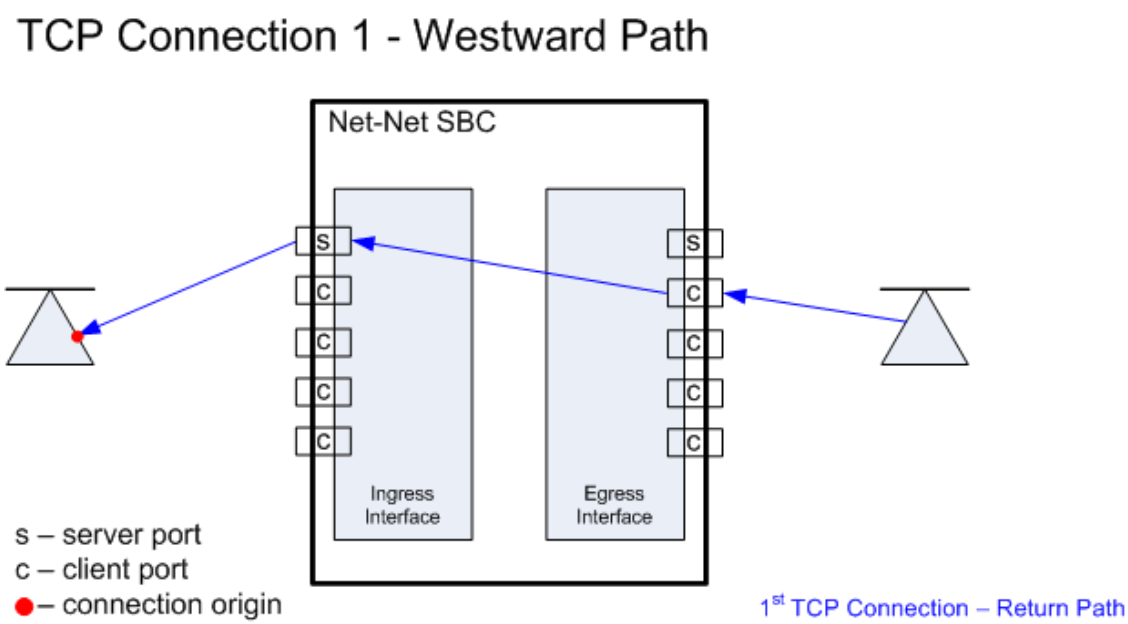
In order to configure the Oracle Communications Session Border Controller to facilitate and support this process, you need to specify the number of ports per side of the call that can transport discrete TCP flows. You can configure one to four ports/flows. For configuration purposes, the Oracle Communications Session Border Controller counts this number as inclusive of the server port. Therefore if you want the Oracle Communications Session Border Controller to provide a maximum of one end-to-end TCP flow, you have to configure two TCP ports; one to receive, and one to send. The receiving port (server) is reused to set up every flow, but the sending port (client) is discrete per flow. For example: for 2 flows in each direction, set the configuration to 3 TCP ports per flow; for 3 flows in each direction, set the configuration to 4 TCP ports per flow, etc.

The server port is used for initiating a new TCP connection. An endpoint sends the first packet to a server port on the ingress interface. The packet is forwarded out of the Oracle Communications Session Border Controller through a client port on the egress interface toward an endpoint:

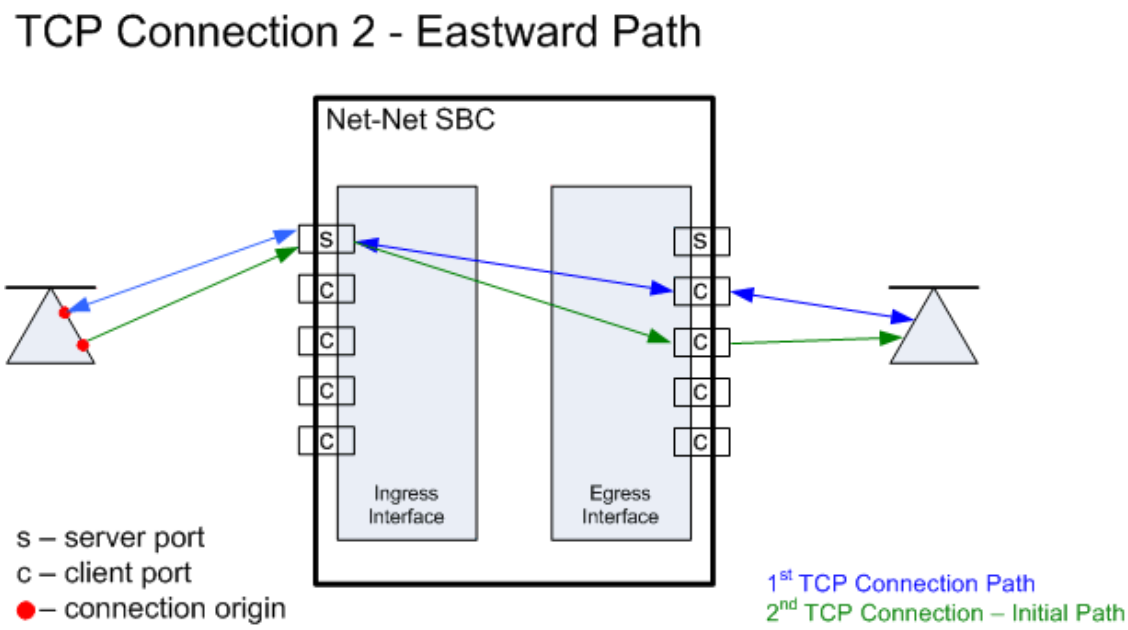


1st TCP Connection – Initial Path

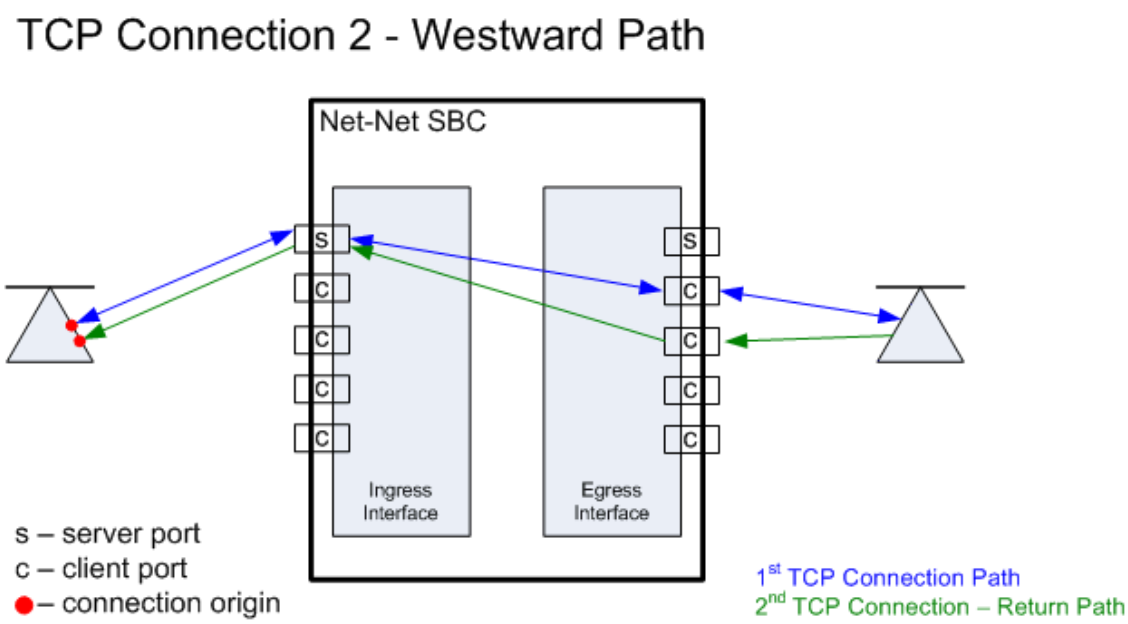
The endpoint responds back to the client port on the egress interface. This message traverses the Oracle Communications Session Border Controller and is forwarded out of the server port on the ingress interface where the initial packet was sent. The remainder of the TCP flow uses the server and client port pair as a tunnel through the Oracle Communications Session Border Controller:



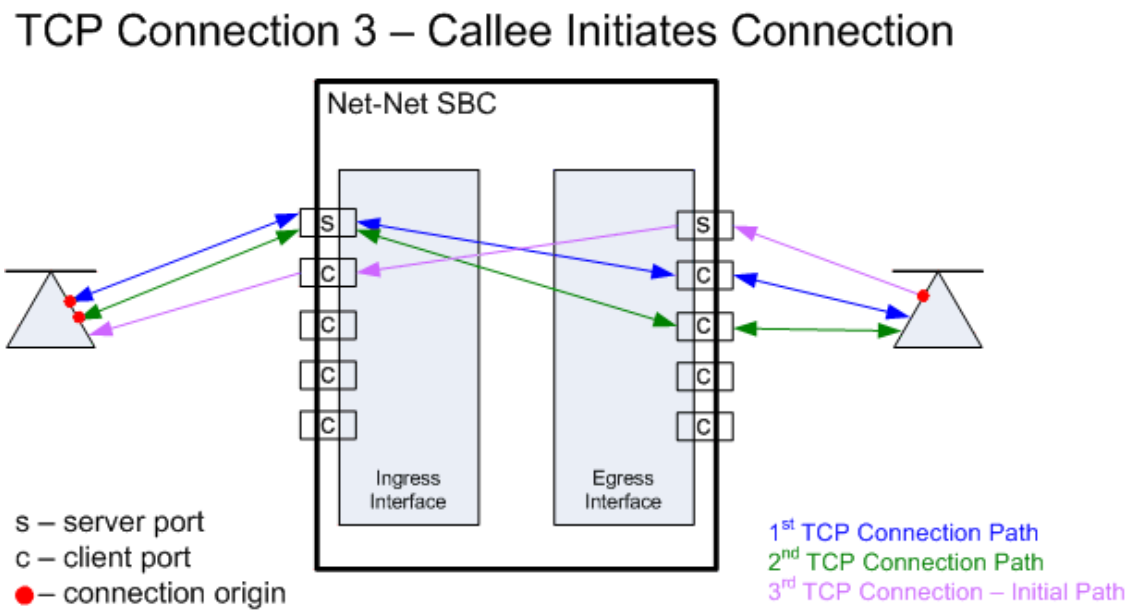
When the second TCP connection is set up in the same direction as in the first example, the first packet is still received on the server port of the ingress interface. The next unused client port is chosen for the packet to exit the Oracle Communications Session Border Controller:



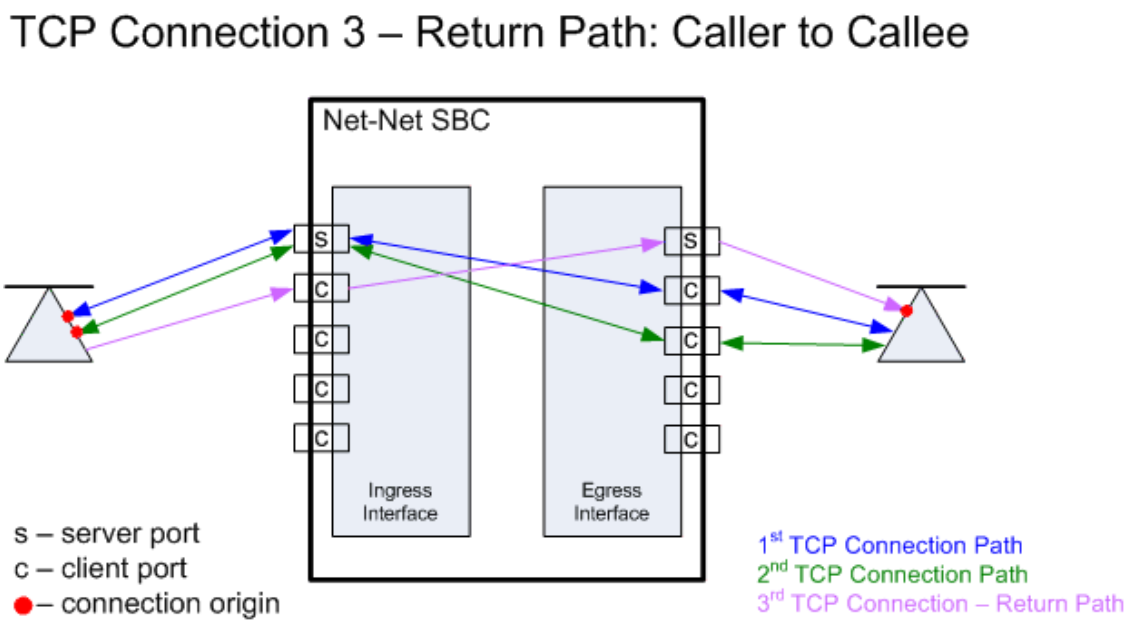
The response takes the same path back to the caller. The remainder of the second TCP connection uses this established path:



When the callee initiates a TCP connection, it must send its initial traffic to the server port on its Oracle Communications Session Border Controller ingress interface. The packet is forwarded out of the first free client port on the egress side of this TCP connection toward the caller.



The caller's response takes the same path back to the callee that initiated this TCP connection. The remainder of the third TCP connection uses this established path.

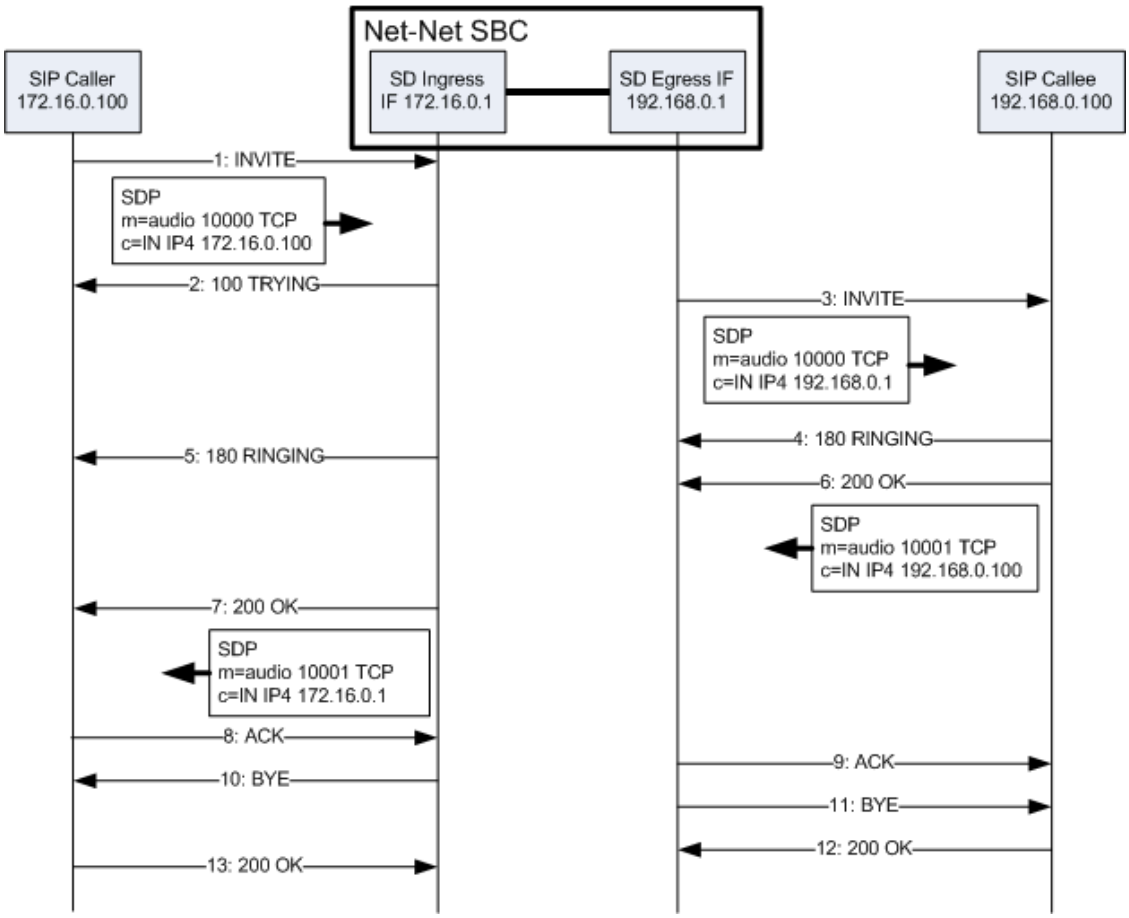


The Oracle Communications Session Border Controller can support a total of eight media-over-TCP connections per call. A maximum of 4 connections are supported as initiated from each side of the call.

SDP Offer Example

The following abbreviated call flow diagram sets up a media-over-TCP flow. Observe that the caller listens for audio over TCP on 172.16.0.10:10000, as described in the SDP offer (1). The Oracle Communications Session Border Controller re-writes the m and c lines in the SDP offer to reflect that it is listening for audio over TCP on its egress interface at 192.168.0.1:10000 (3). The Oracle Communications Session Border Controller then forwards the SIP invite to the callee.

The SIP callee responds with an SDP answer in a 200 OK message. The callee indicates it is listening for the audio over TCP media on 192.168.0.10:10001 (6). The Oracle Communications Session Border Controller re-writes the m and c lines in the SDP answer to reflect that it is listening for audio over TCP on the call's ingress interface at 172.16.0.1:10001 (7). The Oracle Communications Session Border Controller then forwards the SIP invite to the caller.



All interfaces involved with the end-to-end TCP flow have now established their listening IP address and port pairs.

Timers

The Oracle Communications Session Border Controller has three guard timers that ensure a TCP media flow does not remain connected longer than configured. You can set each of these from 0 (disabled) to 999999999 in seconds.

- TCP initial guard timer — Sets the maximum time in seconds allowed to elapse between the initial SYN packet and the next packet in this flow.
- TCP subsequent guard timer — Sets the maximum time in seconds allowed to elapse between all subsequent sequential TCP packets.
- TCP flow time limit — Sets the maximum time that a single TCP flow can last. This does not refer to the entire call.

TCP Port Configuration

To configure media over TCP:

1. Access the **media-manager-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
```

```
ORACLE(media-manager)# media-manager
ORACLE(media-manager-config)#
```

2. **tcp-number-of-ports-per-flow**—Enter the number of ports, inclusive of the server port, to use for media over TCP. The total number of supported flows is this value minus one. The default is **2**. The valid range is:
   - Minimum—2
   - Maximum—4

   ```
   ORACLE(media-manager-config)# tcp-number-of-ports-per-flow 5
   ```

3. **tcp-initial-guard-timer**—Enter the maximum time in seconds allowed to elapse between the initial SYN packet and the next packet in a media-over-TCP flow. The default is **300**. The valid range is:
   - Minimum—0
   - Maximum—999999999

   ```
   ORACLE(media-manager-config)# tcp-initial-guard-timer 300
   ```

4. **tcp-subsq-guard-timer**—Enter the maximum time in seconds allowed to elapse between all subsequent sequential media-over-TPC packets. The default is **300**.
   - Minimum—0
   - Maximum—999999999

   ```
   ORACLE(media-manager-config)# tcp-subsq-guard-timer 300
   ```

5. **tcp-flow-time-limit**—Enter the maximum time in seconds that a media-over-TCP flow can last. The default is **86400**. The valid range is:
   - Minimum—0
   - Maximum—999999999

   ```
   ORACLE(media-manager-config)# tcp-flow-time-limit 86400
   ```

Restricted Media Latching

The restricted media latching feature lets the Oracle Communications Session Border Controller latch only to media from a known source IP address, in order to learn and latch the dynamic UDP port number. The restricting IP address's origin can be either the SDP information or the SIP message's Layer 3 (L3) IP address, depending on the configuration.

About Latching

Latching is when the Oracle Communications Session Border Controller listens for the first RTP packet from any source address/port for the destination address/port of the Oracle Communications Session Border Controller. The destination address/port is allocated dynamically and sent in the SDP. After it receives a RTP packet for that allocated destination address/port, the Oracle Communications Session Border Controller only allows subsequent RTP packets from that same source address/port for that particular Oracle Communications Session Border Controller destination address/port. Latching does not imply that the latched

source address/port is used for the destination of the reverse direction RTP packet flow (it does not imply the Oracle Communications Session Border Controller will perform symmetric RTP).

Restricted Latching

The Oracle Communications Session Border Controller restricts latching of RTP/RTCP media for all calls within a realm. It latches to media based on one of the following:

- SDP: the IP address and address range based on the received SDP c= connect address line in the offer and answer.
- Layer 3: the IP address and address range based on the received L3 IP address of the offer or answer. This option is for access registered HNT endpoints. If the L3 IP address is locally known and cached by the Oracle Communications Session Border Controller as the public SIP contact address, that information could be used instead of waiting for a response. The Oracle Communications Session Border Controller might use the L3 IP address restriction method for all calls regardless of whether the endpoint is behind a NAT or not, for the same realms.

Symmetric Latching

A mode where a device's source address/ports for the RTP/RTCP it sends to the Oracle Communications Session Border Controller (SBC) that are latched, are then used for the destination of RTP/RTCP sent to the device.

After allocating the media session in SIP, the SBC sets the restriction mode and the restriction mask for the calling side as well as for the called side. It sets the source address and address prefix bits in the flow. It also parses and loads the source flow address into the MIBOCO messages. After receiving the calling SDP, the SBC sets the source address (address and address prefix) in the appropriate flow (the flow going from calling side to the called side). After receiving the SDP from the called side, the SBC sets the source address in the flow going from the called side to the calling side.

The SBC uses either the address provided in the SDP or the layer 3 signaling address for latching. You also configure the SBC to enable latching so that when it receives the source flow address, it sets the address and prefix in the NAT flow. When the NAT entry is installed, all the values are set correctly. In addition, sipd sends the information for both the incoming and outgoing flows. After receiving SDP from the called side sipd, the SBC sends information for both flows to the MBCD so that the correct NAT entries are installed.

Enabling restricted latching may make the SBC wait for a SIP/SDP response before latching, if the answerer is in a restricted latching realm. This is necessary because the SBC does not usually know what to restrict latching to until the media endpoint is reached. The only exception could be when the endpoint's contact/IP is cached.

Relationship to Symmetric Latching

The current forced HNT symmetric latching feature lets the Oracle Communications Session Border Controller assume devices are behind NATs, regardless of their signaled IP/SIP/SDP layer addresses. The Oracle Communications Session Border Controller latches on any received RTP destined for the specific IP address/port of the Oracle Communications Session Border Controller for the call, and uses the latched source address/port for the reverse flow destination information.

If both restricted latching and symmetric latching are enabled, the Oracle Communications Session Border Controller only latches if the source matches the restriction, and the reverse

flow will only go to the address/port latched to, and thus the reverse flow will only go to an address of the same restriction.

- Symmetric latching is enabled.
  If symmetric latching is enabled, the Oracle Communications Session Border Controller sends the media in the opposite direction to the same IP and port, after it latches to the source address of the media packet.
- Symmetric latching is disabled.
  If symmetric latching is disabled, the Oracle Communications Session Border Controller only latches the incoming source. The destination of the media in the reverse direction is controlled by the SDP address.

Example 1

A typical example is when the Oracle Communications Session Border Controller performs HNT and non-HNT registration access for endpoints. Possibly the SDP might not be correct, specifically if the device is behind a NAT. Therefore the Oracle Communications Session Border Controller needs to learn the address for which to restrict the media latching, based on the L3 IP address. If the endpoint is not behind a NAT, then the SDP could be used instead if preferred. However, one can make some assumptions that access-type cases will require registration caching, and the cached fixed contact (the public FW address) could be used instead of waiting for any SDP response.

Example 2

Another example is when a VoIP service is provided using symmetric-latching. A B2BUA/proxy sits between HNT endpoints and the Oracle Communications Session Border Controller, and calls do not appear to be behind NATs from the Oracle Communications Session Border Controller's perspective. The Oracle Communications Session Border Controller's primary role, other than securing softswitches and media gateways, is to provide symmetric latching so that HNT media will work from the endpoints.

To ensure the Oracle Communications Session Border Controller's latching mechanism is restricted to the media from the endpoints when the SIP Via and Contact headers are the B2BUA/proxy addresses and not the endpoints', the endpoint's real (public) IP address in the SDP of the offer/answer is used. The B2BUA/proxy corrects the c= line of SDP to that of the endpoints' public FW address.

The Oracle Communications Session Border Controller would then restrict the latching to the address in the SDP of the offer from the access realm (for inbound calls) or the SDP answer (for outbound calls).

Restricted Latching using Address and Port

You can configure the system to latch all media flows within a realm to both the externally provided address and port when you set the **restricted-latching** mode to **sdp-ip-port**. When configured to this setting, the system latches to media based on the IP Address received in the SDP c= connect address line, and the port in the mline in the offer and answer. This differs from standard latching in that the port is left unassigned by the SBC. This feature allows the SBC to better support multiple RTP streams from different ports using the same IP address, such as within forking scenarios.

When configuring latching to **sdp-ip-port**, the SBC supports:

- Latching to IP and port within early media scenarios and call establishment phases

- Re-latching when an SDP update received in a 200 OK is different than the one received in a provisional response
- Re-latching to media based on IP and port within reINVITE/UPDATE scenarios, when the media is updated after call establishment including:
  - Updating the latching after the 200 OK when the media is updated by reINVITE/ UPDATE scenarios
  - Updating the latching within call transfer scenarios involving forking.
- Maintaining latching established during early media stages when the 200 OK does not include SDP
- Maintaining latching established by the most recent provisional response when the 200 OK does not include SDP

> **Note:**
>
> If you downgrade to a version that does not support this feature, the system changes the **restricted-latching** setting to **none**. Upgrades and downgrades to system with feature compatibility retain your setting.

Related Configuration

If you have enabled **rtcp-mux** in conjunction with this feature, the system installs un-collapsed flows for RTP and RTCP that include IP and port in both the east and west realms. This is true if you have enabled **rtcp-mux** and this feature on one or both of these realms. In these cases, the system installs these uncollapsed flows on both realms and supports only the following two port assignments for RTCP:

- RTP port
- RTP port + 1

The table below presents the way the SBC assigns and handles RTCP differently, based on **restricted-latching** configuration and RTCP input.

restricted-latching Configurations	**RTCP sent from UAC mline (RTP) even port to SBC RTP port (even port)**	**RTCP from UAC mline port (RTP) to SBC RTP+1 port (odd port)**	**RTCP from UAC mline port+1 (UAC odd port) to SBC RTP port (even port)**	**RTCP from UAC mline port+1 (odd port) SBC RTP+1 port (odd port)**
UAC realm— **sdp** UAS realm— **disabled** Media is sent from UAC	RTCP is forwarded to RTP port of the UAS via SBC egress even port	RTCP is forwarded to RTP+1 port towards UAS from egress odd (RTP+1) port of SBC	RTCP is forwarded to RTP even port of UAS from egress even SBC port	RTCP is forwarded to RTP+1 port towards UAS from SBC odd port (RTP+1)
UAC realm— **sdp-ip-port** UAS realm— **disabled** Collapsed flows installed	RTCP is forwarded to RTP port of UAS via SBC egress even port	RTCP is forwarded to RTP+1 port towards UAS from egress odd (RTP+1) port of SBC	RTCP is forwarded to RTP even port of UAS from egress even SBC port	RTCP is forwarded to RTP+1 port towards UAS from SBC odd port (RTP+1)

In addition, when you enable this feature the SBC installs fully qualified NAT flows. This effectively disables latching on the IP and port within RTP media. As a result, you should not

enable this feature in conjunction with features that require explicit RTP packet based latching. For example, this feature effectively overrides dynamic-latching.

Reporting on the Feature

For UAC to UAS call when the feature is enabled on both the realms, the **show nat in-tabular** command displays the NAT flow similar to the output below. Note the assigment of port 0 in the first output below, In this case, **restricted-latching** is set to **sdp**.

```
ORACLE# show nat in-tabular
Index   Prot    Intf:Vlan  Src IP:Port                    Dst IP:Port
-------------------------------------------------------------------------------
2       udp     I=0/0:300  192.168.204.100:0        192.168.204.124:10000
                O=0/0:100  172.16.204.124:10000     172.16.204.100:11000
3       udp     I=0/0:100  172.16.204.100:0         172.16.204.124:10000
                O=0/0:300  192.168.204.124:10000    192.168.204.100:10000
```

Note the assigment of port 10000 instead of 0 in the second outut below, In this case, **restricted-latching** is set to **sdp-ip-port**.

```
ORACLE# show nat in-tabular
Index Prot    Intf:Vlan   Src IP:Port                Dst IP:Port
-------------------------------------------------------------------
2       udp   I=0/0:300  192.168.204.100:10000  192.168.204.124:10000
              O=0/0:100  172.16.204.124:10000   172.16.204.100:11000
3       udp   I=0/0:100  172.16.204.100:11000   172.16.204.124:10000
              O=0/0:300  192.168.204.124:10000  192.168.204.100:10000
```

The SBC installs these fully qualified flows on offer-answer completion, before it receives the RTP.

Call Flows Supporting Restricted Latching to Address and Port

A key problem resolved by latching on IP and port is the handling of multiple streams created by a single external device, such as an Enhanced Communications Network Application Server (ECN AS) forking an INVITE. Without this feature, the system implements restricted latching such that the latching is dependent on the external device, which may adversely impact which RTP stream (or streams) get played back to the caller.

Parallel Ringing before Answer

Consider a scenario wherein an ECN AS uses parallel forking to route a call via the SBC to several users. The ECN AS hides the multiple early dialogs from the SBC and forwards only one of them. There are, however, multiple RTP streams created from the Media Gateway (MGW) towards the SBC, one for each branch. The best way to setup such a call would result in the caller receiving only the RTP in the 18x SDP response from the ECN AS.

When you configure **restricted-latching** to **sdp-ip-port**, the SBC can also handle SDP changes, including RTP target and source. If the initial SDP becomes invalid within this forking scenario, the ECN AS would update the SBC with subsequent SDP. This update could come in an UPDATE with SDP or a new 18x with SDP, depending on the environment's support for 100rel/PRACK. The SBC would handle these changes, including changing the callee.

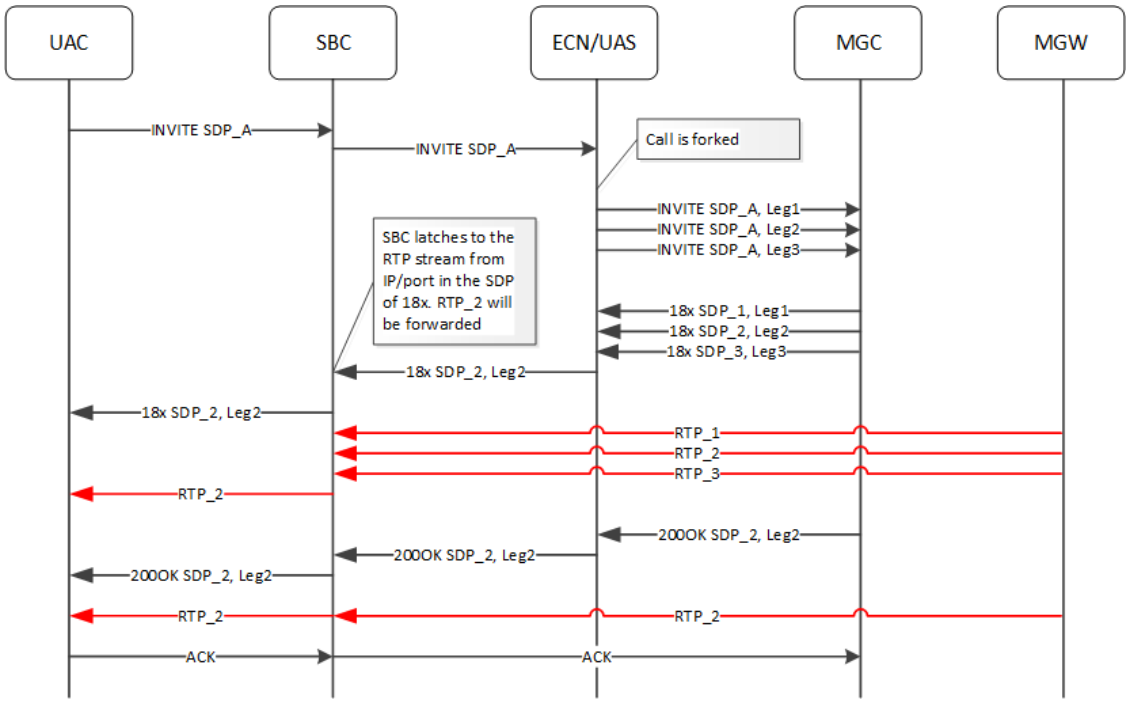
When you set **restricted-latching** to **sdp**, the system successfully blocks RTP streams from different addresses. But if there are multiple RTP streams coming from different ports on a single IP address, the system admits all of these. This can result in the calling party hearing a

mixed early media stream. When set to **sdp-ip-port**, however, the SBC latches based on the IP and port in the SDP from the ECN AS, thereby limiting the audible RTP to a single flow.

> **Note:**
>
> The AS updates the SDP only if a called party was selected during the answer phase other than the called party that was selected during alerting phase. Therefore, it is important that the SBC performs latching and re-latching based on IP address and port from the SDP. This way, the AS is also aware of which called party media stream is active.

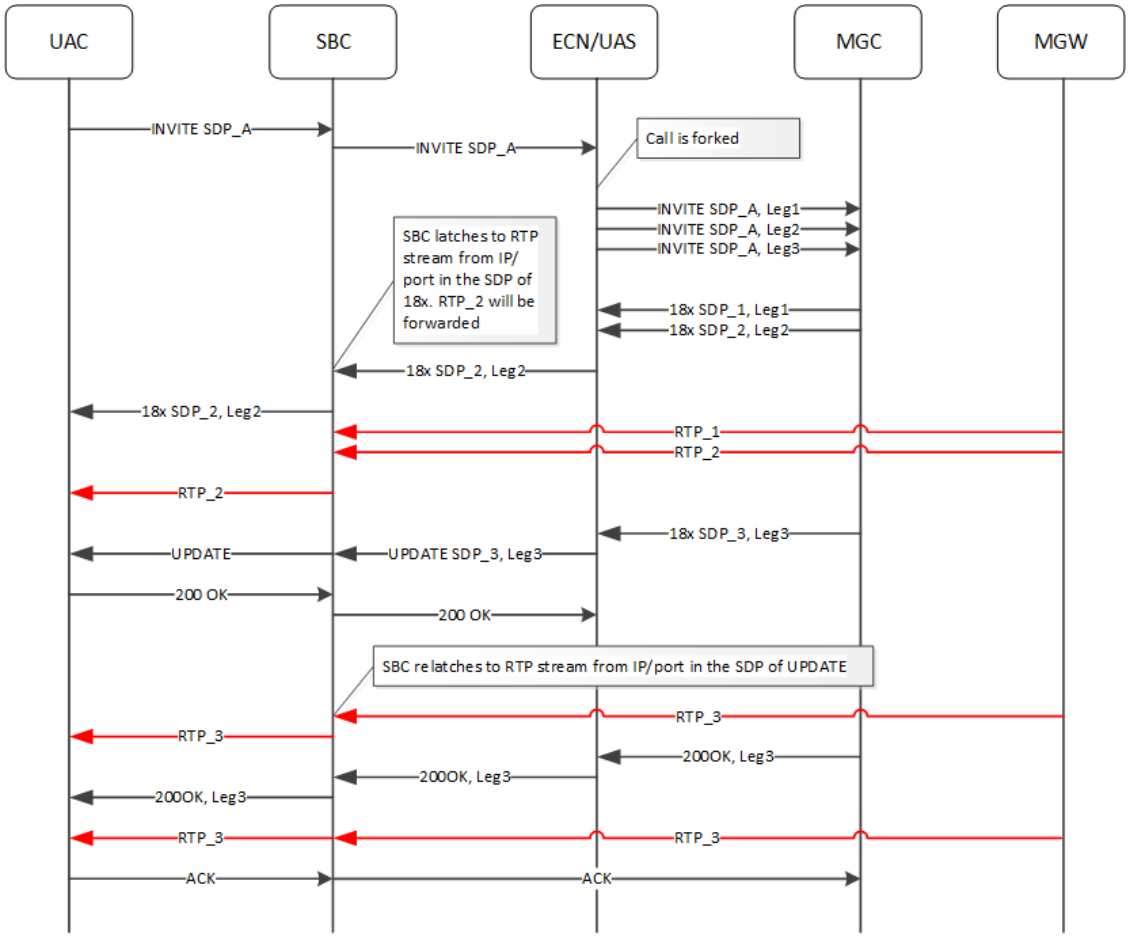
> **Note:**
>
> If the final 200 OK for the INVITE does not contain SDP, the SBC stays latched to the most recent IP/port received in a 18x during the early media stage.

In the call flow below, you have configured **restricted-latching** to **sdp-ip-port** on the UAS realm. The called stations could be behind the Media Gateway (MGW) interfacing the PSTN/PLMN) or multiple IP's, and served by a Media Gateway Controller (MGC).



Parallel Ringing and Re-Latching before Answer Based on an UPDATE

If an UPDATE comes from the ECN before the call is answered, the SBC is able to re-latch to a new RTP stream, as shown below. In the call flow, the SBC latches to SDP_2, forwarding only that RTP. The MGC, however, issues a 18x requesting SDP_3 before the call is answered. Upon receiving this UPDATE, the SBC re-latches to SDP_3. Subsequently, the call is answered and RTP_3 media proceeds without issue.



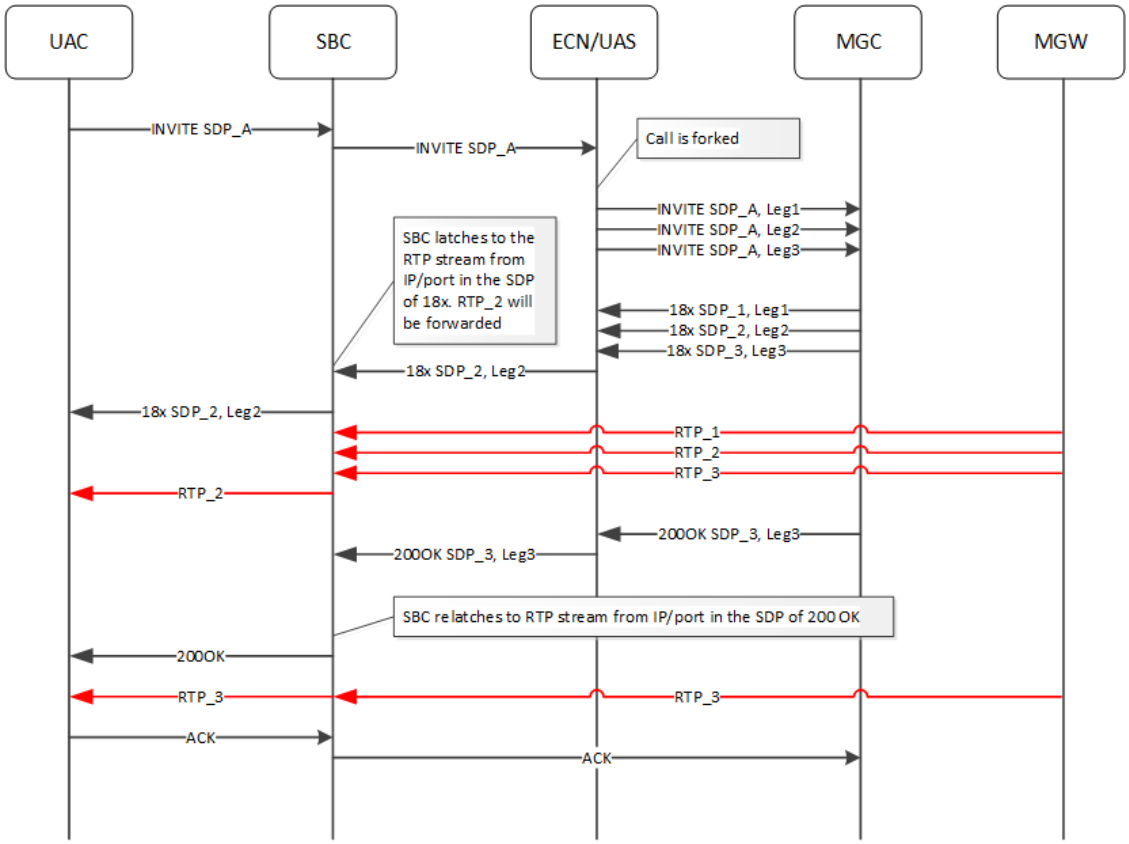
Latching during Answer

At the end of the signaling, the ECN AS sends a 200 OK that often has the SDP that the SBC must forward to the calling party. Without enhanced restricted latching, the SBC latches to the first RTP stream that arrives after the 200 OK. This RTP stream may not be the same RTP stream identified in the SDP of the 200 OK, resulting in silence at the caller.

When you set **restricted-latching** to **sdp**, the SBC admits any RTP stream from the IP in the SDP. When you set **restricted-latching** to **sdp-ip-port**, the SBC controls the latching using both IP and port received in the 200 OK SDP. This setting ensures that the correct RTP stream gets forwarded.

> **Note:**
>
> Note: If the SDP is not updated after the early media stages, the 200 OK may not include any SDP. Therefore, it is important that the AS knows the media stream onto which the SBC has latched. This requires enhanced restricted latching.

In the call flow below, you have configured **restricted-latching** to **sdp-ip-port** on the UAS realm. The called stations could be behind the Media Gateway (MGW) interfacing the PSTN/ PLMN) or multiple IP's, and served by a Media Gateway Controller (MGC).



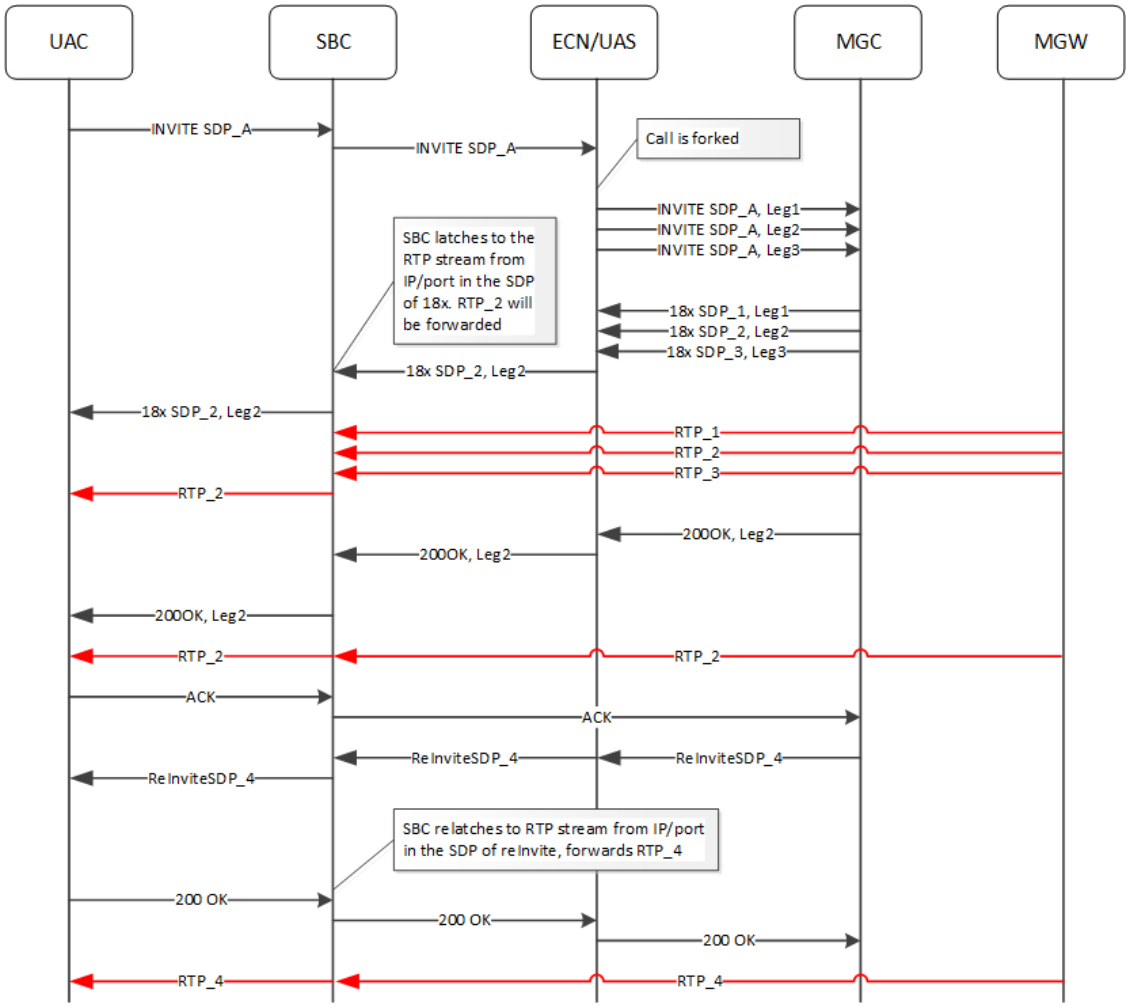
Latching after 200 OK in Case of reINVITE/UPDATE

Applicable scenarios include media re-negotiation after the call is answered are supported. These scenarios may happen when the ECN AS uses parallel forking to redirect or transfer the call after answer.

When you set **restricted-latching** to **sdp**, the SBC admits streams from the same IP, which could be multiple streams if multiple endpoints are behind the gateway. Subsequently, the SBC forwards all RTP streams it receives from, in this case, an MGW.

Depending on the calling party's client, the calling party would hear either a mix of ringback tones, silence, or a single ringback tone. When you set **restricted-latching** to **sdp-ip-port**, the SBC latches the media based on the IP and port in the reINVITE/UPDATE received after the call has been established. This results in the SBC forwarding only the RTP stream identified in the SDP from ECN AS to the calling party.

In the call flow below, you have configured **restricted-latching** to **sdp-ip-port** on the UAS realm. The called stations could be behind the Media Gateway (MGW) interfacing the PSTN/ PLMN) or multiple IP's, and served by a Media Gateway Controller (MGC).



Restricted Latching Configuration

To configure restricted latching:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Select the realm where you want to apply this feature.

```
ORACLE(realm-config)# select
identifier:
1: Acme_Realm <none>           0.0.0.0
2: H323REALM  <none>           0.0.0.0
selection:1
ORACLE(realm-config)#
```

5. **restricted-latching**— Enter the restricted latching mode. The default is **none**. The valid values are:
   - **none**—No restricted-latching used
   - **sdp**—Use the address provided in the SDP for latching
   - **peer-ip**—Use the layer 3 signaling address for latching
   - **sdp-ip-port**—Latch to media based on the IP Address received in the SDP c= connect address line, and the port in the mline in the offer and answer.
6. **restriction-mask**— Enter the number of address bits you want used for the source latched address. This field will be used only if the restricted-latching is used. The default is **32**. When this value is used, the complete IP address is matched for IPv4 addresses. The valid range is:
   - Minimum—1
   - Maximum—128

Media Release Across SIP Network Interfaces

This feature lets the Oracle Communications Session Border Controller release media between two SIP peers, between two realms on two network interfaces of the same Oracle Communications Session Border Controller. Use this feature when you want the Oracle Communications Session Border Controller to release media for specific call flows, regardless of the attached media topology.

Media Release Configuration

To configure media release across network interfaces:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **media-manager** and press Enter to access the media-level configuration elements.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. Select the realm where you want to apply this feature.

```
ORACLE(realm-config)# select
identifier:
1: Acme_Realm <none>           0.0.0.0
2: H323REALM  <none>           0.0.0.0
selection:1
ORACLE(realm-config)#
```

5. **mm-in-system**—Set this parameter to **enabled** to manage/latch/steer media in the Oracle Communications Session Border Controller. Set this parameter to **disabled** to release media in the Oracle Communications Session Border Controller.

> **Note:**
>
> Setting this parameter to disabled will cause the Oracle Communications Session Border Controller to NOT steer media through the system (no media flowing through this Oracle Communications Session Border Controller).

The default is **enabled**. The valid values are:

- enabled | disabled

Media Release Behind the Same IP Address

The media management behind the same IP feature lets the Oracle Communications Session Border Controller release media when two endpoints are behind the same IP address, in the same realm. Using this feature prevents the media for intra-site calls from going through the Oracle Communications Session Border Controller. You can use this feature for both hosted NAT traversal (HNT) and non-HNT clients. It works with NATed endpoints and for non-NATed ones that are behind the same IP.

Additional Media Management Options

Additional media management options include:

- Media directed between sources and destinations within this realm on this specific Oracle Communications Session Border Controller. Media travels through the Oracle Communications Session Border Controller rather than straight between the endpoints.
- Media directed through the Oracle Communications Session Border Controller between endpoints that are in different realms, but share the same subnet.
- For SIP only, media released between multiple Oracle Communications Session Border Controllers.
  To enable SIP distributed media release, you must set the appropriate parameter in the realm configuration. You must also set the SIP options parameter to media-release with the appropriate header name and header parameter information. This option defines how the Oracle Communications Session Border Controller encodes IPv4 address and port information for media streams described by, for example, SDP.

Configuring Media Release Behind the Same IP Address

You need to configure both the mm-in-realm and mm-same-ip parameters for the realm:

- If the mm-in-realm parameter is disabled, the mm-same-ip parameter is ignored.
- If the mm-in-realm parameter is enabled and the mm-same-ip parameter is disabled, media will be managed in the realm but released if the two endpoints are behind the same IP address.

To configure media management:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

   From this point, you can configure realm parameters. To view all realm configuration parameters, enter a **?** at the system prompt.

4. **mm-in-realm**—Enable if you plan to use **mm-same-ip**. If this parameter is disabled, the **mm-same-ip** parameter is ignored. If you set this to **enabled** and mm-same-ip to **disabled**, media is managed in the realm but released if the two endpoints are behind the same IP address. The default is **disabled**. The valid values are:
   - enabled | disabled
5. **mm-same-ip**—Enable if you want media to go through this Oracle Communications Session Border Controller, if **mm-in-realm** is **enabled**. When **disabled**, the media will not go through the Oracle Communications Session Border Controller for endpoint that are behind the same IP. The default is **enabled**. The valid values are:
   - enabled | disabled

Bandwidth CAC for Media Release

The bandwidth CAC for media release feature adds per-realm configuration that determines whether or not to include inter-realm calls in bandwidth calculations. When you use this feature, the Oracle Communications Session Border Controller's behavior is to count and subtract bandwidth from the used bandwidth for a realm when a call within a single site has its media released. When you do not enable this feature (and the Oracle Communications Session Border Controller's previous behavior), the Oracle Communications Session Border Controller does not subtract the amount of bandwidth.

In other words:

- When you enable this feature, an inter-realm media-released call will decrement the maximum bandwidth allowed in that realm with the bandwidth used for that call.
- When you disable this feature (default behavior), and inter-realm media-released call will not decrement the maximum bandwidth allowed for that call.

Bandwidth CAC Configuration

To enable bandwidth CAC for media release:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Select the realm where you want to want to add this feature.

   ```
   ORACLE(realm-config)# select
   ```

5. **bw-cac-non-mm**—Enable this parameter to turn on bandwidth CAC for media release. The default is **disabled**. The valid values are:
   - enabled | disabled
6. Save and activate your configuration.

Media Release between Endpoints with the Same IP Address

You can configure your Oracle Communications Session Border Controller to release media between two endpoints even when one of them:

- Is directly addressable at the same IP address as a NAT device, but is not behind a NAT device
- Is at the same IP address of a NAT device the other endpoint is behind

You enable this feature on a per-realm basis by setting an option in the realm configuration.

When this option is not set, theOracle Communications Session Border Controller will (when configured to do so) release media between two endpoints sharing one NAT IP address in the same realm or network.

Media Release Configuration

In order for this feature to work properly, the following conditions apply for the realm configuration:

- Either the **mm-in-realm** or the **mm-in-network** parameter must be disabled; you can have one of these enabled as long as the other is not. The new option will apply to the parameter that is disabled.
- If either the **mm-in-realm** or **mm-in-network** parameter is enabled, then the **mm-same-ip** parameter must be disabled.

To enable media release between endpoints with the same IP address:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter.

```
ORACLE(media-manager)# realm-config
```

   If you are adding support for this feature to a pre-existing realm, then you must select (using the ACLI **select** command) the realm that you want to edit.

4. **options**—Set the options parameter by typing **options**, a Space, the option name **release-media-at-same-nat** with a plus sign in front of it, and then press Enter.

```
ORACLE(realm-config)# options +release-media-at-same-nat
```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the realm configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

Media Release Behind the Same NAT IP Address

You can now configure your Oracle Communications Session Border Controller to release media between endpoints sharing the same NAT IP address, even if one endpoint is at—but not behind—the same NAT. This feature expands on the Oracle Communications Session Border Controller'S pre-existing ability to release media between calling and called parties behind the same IP address/NAT device in the same realm or network.

Media Release Configuration

For this feature to work properly, your realm configuration should either have the **mm-in-realm** or **mm-in-network** parameter set to disabled, unless the **mm-same-ip** parameter is set to disabled. If the **mm-same-ip** parameter is enabled, then **mm-in-realm** or **mm-in-network** can both be enabled.

To set the option that enables media release behind the same IP address:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

If you are adding support for this feature to a pre-existing realm, then you must select (using the ACLI **select** command) the realm that you want to edit.

4. **options**—Set the options parameter by typing **options**, a Space, the option name **release-media-at-same-nat** with a plus sign in front of it, and then press Enter.

```
ORACLE(realm-config)# options +release-media-at-same-nat
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the realm configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

Codec Reordering

Certain carriers deploy voice services where their peering partners do not use the carriers' preferred codecs. The Oracle Communications Session Border Controller can now reorder the codecs so that the preferred one is selected first.

Take the example of a carrier that deploys a voice service using G.729 rather than G.711. If that carrier has a peering partner providing call origination for the VoIP customers with G.711 used as the preferred codec, there can be issues with codec selection.

The Oracle Communications Session Border Controller resolves this issue by offering its codec reordering feature. Enabled for realms and session agents, this feature gives the Oracle Communications Session Border Controller the ability to reorder the default codec in an SDP offer to the preferred codec before it forwards the offer to the target endpoint. When you enable this feature, you increase the probability that the target endpoint will choose the preferred codec for its SDP answer, thereby avoiding use of the undesired codec.

You enable codec reordering feature by setting the preferred-codec=X (where X is the preferred codec) option in the realm and session agent configurations. You set it in the realm from which the Oracle Communications Session Border Controller receives SDP offers (in requests or responses), and for which the media format list needs to be reordered by the Oracle Communications Session Border Controller prior to being forwarded. To configure additional codec ordering support for cases when a response or request with an SDP offer is from a session agent, you can set this option in the session agent configuration.

If you enable the option, the Oracle Communications Session Border Controller examines each SDP media description before if forwards an SDP offer. And if necessary, it performs reordering of the media format list to designate that the preferred codec as the default.

The Oracle Communications Session Border Controller determines preferred codecs in the following ways:

- If the response or request with an SDP offer is from a session agent, the Oracle Communications Session Border Controller determines the preferred codec by referring to the session agent configuration. You set the preferred codec for a session agent by configuring it with the preferred-codec=X option.
- If the response or request with an SDP offer is not from a session agent or is from a session agent that does not have the preferred-codec=X option configured, the Oracle Communications Session Border Controller determines the preferred codec by referring to the preferred-codec=X option in the realm.
- If the Oracle Communications Session Border Controller cannot determine a preferred codec, it does not perform codec reordering.

The way that the Oracle Communications Session Border Controller performs codec reordering is to search for the preferred codec in the SDP offer's media description (m=) line, and designate it as the default codec (if it is not the default already). After it marks the preferred codec as the default, the Oracle Communications Session Border Controller does not perform any operation on the remaining codecs in the media format list.

> **Note:**
>
> that the Oracle Communications Session Border Controller performs codec reordering on the media format list only. If the rtpmap attribute of the preferred codec is present, the Oracle Communications Session Border Controller does not reorder it.

Preferred Codec Precedence

When you configure preferred codecs in session agents or realms, be aware that the codec you set for a session agent takes precedence over one you set for a realm. This means that if you set preferred codecs in both configurations, the one you set for the session agent will be used.

In the case where the Oracle Communications Session Border Controller does not find the session agent's preferred codec in the SDP offer's media format list, then it does not perform codec reordering even if the media format list contains the realm's preferred codec.

Codec Reordering Configuration

When you configure codec ordering, the codec you set in either the session agent or realm configuration must match the name of a media profile configuration. If your configuration does not use media profiles, then the name of the preferred codec that you set must be one of the following:

- PCMU
- G726-32
- G723
- PCMA
- G722
- G728
- G729

> **Note:**
>
> If you configure this feature for a session agent, you must configure it for the associated realm as well. Otherwise, the feature will not work correctly.

Setting a Preferred Codec for a Realm

To set a preferred codec for a realm configuration:

These instructions assume that you want to add this feature to a realm that has already been configured.

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Select the realm where you want to apply this feature.

   ```
   ORACLE(realm-config)# select
   identifier:
   1: public     media2:0         0.0.0.0
   2: private    media1:0         0.0.0.0
   selection:1
   ORACLE(realm-config)#
   ```

5. **options**—Set the **options** parameter by typing **options**, a Space, the option name preceded by a plus sign (+) (**preferred-codec=X**), and then press Enter. X is the codec that you want to set as the preferred codec.

   ```
   ORACLE(realm-config)# options +preferred-codec=PCMU
   ```

   If you type options preferred-codec=X, you will overwrite any previously configured options. In order to append the new option to the realm-config's options list, you must prepend the new option with a plus sign as shown in the previous example.

6. Save and activate your configuration.

Setting a Preferred Codec for a Session Agent

To set a preferred codec for a session agent configuration:

These instructions assume that you want to add this feature to a session agent that has already been configured.

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

4. Select the session agent where you want to apply this feature.

```
ORACLE(session-agent)# select
<hostname>:
1: acmepacket.com realm=       ip=
2: sessionAgent2  realm=tester ip=172.30.1.150
selection:
selection:1
ORACLE(session-agent)#
```

5. **options**—Set the options parameter by typing **options**, a Space, the option name preceded by a plus sign (+) (**preferred-codec=X**), and then press Enter. X is the codec that you want to set as the preferred codec.

```
ORACLE(session-agent)# options +preferred-codec=PCMU
```

If you type options preferred-codec=X, you will overwrite any previously configured options. In order to append the new option to the session agent's **options list, you must prepend the new option with a plus sign as shown in the previous example.**

6. Save and activate your configuration.

Media Profiles Per Realm

For different codecs and media types, you can set up customized media profiles that serve the following purposes:

- Police media values
- Define media bandwidth policies
- Support H.323 slow-start to fast-start interworking

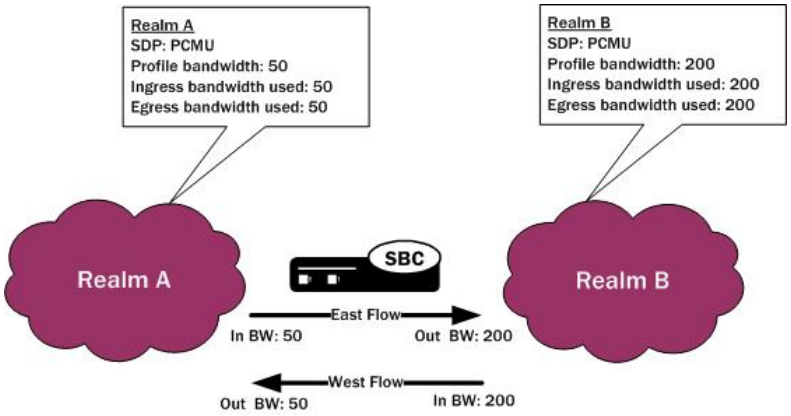
You can use media policies globally for the Oracle Communications Session Border Controller, or—starting with Release C6.1.0—you can configure them for application on a per-realm basis. For a realm, you can configure a list of media profiles you want applied. The Oracle Communications Session Border Controllermatches the value you set for the **match-media-profiles** parameter, and then applies those media profiles to the realm itself and to all of its child realms (but not to its parent realms).

> **Note:**
>
> This feature has no impact on the ways the Oracle Communications Session Border Controller uses media profiles non-realm applications such as: H.323 interfaces, SIP interfaces, IWF, session agents, codec policies, and policy attributes.

Call Admission Control and Policing

The Oracle Communications Session Border Controller supports call admission control (CAC) based on realm, and it applies the limits on either ingress or egress bandwidth counters. If a calls exceeds bandwidth on either the ingress or egress side, the Oracle Communications Session Border Controller rejects the call. You can also use per-user CAC, which limits the maximum bandwidth from the east and west flows for both the TO and FROM users.

When you apply media profiles to a realm, the Oracle Communications Session Border Controller applies bandwidth policing from the flow's ingress realm media profile. In the diagram below, the Oracle Communications Session Border Controller policies traffic for Realm A based Realm A's policing values, and the same is true for Realm B.



Media Profile Configuration

This section shows you how to configure multiple media profiles per realm, and it explains how to use wildcarding.

To reference a media profile in this list, you need to enter its name and subname values in the following format <name>::<subname>. Releases C6.1.0 and later accept the subname so you can configure multiple media profile for the same codec; the codec **name** customarily serves and the name value for a media profile configuration.

About Wildcarding

You can wildcard both portions (name and subname) of this value:

- When you wildcard the **name** portion of the value, you can provide a specific subname that the Oracle Communications Session Border Controller uses to find matching media profiles.

- When you wildcard the subname portion of the value, you can provide a specific **name** that the Oracle Communications Session Border Controller uses to find matching media profiles.

You can also enter the name value on its own, or wildcard the entire value. Leaving the subname value empty is also significant in that it allows the realm to use all media profile that have no specified **subname**. However, you cannot leave the **name** portion of the value unspecified (as all media profiles are required to have names).

Consider the examples in the following table:

Syntax	Example Value	Description
<name>	PCMU	Matches any and all media profiles with the name value configured as PCMU. This entry has the same meaning as a value with this syntax: <name>::*.
<name>::	PCMU::	Matches a media profile with the name with the name value configured as PCMU with an empty subname parameter.
<name>::<subname>	PCMU::64k	Matches a media profiles with the name with the name value configured as PCMU with the subname parameter set to 64k.
*	*	Matches anything, but does not have to be a defined media profile.
::	*::*	Matches any and all media profiles, but requires the presence of media profile configurations.
*::<subname>	*::64k	Matches all media profiles with this subname. You might have a group of media profiles with different names, but the same subname value.
*::	*::	Matches any media profiles with an empty subname parameter.
::	::	Invalid
::*	::*	Invalid

The Oracle Communications Session Border Controller performs matching for wildcarded **match-media-profiles** values last. Specific entries are applies first and take precedence. When the Oracle Communications Session Border Controller must decide between media profiles matches, it selects the first match.

To use media profiles for a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter. If you are adding this feature to a pre-existing realm configuration, you will need to select and edit your realm.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. **match-media-profiles**—In the form **<name>::<subname>**, enter the media profiles you would like applied to this realm. These values correspond to the name and subname parameters in the media profile configuration. You can wildcard either of these portions of the value, or you can leave the <subname> portion empty.

   This parameter has no default.

5. Save and activate your configuration.

Multiple Media Profiles

You can use the media profiles configuration to set up:

- One media profile for a particular SIP SDP encoding (such as G729), where the name of the profile identifies it uniquely. This behavior is your only option in Oracle Communications Session Border Controller release prior to Release C6.1.0.
- Multiple media profiles for the same SIP SDP encoding. Available in Release C6.1.0 and forward, you can create multiple media profiles for the same encoding. To do so, you add a subname to the configuration, thereby identifying it uniquely using two pieces of information rather than one.

The sections below provide two descriptions of deployments where using multiple profiles for the same codec would solve codec and packetization problems for service providers.

Use Case 1

Service Provider 1 peers with various carriers, each of which uses different packetization rates for the same codec. For example, their Peer 1 uses 10 milliseconds G.711 whereas their Peer 2 uses 30 milliseconds for the same codec. The difference in rates produces a difference in bandwidth consumption—resulting in a difference in SLA agreements and in Oracle Communications Session Border Controller call admission control (CAC) and bandwidth policing. Service Provider 1 uses the Oracle Communications Session Border Controller's media profile configuration parameters to determine CAC (**req-bandwidth**) and bandwidth policing (**avg-rate-limit**). Because this service provider's peers either do not use the SDP p-time attribute or use it inconsistently, it is difficult to account for bandwidth use. And so it is likewise difficult to set up meaningful media profiles.

The best solution for this service provider—given its traffic engineering and desire for the cleanest routing and provisioning structures possible—is to define multiple media profiles for the same codec.

Use Case 2

Service Provider 2 supports H.263 video, for which the Oracle Communications Session Border Controller offers a pre-provisioned media profile with a set bandwidth value. And yet, H.263 is not a codec that has a single bandwidth value. Instead, H.263 can have different bandwidth values that correspond to various screen resolution and quality. While it is true that the Oracle Communications Session Border Controllercan learn the requisite bandwidth value from SDP, not all SDP carries the bandwidth value nor do system operators always trust the values communicated.

Configuring multiple media profiles for the same codec (here, H.263) helps considerably with this problem—and moves closer to complete solution. Service Provider 2 can configure H.263 media profiles capable of handling the different bandwidth values that might appear.

Multiple Media Profiles Configuration

Configuring the **subname** parameter in the media profiles configuration allows you to create multiple media profiles with the same name.

To configure the subname parameter for a media profile:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **media-profile** and press Enter. If you are adding this feature to a pre-existing media profile configuration, you will need to select and edit your media profile.

   ```
   ORACLE(session-router)# media-profile
   ORACLE(media-profile)#
   ```

4. **subname**—Enter the subname value for this media profile. Information such as the rate or bandwidth value make convenient subname values. For example, you might set the **name** of the media profile as PCMU and the **subname** as 64k.

   This parameter is not require and has no default.

5. Save and activate your configuration.

Per-Realm Media Guard Timers

Oracle Communications Session Border Controller realm configurations support media guard timers whose settings take precedence over global media guard timers configured in the media manager. Both generic flow and TCP-specific flow timer settings are available. The user configures these timers in seconds in the realm-config.

Media guard timer parameters configured within a realm use the same syntax and define the same windows as the global timers. They differ in that they affect flows that traverse the realm only. Applicable timers include:

- **flow-time-limit**
- **initial-guard-timer**
- **subsq-guard-timer**
- **tcp-flow-time-limit**
- **tcp-initial-guard-timer**
- **tcp-subsq-guard-timer**

Per-realm media guard timer settings differ slightly from the global timers:

- The default value of -1 disables the realm setting, allowing the system to fall back to the global timer settings.

- A value of 0 disables the use of that type of timer for all flows traversing that realm, regardless of whether there are enabled ingress, egress or global settings.
- Timer ranges differ, as documented in the command reference.

Important operational considerations include:

- The system refers to both ingress and egress realm settings to time each flow, using the lower settings to resolve setting conflicts.
- Upon the expiry of the flow timer sequence, the Oracle Communications Session Border Controller sends a BYE that includes reason header indicating that the system has cleared the session due to media flow guard timer expiry.
- This feature interacts with guard-notify-gap in the media manager. When a flow guard timer expiry is received by MBCD, and if the required 'gap' since the last notification has not elapsed, the system queues the new notification to be sent when the required notify gap time has elapsed.

> **Note:**
>
> Media guard timers in static flow configurations are not impacted by per-realm (or global) media timers. Per-realm and global timers are for dynamic flows.

SIP Disable Media Inactivity Timer for Calls Placed on Hold

Hardware-based media flow guard timers detect when a call has lost media while it is being relayed through the Oracle Communications Session Border Controller. In response, the system tears down the call.

You can configure **disable-guard-timer-sendonly** to disable media inactivity timers for calls placed on hold. The Oracle Communications Session Border Controller disableds initial and subsequent guard timers for media when the SIP or IWF call is put on hold with a 0.0.0.0 address in:

- The c=connection line
- An a=inactive attribute
- An a=sendonly attribute

It should be noted that disabling the media inactivity timers will also disable the guard timers for calls which are not necessarily on hold, but simply are one-way audio applications.

Media Inactivity Timer Configuration

To disable the media inactivity timer for calls placed on hold:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **media-manager** and press Enter.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **media-manager-config** and press Enter.

```
ORACLE(media-manager)# media-manager-config
ORACLE(media-manager-config)#
```

4. **options**—Set the options parameter by typing **options**, a Space, the option-name **disable-guard-timer-sendonly** with a plus sign in front of it, and then press Enter.

```
ORACLE(media-manager-config)# options +disable-guard-timer-sendonly
```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the SIP interface configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

Media Manager Configuration for Virtual Machines

The SBC provides you with a means of tuning the media manager for VM deployments.

As the SBC can classify traffic for use in DoS policing, bandwidth may be reserved for certain traffic types. Reserved bandwidth is expressed as a percentage of maximum available system bandwidth. The system's maximum bandwidth is determined by the hardware configuration and the number of available signaling cores. The maximum system bandwidth is defined as the speed of ingress traffic sent to the host, measured in packets per second (PPS). It is reported in the **show platform limits** command, referring to the "Maximum Signaling rate".

The following configuration options are available in the **media-manager-config**. These options are used to configure reserved bandwidth for application signaling, and ARP, and untrusted traffic.

- **max-signaling-packets**—Set the maximum overall bandwidth available for the host path in packets per second, which includes signaling messages from trusted and untrusted sources. The maximum value for each platform is used as the default value for that platform.
  - The maximum depends on the platform, as follows:
    - Acme Packet 1100 platform: the maximum is 10,000
    - Acme Packet 3900 platform: the maximum is 40,000
    - Acme Packet 3950/4900 platform: the maximum is 110,000
    - COTs and VM platforms: the maximum is system dependent
- **min-untrusted-signaling**—The minimum percentage of maximum system bandwidth available for untrusted traffic. The rest of the bandwidth is available for trusted resources, but can also be used for untrusted sources per max-untrusted-signaling. Default: 30. Range: 1-100.
- **max-untrusted-signaling**—The percentage of the maximum signaling packets you want to make available for messages coming from untrusted sources. This is a floating highwater mark and is only available when not in use by trusted sources. Default: 100. Range:1-100.
- **tolerance-window**—The size of the window, in seconds, used to measure host access limits for measuring the invalid message rate and maximum message rate for the realm configuration. Default: 30. Range: 0-4294967295.

- **max-arp-rate**—The maximum percentage or max-signaling-packets available for ARP traffic. Default: 30. Range: 1-100.

The user can also set controls on untrusted traffic from either realm or static ACL configuration using the **untrusted-signal-threshold** parameter.

5
SIP Signaling Services

This chapter explains how to configure the Oracle Communications Session Border Controller to support Session Initiation Protocol (SIP) signaling services for hosted IP services applications. SIP is a text-based application-layer signaling protocol that creates, identifies, and terminates multimedia sessions between devices.

About the Oracle Communications Session Border Controller and SIP

This section describes the Oracle Communications Session Border Controller's support of SIP. It provides the basic information you need to understand before you configure the Oracle Communications Session Border Controller for SIP signaling.

Types of SIP Devices

There are four types of SIP devices:

- SIP user agent (UA) is an endpoint in SIP end-to-end communication. A UA is a user agent client (UAC) when it initiates a request and waits to receive a response. A UA is a user agent server (UAS) when it receives a request and generates a response. A given UA will be a UAC or a UAS depending on whether it is initiating the request or receiving the request.
- A SIP proxy (or proxy server) is an intermediary entity that acts as both a server and a client for the purpose of making requests on behalf of other clients. A proxy server's primary role is routing. Its job is to ensure that a request is sent to another entity closer to the targeted user. A proxy interprets, and if necessary, rewrites specific parts of a request message before forwarding it.
- A SIP redirect server is a UAS that generates redirect responses to requests it receives, directing the client to contact an alternate set of targets. Unlike a proxy which forwards the request to the alternate set of targets, the redirect response tells the UAC to directly contact the alternate targets.
- A SIP registrar is a server that accepts REGISTER requests and places the information it receives in those requests into the location service for the domain it handles. Proxies and redirect servers can use the information from the location service to determine the location of the targeted user.
  A redirect server and a registrar are each a special type of UA because they act as the UAS for the requests they process.

Basic Service Models

The Oracle Communications Session Border Controller operates as a back-to-back user agent (B2BUA) within the following two basic service models:

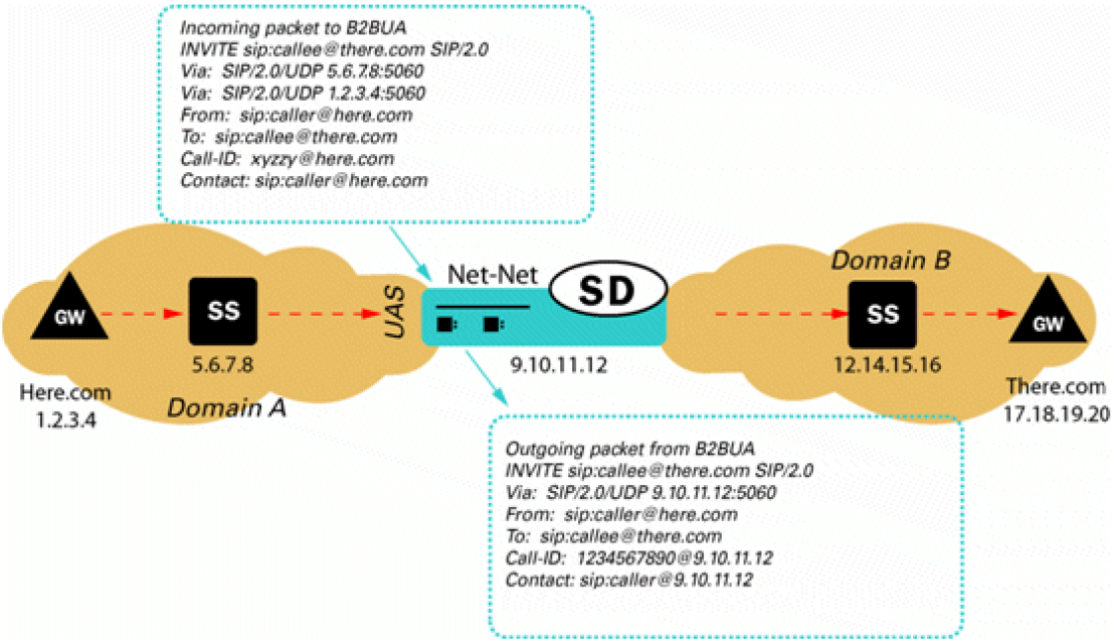
- peering
- hosted IP services

About B2BUA

A B2BUA is a logical entity that receives a request and processes it as a user agent server (UAS). In order to determine how the request should be answered, it acts as a user agent client (UAC) and generates requests. It maintains dialog state and must participate in all requests sent on the dialogs it has established.

SIP B2BUA Peering

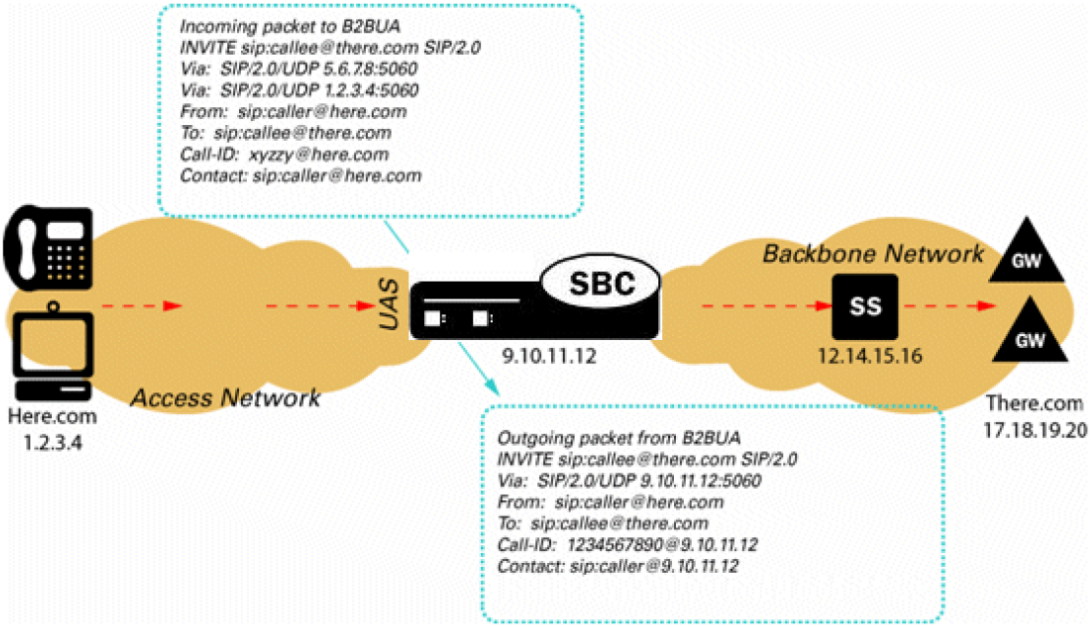
The Oracle Communications Session Border Controller operates as a SIP B2BUA. It terminates SIP sessions and re-originates them as new sessions as they are routed through the Oracle Communications Session Border Controller. For each session, it establishes NAPT translations and re-writes SDP to allow all session related media to be routed through the Oracle Communications Session Border Controller. It generates new call IDs and modifies SIP headers to prevent any protected SIP addresses and route information from being transmitted to external peers. The Oracle Communications Session Border Controller supports multiple SIP interfaces that are associated with a set of media ports, thus appearing as multiple virtual SIP gateways.



B2BUA Hosted IP Services

The Oracle Communications Session Border Controller acts as an outbound proxy for SIP endpoints and performs the operations required to allow UAs behind NATs to initiate and terminate SIP sessions (Hosted NAT Traversal).

The Oracle Communications Session Border Controller caches registration requests from SIP endpoints and forwards them to the appropriate softswitch or registrar in its backbone network. All subsequent signaling between the endpoint and the backbone network is through the Oracle Communications Session Border Controller. Also, all calling features such as caller ID, call waiting, three-way calling, and call transfer are all supported transparently through the Oracle Communications Session Border Controller.



SIP B2BUA and L3 L5 NAT

For each SIP session, the Oracle Communications Session Border Controller establishes NAPT translations and re-writes SDP to route all session related media through the Oracle Communications Session Border Controller. These actions make the Oracle Communications Session Border Controller look like a SIP gateway. Also, the Oracle Communications Session Border Controller support of multiple SIP interfaces associated with different network interfaces makes it appear as multiple virtual SIP gateways.

This functionality enables the Oracle Communications Session Border Controller to deliver VoIP services to multiple end users, across a VPN backbone.

About SIP Interfaces

The SIP interface defines the transport addresses (IP address and port) upon which the Oracle Communications Session Border Controller receives and sends SIP messages. You can define a SIP interface for each network or realm to which the Oracle Communications Session Border Controller is connected. SIP interfaces support both UDP and TCP transport, as well as multiple SIP ports (transport addresses). The SIP interface's SIP NAT function lets Hosted NAT Traversal (HNT) be used in any realm.

SIP INVITE Message Processing

When the session agent element on the softswitch side of the message flow (ingress session agent) has the gateway contact parameter configured as an option, the Oracle Communications Session Border Controller looks for the URI parameter (as defined by the gateway contact parameter) in the Request-URI and decodes the gateway address.

Example

The following example shows a SIP INVITE message from a softswitch to a Oracle Communications Session Border Controller.

```
INVITE sip:05030205555@ss-side-ext-address;gateway=encoded-gw-address
From: "Anonymous"<sip:anonymous@anonymous.invalid>;tag=xxxx
To: <sip:05030205555@ss-side-ext-address;user=phone>
```

The following example shows a SIP INVITE message from a Oracle Communications Session Border Controller to a gateway.

```
INVITE sip:05030205555@gw-ip-address SIP/2.0
From: "Anonymous"<sip:anonymous@anonymous.invalid>;tag=SDxxxx-xxxx
To: <sip:05030205555@ hostpart;user=phone>
```

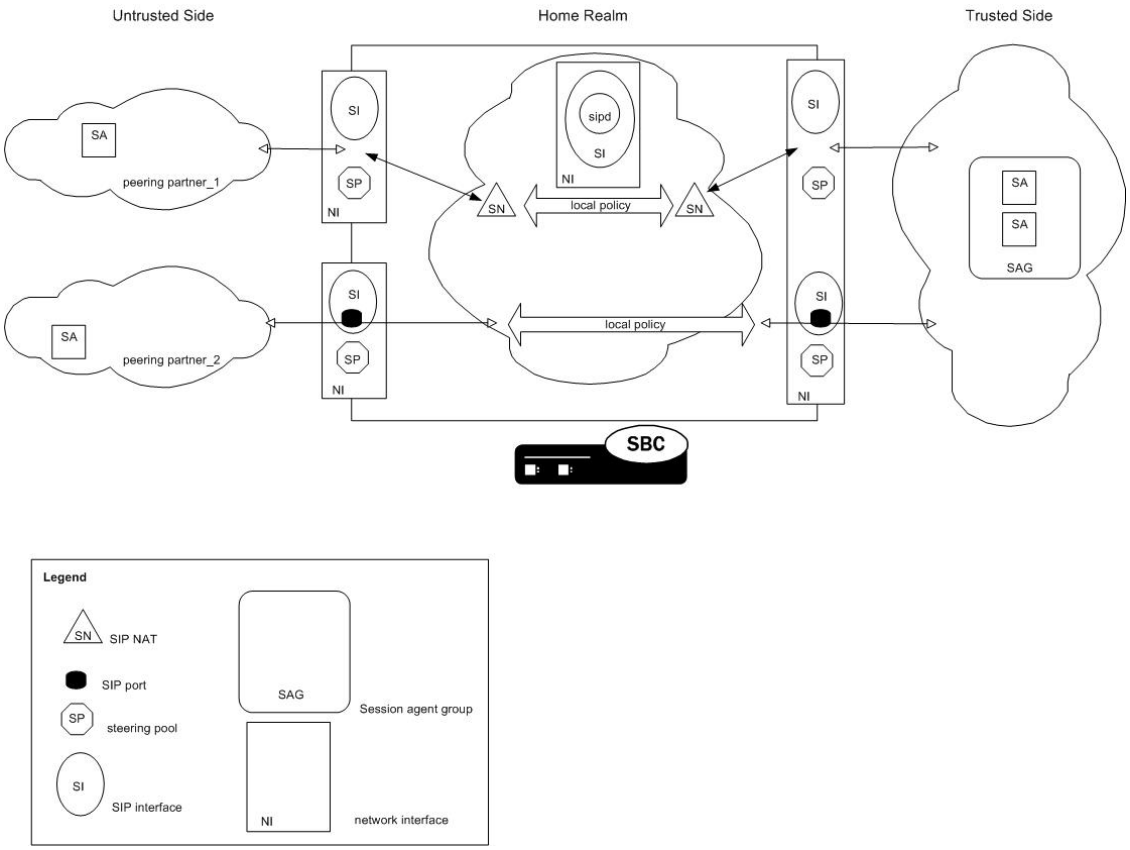
The Oracle Communications Session Border Controller converts the hostpart in the To header except in the following scenarios:

- when the original hostpart value received is an Fully Qualified Domain Name (FQDN)
- when the Oracle Communications Session Border Controller is configured not to NAT the To headers.

Oracle recommends configuring the Oracle Communications Session Border Controller to NAT the To headers to ensure the security of protected addresses. Otherwise, the outgoing hostpart is set to the SIP NAT's external proxy address for the SIP NAT's external realm.

Configuring the Oracle Communications Session Border Controller for SIP Signaling

This section contains a diagram of a B2BUA peering environment that illustrates the Oracle Communications Session Border Controller components you need to configure.



Home Realm

This section explains how to configure a home realm. The home realm applies only to a SIP configuration. It represents the internal default realm or network for the Oracle Communications Session Border Controller and is where the Oracle Communications Session Border Controller's SIP proxy is located.

Overview

You primarily use a home realm when using the SIP NAT function to connect multiple realms/networks to the Oracle Communications Session Border Controller. You define the home realm defined as either public or private for the purposes of using the SIP NAT function. If the home realm is public, all external realms are considered private. If the home realm is private, all external networks are considered public. Usually the home realm is public.

Messages are encoded (for example, the topology is hidden) when they pass from a private to a public realm. Messages are decoded when the pass from a public realm to a private realm.

These external realms/networks might have overlapping address spaces. Because SIP messages contain IP addresses, but no layer 2 identification (such as a VLAN tag), the SIP proxy must use a single global address space to prevent confusing duplicate IP addresses in SIP URIs from different realms.

SIP NAT Function

The SIP NAT function converts external addresses in SIP URIs to an internal home realm address. Usually the external address is encoded into a cookie that is added to the userinfo

portion of the URI and the external address is replaced with a home realm address unique to the SIP NAT (the SIP NAT home address).

URIs are encoded when they pass from a private realm to a public realm. When an encoded URI passes back to the realm where it originated, it is decoded (the original userinfo and host address are restored). The encoding/decoding process prevents the confusion of duplicate addresses from overlapping private addresses. It can also be used to hide the private address when a SIP message is traversing a public network. Hiding the address occurs when it is a private address; or when the owner of the private network does not want the IP addresses of their equipment exposed on a public network or on other private networks to which the Oracle Communications Session Border Controller connects.

Home Realm's Purpose

A home realm is required because the home address for SIP NATs is used to create a unique encoding of SIP NAT cookies. You can define the home realm as a network internal to the Oracle Communications Session Border Controller, which eliminates the need for an actual home network connected to the Oracle Communications Session Border Controller. You can define this virtual home network if the supply of IP addresses is limited (because each SIP NAT requires a unique home address), or if all networks to which the Oracle Communications Session Border Controller is connected must be private to hide addresses.

For example, you can define a public home realm using the loopback network (127.0.0.0) and using the home realm address prefix (for example, 127.0.0.0/8) for encoding addresses that do not match (all addresses outside 127.0.0.0/8) in SIP NAT cookies. The SIP NAT address prefix field can be used to accomplish this while keeping the ability to define an address prefix for the ream for ingress realm determination and admission control. By defining the SIP NAT address prefix as 0.0.0.0, the home realm address prefix is used to encode addresses that do not match.

Home Realm Configuration

To configure the home realm:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   From this point, you can configure SIP configuration parameters. To view all sip-config parameters, enter a **?** at the system prompt.

4. **home-realm-id**—Enter the name of the realm you want to use for the realm ID. For example, **acme**.

   The name of the realm must correspond to the identifier value you entered when you configured the realm.

5. **egress-realm-id**—Optional. Enter the egress realm ID to define the default route for SIP requests addressed to destinations outside the home realm's address prefix.

   If you enter a value for this optional field, it must correspond to the identifier value you entered when you configured the realm.

   > **Note:**
   >
   > You should leave this parameter blank for access/backbone applications. When left blank, the realm specified in the home-realm-id parameter is used by default.

6. **nat-mode**—Indicate the SIP NAT mode. The default is **none**. The valid values are:

   - **public**—Indicates the subnet defined in the addr-prefix-id field of the home realm is public and the subnet defined in the addr-prefix-id field of all external realms identified in the SIP NAT are private networks. IPv4 addresses are encoded in SIP messages received from the external realm defined by the SIP NAT. The IPv4 addresses are decoded in messages that are sent to the realm.
   - **private**—Indicates the subnet defined in the addr-prefix-id field of the home realm is private and the subnet defined in the addr-prefix-id field of all external realms identified in the SIP NAT are public networks. IPv4 addresses are encoded in SIP messages sent to the external realm defined by the SIP NAT and decoded in messages received from the realm.
   - **none**—No SIP NAT function is necessary.

     The following example shows the SIP home realm configured for a peering network.

```
sip-config
        state                           enabled
        operation-mode                  dialog
dialog-transparency        disabled
        home-realm-id                   acme
        egress-realm-id
        nat-mode                        Public
        registrar-domain
        registrar-host
        registrar-port                  0
        init-timer                      500
        max-timer                       4000
        trans-expire                    32
        invite-expire                   180
        inactive-dynamic-conn           32
        red-sip-port                    1988
        red-max-trans                   10000
        red-sync-start-time             5000
        red-sync-comp-time              1000
        last-modified-date              2005-03-19 12:41:28
```

SIP Interfaces

This section explains how to configure a SIP interface. The SIP interface defines the transport addresses (IP address and port) upon which theOracle Communications Session Border Controller receives and sends SIP messages.

Overview

The SIP interface defines the signaling interface. You can define a SIP interface for each network or realm to which the Oracle Communications Session Border Controller is connected. SIP interfaces support both UDP and TCP transport, as well as multiple SIP ports (transport addresses). The SIP interface also lets Hosted NAT Traversal (HNT) be used in any realm.

The SIP interface configuration process involves configuring the following features:

- address and transport protocols (SIP ports)
- redirect action
- proxy mode
- trust mode

About SIP Ports

A SIP port defines the transport address and protocol the Oracle Communications Session Border Controller will use for a SIP interface for the realm. A SIP interface will have one or more SIP ports to define the IP address and port upon which the Oracle Communications Session Border Controller will send and receive messages. For TCP, it defines the address and port upon which the Oracle Communications Session Border Controller will listen for inbound TCP connections for a specific realm.

You need to define at least one SIP port, on which the SIP proxy will listen for connections. If using both UDP and TCP, you must configure more than one port. For example, if a call is sent to the Oracle Communications Session Border Controller using TCP, which it needs to send out as UDP, two SIP ports are needed.

Preferred SIP Port

When a SIP interface contains multiple SIP ports of the same transport protocol, a preferred SIP port for each transport protocol is selected for outgoing requests when the specific SIP port cannot be determined. When forwarding a request that matched a cached registration entry (HNT or normal registration caching), the SIP port upon which the original REGISTER message arrived is used. Otherwise, the preferred SIP port for the selected transport protocol is used. When selecting the preferred SIP port, the default SIP port of 5060 will be selected over other non-default ports.

For SIP interfaces using the SIP NAT function, the preferred SIP port address and port will take precedence over the external address of the SIP NAT when they do not match. If both TCP and UDP SIP ports are defined, the address and port of the preferred UDP port is used.

Proxy Mode

The Oracle Communications Session Border Controller's proxy mode determines whether it forwards requests received on the SIP interface to target(s) selected from local policy; or sends a send a redirect response to the previous hop. Sending the redirect response causes the previous hop to contact the targets directly.

If the source of the request matches a session agent with a proxy mode already defined, that mode overrides the proxy mode defined in the SIP interface.

You can configure the proxy mode to use the Record-Route option. Requests for stateless and transaction operation modes are forwarded with a Record-Route header that has the Oracle

Communications Session Border Controller's addresses added. As a result, all subsequent requests are routed through the Oracle Communications Session Border Controller.

Redirect Action

The redirect action is the action the SIP proxy takes when it receives a SIP Redirect (3xx) response on the SIP interface. If the target of the request is a session agent with redirect action defined, its redirect action overrides the SIP interface's.

You can set the Oracle Communications Session Border Controllerto perform a global redirect action in response to Redirect messages. Or you can retain the default behavior where the Oracle Communications Session Border Controller sends SIP Redirect responses back to the previous hop (proxy back to the UAC) when the UAS is not a session agent.

The default behavior of the Oracle Communications Session Border Controller is to recurse on SIP Redirect responses received from the user agent server (UAS) and send a new request to the Contact headers contained in the SIP Redirect response.

Instead of this default behavior, the Oracle Communications Session Border Controller can proxy the SIP Redirect response back to the user agent client (UAC) using the value in the session agent's redirect action field (when the UAS is a session agent). If there are too many UASes to define as individual session agents or if the UASs are HNT endpoints, and SIP Redirect responses need to be proxied for UASs that are not session agents; you can set the default behavior at the SIP Interface level.

SIP maddr Resolution

Release S-C6.2.0 provides enhanced resolution of addresses found in SIP contact headers, or in the maddr (multicast address) parameter of SIP 3xx REDIRECT messages. Previous releases resolved these addresses as either a host address or as a session agent name. With Release 6.2.0 these addresses can also be resolved as session agent group (SAG) names.

Support for SAG-based resolution is provide by a new **sip-config** parameter, **sag-lookup-on-redirect**. By default, SAG lookup is disabled, providing compatibility with prior releases.

The following sample SIP REDIRECT and ACLI configuration fragment illustrate enhanced processing.

```
Status-Line: SIP/2.0 302 Moved
Message Header
Via: SIP/2.0/UDP
192.168.200.224:5060;branch=z9hG4bKa0fs40009o90sc8oo780.1
From: <sip:1111@192.168.1.222:6000>;tag=1
To: sut <sip:2223@192.168.1.224:5060>;tag=11
Call-ID: 1-28515@192.168.1.222
CSeq: 1 INVITE
Contact: <sip:1111@192.168.1.223;maddr=test.acmepacket.com>
Privacy: user;id;critical;session
P-Preferred-Identity: sipp <sip:sipp@192.168.200.222:5060>
P-Asserted-Identity: abc.com
Subject: abc
Proxy-Require: privacy,prack,abc
Content-Length: 0

session-group
        group-name                      test.acmepacket.com
        description
```

```
        state                         enabled
        app-protocol                  SIP
        strategy                      Hunt
        dest
                                      192.168.200.222
                                      192.168.200.223
...
...
```

In this case, when the Oracle Communications Session Border Controller receives the 302, it resolves the information from maddr to a SAG name. In the above example, it will resolve to the configured SAG – test.acmepacket.com. The destinations configured in SAG test.acmepacket.com will be used to route the call.

SAG-based address resolution is based on the following set of processing rules.

1. When the Contact URI does not have an maddr parameter, and the hostname is not an IP Address, the Oracle Communications Session Border Controller will look for a SAG matching the hostname.
2. When the Contact URI has an maddr parameter that contains an IP address, the Oracle Communications Session Border Controller will not look for a SAG; it will use the IP Address as the target/next-hop.
3. When the Contact URI has an maddr parameter that contains a non-IP-address value, the Oracle Communications Session Border Controller will look for a SAG matching the maddr parameter value.

   The above logic can be turned on by enabling sag-lookup-on-redirect in the sip-config object as shown below.

SIP maddr Resolution Configuration

To configure the Oracle Communications Session Border Controller to perform SAG-based maddr resolution:

1. From superuser mode, use the following command sequence to access sip-config configuration mode. While in this mode, you configure SAG-based address resolution.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# session-router
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

2. Use the **sag-lookup-on-redirect** parameter to enable SAG-based maddr resolution.
3. Use **done**, **exit**, and **verify-config** to complete SAG-based address resolution.

Trust Mode

The Oracle Communications Session Border Controller supports the Calling Identity privacy requirements based on RFC 3323 and RFC 3325. The trust mode in the SIP interface determines whether the source and destination of a request is a trusted entity. With the implementation of this feature, the Oracle Communications Session Border Controller can understand and support the privacy headers and provide the capability for anonymous packets

The Oracle Communications Session Border Controller, which acts as a boundary device between the trusted platform and the untrusted Internet, understands the following headers:

- Privacy Header
- P-Asserted-Identity Header
- P-Preferred-Identity Header

Depending on the value of these headers and the mode in which the Oracle Communications Session Border Controller is being operated (B2BUA or the proxy), the appropriate actions are performed.

About the Process

On receiving a message, the Oracle Communications Session Border Controller checks whether the message source is trusted or not. It checks the SIP interface's trust mode value and, if the source is a session agent, the session agent's trust me value. Depending on these values, the Oracle Communications Session Border Controller decides whether the request's or response's source is trusted. If it receives message from a trusted source and the message contains the P-Asserted-Identity header field, the Oracle Communications Session Border Controller passes this message to the outgoing side. The outgoing side then decides what needs to be done with this request or response.

If the request or the response is received from an untrusted source, the Privacy header value is id (privacy is requested), and the P-Asserted-Identity header field is included, the Oracle Communications Session Border Controller strips the Privacy and the P-Asserted-Identity headers and passes the request or the response to the outgoing side.

If the request or the response contains the P-Preferred-Identity header and the message source is untrusted, the Oracle Communications Session Border Controller strips the P-Preferred-Identity header from the request or the response and passes the message to the outgoing side.

If the source is trusted or privacy is not requested (the value of the Privacy Header is not id) and the request or the response contains the P-Preferred-Identity header, the Oracle Communications Session Border Controller performs the following actions:

- inserts the P-Asserted-Identity header field with the value taken from the P-Preferred-Identity header field
- deletes the P-Preferred-Identity header value
- passes this request or the response to the Outgoing side for the appropriate action, depending on the whether the destination is trusted or not

After the Oracle Communications Session Border Controller passes the request or the response to the outgoing side, it checks whether the destination is trusted by checking the SIP interface's trust mode value and the session agent's trust me value (if the destination is configured as session agent).

- The destination is trusted
  The Oracle Communications Session Border Controller does nothing with the request or the response and passes it to the destination. If the P_Asserted_Identity headers are present, they are passed to the session agent (if the destination is configured as session agent).
- The destination is untrusted
  The Oracle Communications Session Border Controller looks at the value of the Privacy header. If set to id, the Oracle Communications Session Border Controller removes all the P-Asserted-Identity headers (if present). It strips the Proxy-Require header if it is set to privacy. The Oracle Communications Session Border Controller also sets the From field of SIP header to Anonymous and strips the Privacy header.

If the Privacy header is set to none, the Oracle Communications Session Border Controller does not remove the P-Asserted-Identity header fields.

If there is no Privacy header field, the SD will not remove the P-Asserted-Identity headers.

To implement this feature, you need to configure the session agent's trust me parameter to enabled (if the message source is a session agent) and the SIP interface's trust mode to the appropriate value.

Call Duration Counters

The Oracle Communications Session Border Controller maintains aggregate call duration in seconds for the current period, lifetime total and the lifetime-period-maximum. These counters are maintained for each session agent, realm, SIP Interface, and globally across the system. The call duration counter can count up to a 32 bit value, after which time it rolls over.

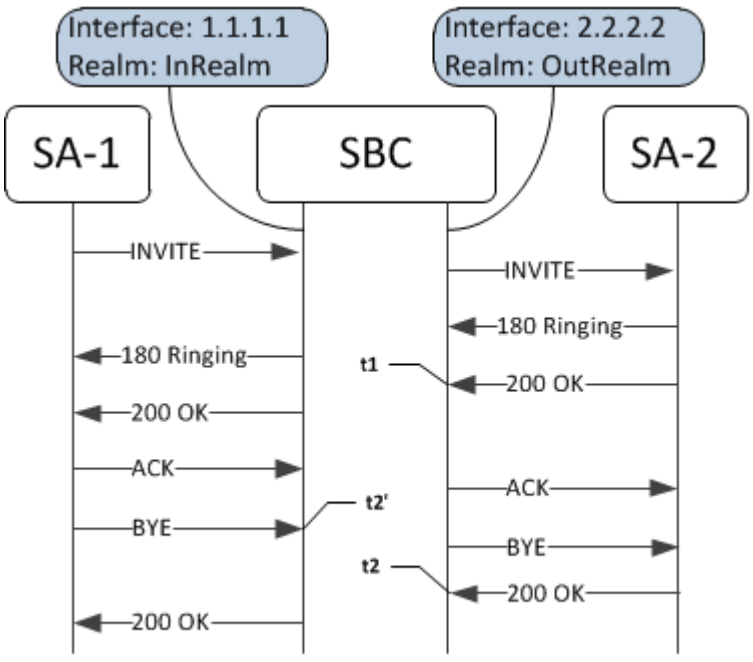
The call duration counters are displayed in the following show commands:

- show sipd agents
- show sipd realms
- show sipd interface
- show sipd status

Call Duration Calculation

Call duration is calculated as the time between (t1) when the SBC receives the 200OK for the INVITE from terminating endpoint, and (t2) the time when SBC receives the final 200OK for the BYE message from terminating endpoint, regardless of whether media is released. If the **set-disconnect-time-on-bye** parameter is enabled in the **sip-config**, then the call termination time (t2') is when the SBC receives the BYE message originally from the endpoint ending the call.

Figure 5-1 Call Duration Calculation Example - Ladder Diagram



t2' when `sip-config > set-disconnect-time-on-bye=enabled`

Table 5-1 Call Duration Calculation Example - Results

Element	Inbound Duration (sec)	Outbound Duration (sec)
Session Agent: SA-1	t2 - t1	0
Session Agent: SA-2	0	t2 - t1
Realm: InRealm	t2 - t1	0
Ream: OutRealm	0	t2 - t1
Interface: 1.1.1.1	t2 - t1	0
Interface: 2.2.2.2	0	t2 - t1

The global system call duration for the previous example is t2' - t1 seconds if the **set-disconnect-time-on-bye** parameter is enabled.

Configurable Timers and Counters

SIP timers and counters can be set in the global SIP configuration, and two can be specific for individual SIP interfaces.

You can set the expiration times for SIP messages, and you can set a counter that restricts the number of contacts that the Oracle Communications Session Border Controller tries when it receives a REDIRECT. These are similar to two parameters in the global SIP configuration, trans-expire and invite-expire. You can also set a parameter that defines how many contacts/routes the Oracle Communications Session Border Controller will attempt on redirect.

Timer to Tear Down Long Duration Calls

The Oracle Communications Session Border Controller currently provides the “flow-time-limit” timer to terminate long duration calls. However, this timer is reset whenever the Oracle Communications Session Border Controller receives a Re-INVITE or UPDATE message, even when it is provided for the session timer. This feature adds a non-resettable timer that, when enabled and upon expiration, tears down long duration calls.

When the “flow-time-limit” timer for terminating long media flow expires, the Oracle Communications Session Border Controller sends a SIP BYE or H323 Release Complete message to tear down the long call. However, this timer is reset whenever the SBC receives a Re-INVITE or UPDATE message. In most call scenarios, long duration calls are terminated with the expiration of this timer, but there are some cases where a call can stay connected for a longer duration. For example, if a user connects to an IVR service and does not hang up the phone receiver properly, there is no way for the network provider to free up the IVR resources if the user devices send session updating requests. To prevent this situation, this feature adds a new timer **session-max-life-limit**, which starts when the call or session is established and does not reset for any session update, keep-alive or SBC switchover. On expiry, the call is torn down if it’s in established state.

The new timer **session-max-life-limit** can be provisioned in the following configuration elements, in order of precedence from highest to lowest: **session-agent**, **realm-config**, **sip-interface**, and **sip-config**. Its range of values is {0-2073600} seconds with an additional special case value of “Unlimited”, which is treated as the highest possible value. The default value is 0 (no timer).

Difference between 0 and Unlimited

No timer is created when **session-max-life-limit** is configured to either the value 0 or “Unlimited”, so no timeout can occur. The difference between the two values is how they are

handled when determining which value of **session-max-life-limit** to use when there are several specified within the various configuration elements. When a session is created the timer examines both the ingress side and the egress side and, in cases where both sides have a configured value for **session-max-life-limit**, uses the side with the lower (stricter) value. On each side, the SBC reviews the configuration elements relevant to the session and uses the value of **session-max-life-limit** from the configuration element with the highest precedence (**session-agent**, then **realm-config**, then **sip-interface**, and lastly**sip-config**). When the value is set to 0, the configuration element is ignored and the next configuration element in the precedence chain is looked at. A value between 1 and 2073600 (24 days) or the value “Unlimited” is treated as a valid configured value. In this case the SBC will not move onto the next element in the precedence chain and the value is used in the final comparison between the egress and ingress values. The value “Unlimited” is viewed as the highest possible value, and therefore is considered greater than any other value it is compared against. The value 0 is skipped over and completely ignored.

For example, on the ingress side the value of **session-max-life-limit** in **realm-config** is set to 86400 and the value of **session-max-life-limit** in **session-agent** is set to "Unlimited". The **session-agent** value has a higher precedence than the **realm-config** value so, therefore, the value “Unlimited” is used for the ingress side. On the egress side the value of **session-max-life-limit** in **realm-config** is set to 43200 and the value of **session-max-life-limit** in **session-agent** is set to 0 (no timer), so the value of **session-max-life-limit** in **realm-config** is used. When compared against the ingress side the value 43200 is less than “Unlimited”; therefore, the value set for the timer is 43200.

Timer to Tear Down Long Duration Calls Configuration

Use the following procedure to configure, in the **session-agent**, **realm-config**, **sip-interface**, and **sip-config** configuration elements, a non-resettable timer that, when enabled and upon expiration, tears down long duration calls.

Although the timer occurs in four separate configuration elements, for brevity only the procedure for configuring **realm-config** is shown as the general procedure does not vary for the other configuration elements.

For the **realm-config** configuration element:

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Select the **realm-config** object to edit.

```
ORACLE(realm-config)# select
identifier:
1: realm01 left-left:0 0.0.0.0

selection: 1
ORACLE(realm-config)#
```

3. **session-max-life-limit** — Enter the maximum interval in seconds before the SBC must terminate long duration calls. The value supercedes the value of **session-max-life-limit** in the **sip-interface** and **sip-config** configuration elements and is itself superceded by the value of **session-max-life-limit** in the **session-agent** configuration element. The default value is 0 (off/ignored).

4. Type **done** to save your configuration.

Asymmetric Preconditions

This feature allows you to reserve network resources for a session before the called party is alerted by establishing preconditions for individual call legs. Currently, the Oracle Communications Session Border Controller transparently passes precondition attributes in SIP signaling and the UEs negotiate preconditions end to end. However, some networks support the SIP preconditions and other networks do not. To help provide precondition interworking between these networks, the Oracle Communications Session Border Controller supports SIP preconditions on a per call leg basis.

Some architectures require minimizing the chance of session establishment failure after alerting the called party. One source of failure is the inability to reserve network resources for a session, which can cause media clipping and "ghost rings". The solution is to allow preconditions to reserve network resources for the session before alerting the called party. A precondition is a set of constraints about the session which are introduced in the offer. The recipient of the offer generates an answer, but does not alert the user or otherwise proceed with session establishment until the preconditions are met. This can be known through a local event (such as a confirmation of a resource reservation), or through a new offer sent by the caller. The concept of preconditions is explained in RFC 3312, updated by RFC 4032, and also 3GPP TS 24.229.

The Oracle Communications Session Border Controller handles preconditions either leg by leg or transparently passes preconditions through in SDP based on the configuration. When leg by leg management is done, the SBC can behave as a UAS or a UAC. When behaving as a UAS, the SBC complies with 3GPP TS 24.229 Sections 5.1.4.1 and 6.1.3. When the parameter **asymmetric-preconditions** is enabled on the ingress interface and disabled for the egress interface at the SBC:

- The SBC does not use preconditions when the received INVITE request does not include the **precondition** option tag in the Supported or Require header fields.
- When the received INVITE request includes the **precondition** option tag in the Supported or Require header fields, the SBC uses the precondition mechanism and inserts a Require header field with the **precondition** option tag in any response including an SDP or subsequent request (also with SDP) that it sends to the originating UE during session establishment.
- When the received INVITE request includes the **100rel** and **preconditions** option tags and the SDP offer contains no precondition attributes, the equipment behaves as if the INVITE was received without an SDP. In this case the SBC just proxies the request and no preconditions interworking occurs.
- When the received INVITE request includes the **100rel** and **preconditions** option tags and there is no SDP (content) in the incoming INVITE, the SBC treats the INVITE as an offerless case and preconditions interworking occurs.
- The SBC always has resources reserved, so the value of the SDP parameter **direction-tag** in the preconditions current attribute line will always be **sendrecv** for the SDP parameter **status-type** value **local** for the SBC.

When behaving as a UAC, the SBC complies with RFC 3312 and 3GPP TS 24.229 Sections 5.1.3.1 and 6.1.2. When the parameter **asymmetric-preconditions** is enabled on the egress interface and disabled for the ingress interface, upon generating an initial INVITE request using the precondition mechanism, the SBC indicates preconditions interworking by including the precondition option tag in the Supported header field and not in the Require header.

- The SBC always has resources reserved, so the value of the SDP parameter **direction-tag** in the preconditions current attribute line will always be **sendrecv** for the SDP parameter **status-type** value **local** for the SBC.
- If the UE answers with a request for confirmation of resources, the SBC resends the UPDATE with **sendrecv** on the local preconditions for the SBC. As the SBC always confirms the preconditions in the first response or in the request it sends towards the UE, there is no need for the UE to confirm resources on the SBC.

When appropriately configured, the Oracle Communications Session Border Controller inserts SDP into an outgoing INVITE when the corresponding incoming INVITE has none. Because no SDP information is available for the session, the Oracle Communications Session Border Controller uses a media profile from a previously configured list to determine the content to insert. You cannot enable asymmetric preconditions without first enabling PRACK interworking by setting the value of **sip-interface**, **options** to **100rel-interworking**. The SBC does precondition interworking by creating SDP offers or answers before the actual ones have reached the UE; thus, transcoding policies are needed to cover the cases where different codecs are negotiated. However, in cases where different codecs are not expected, interworking works without defining codec policies. When codec policies are not defined and a final SDP answer comes with a different codec, the SBC will drop the call with 488 Not Acceptable.

To establish preconditions interworking, you must first enable it on the SIP interface with the parameter **asymmetric-preconditions** and then define when the initial offer will be sent to the endpoint that doesn't support preconditions with the parameter **asymmetric-preconditions-mode**. When the value of **asymmetric-preconditions-mode** is **send-with-nodelay**, the SBC forwards the INVITE as soon as it is received; however, it strips the **precondition** option tag from the Require and Supported header fields and also removes the preconditions related SDP. This triggers preconditions interworking on the calling side of the SBC. Responses received from the called party are queued until resource reservation is complete on the calling side. When resource reservation is complete, all buffered responses from the called party are sent to the calling party (after, if necessary, removing the SDP as in PRACK interworking) and the call proceeds as normal. When the value of **asymmetric-preconditions-mode** is **send-with-delay** on the egress, the initial INVITE forwarded to the called party is held until preconditions are met by the calling party. For offerless 18x INVITEs, that is, when the incoming INVITE has no STP, the SBC inserts the SDP, as configured in the media profile names listed in **add-sdp-profiles-in-msg**, in the 18x (183) response towards the UE.

Asymmetric Preconditions Configuration Guidelines

Set the **asymmetric-preconditions** parameter to **enabled** on any **sip-interface** that connects to networks requiring preconditions support.

> **Note:**
>
> Offer-less scenarios do not use SDP attributes to denote the use of preconditions. All such messaging uses precondition tags.

Egress	Ingress	Notes
disabled	disabled	INVALID configuration Proxy the request, no IWF

Egress	Ingress	Notes
disabled	enabled	If the INVITE has no precondition attributes, then proxy. If the INVITE has precondition tags and attributes, trigger precondition IWF. If, the egress interface has **asymmetric-preconditions-mode** set to **send-with-no delay**, the INVITE will be forwarded immediately as soon as SBC receives it. If, the egress interface has asymmetric-preconditions-mode=send-with-delay, the INVITE will be held until preconditions are complete and SBC will forward it.
enabled	disabled	If, Incoming INVITE has preconditions, then proxy, no IWF. If, Incoming INVITE has no preconditions, insert precondition tags and SDP. If response comes with precondition tag, then continue with IWF. If response has no precondition option tags, no IWF - disable the functionality and proxy.
enabled	enabled	INVALID configuration Proxy the request, no IWF

When an **INVITE** arrives with both precondition tags and precondition SDP attributes, the SBC behaves as listed below, sending the message with or without delay, based on the **asymetric-preconditions-mode** configuration on the outgoing interface.

- The SBC performs preconditions-to-nonpreconditions interworking by stripping the precondition tags and attributes and forwarding when it is configured with:
  - Incoming interface:
    - **100rel-interworking** option **enabled**
    - **asymetric-preconditions** parameter set to **enabled**
  - Outgoing interface:
    - **asymetric-preconditions** parameter set to **disabled**
- The SBC proxies the request, and does not perform interworking when it is configured with:
  - Incoming interface:
    - **100rel-interworking** option **disabled**
    - **asymetric-preconditions** parameter set to **disabled**
  - Outgoing interface:
    - **100rel-interworking** option **enabled**
    - **asymetric-preconditions** parameter set to **enabled**
- The SBC proxies the request, and does not perform interworking when it is configured with:
  - Incoming and outgoing interfaces have **asymetric-preconditions enabled**

  - Incoming and outgoing interfaces have **asymetric-preconditions disabled**

In situations when the **INVITE** arrives with no preconditions tags and no precondition SDP attributes, the SBC behaves as listed below.

- The SBC proxies the request, and does not perform interworking when it is configured with:
  - Incoming interface:
    - **100rel-interworking** option **enabled**
    - **asymetric-preconditions** parameter set to **enabled**
  - Outgoing interface:
    - **asymetric-preconditions** parameter set to **disabled**
- The SBC performs nonpreconditions-to-preconditions interworking by inserting the precondition tags and attributes and forwarding when it is configured with:
  - Incoming interface:
    - **100rel-interworking** option **disabled**
    - **asymetric-preconditions** parameter set to **disabled**
  - Outgoing interface:
    - **100rel-interworking** option **enabled**
    - **asymetric-preconditions** parameter set to **enabled**

  The SBC proxies the request, and performs no interworking when it is configured with:
  - Incoming and outgoing interfaces have **asymetric-preconditions enabled**
  - Incoming and outgoing interfaces have **asymetric-preconditions disabled**

Transcoder Free Operation for Asymmetric Preconditions

You can configure the SBC to avoid using transcoding resources while supporting call flows with asymmetric preconditions. After establishing a call that includes transcoding, the SBC can trigger this Transcoder Free Operation (TrFO) feature if the asymmetric preconditions parameter is present in the caller's SDP and a compatible codec can still be identified. Having determined that the call can proceed without transcoding, the SBC originates a reINVITE towards the calling party containing the called side codec. Once the reINVITE is completed, the call can continue without transcoding. The negotiated codec on the called party side must have been included in the calling party's original offer (after ingress codec-policy execution).

When preconditions are enabled on either the caller or callee side and disabled on the other side, the SBC is able to trigger preconditions interworking. The SBC stores all the provisional and final responses from the callee until the preconditions are met. At this point in the call flow, the negotiated codec in the 200 OK may be different than that of the calling side triggering transcoding. To avoid this transcoding, you can configure the SBC to issue a re-INVITE to the caller after call establishment with a compatible codec on the called side. The SBC initiates this re-INVITE only if the following conditions are true:

- Transcoding is induced by asymmetric preconditions
- The negotiated codec on the called side is within the allowed codecs of the calling party's initial offer

To determine whether it can send out this re-INVITE, the SBC retains the codec list sent by the calling party, usually within the initial offer with all supported codecs. It also monitors the result of the ingress **codec-policy** for compatible codecs.

Important limitations to when the SBC can use TrFO with asymmetric preconditions include:

- Although asymmetric preconditions are supported for either side of a call, the SBC only supports TrFO for the caller side. If asymmetric preconditions are applied on the called interface or on both the interfaces, thisTrFO feature does not work.
- This feature does not apply to call flows with offerless INVITEs.
- The TrFO for ringback and asymmetric preconditions features can conflict with each other. If there is a configuration wherein a session agent has ringback enabled, and TrFO for Asymmetric Preconditions is enabled on that session agent's realm, the configuration is invalid and, thisTrFO feature does not work.
- The SBC does not fully support TrFO when you configure the **feature-trfo** parameter with both **ringback** and **asymmetric-preconditions**. If you configure both **ringback** and **asymmetric-preconditions** on the ingress and egress realms, such that the system is expected to perform both functions simultaneously on opposite ends of a call, the TrFO would be applicable only to one of the features.

Configuration

This functionality requires that you configure the EVS WB media profile. In addition, you must configure the initial INVITE ingress realm with the **feature-trfo** parameter using the syntax below.

```
ORACLE(realm-config)# feature-trfo asymmetric-preconditions
```

Under the conditions described in this section, this configuration allows the SBC to force SDP re-negotiation and prevents the call from requiring transcoding.

As mentioned above, although you can configure the **feature-trfo** parameter with multiple parameters, the SBC only acts on one of those parameters at any give time. Under the condition where more than one parameter applies, the SBC refers to your configuration's parameter order to determine which function to perform:

- If the configuration order appear with ringback first, the SBC applie TrFO for ringback. (**feature-trfo : ringback,asymmetric preconditions**).
- If the configuration order appear with asymmetric preconditions first, the SBC applie TrFO for asymmetric preconditions. (**feature-trfo : asymmetric preconditions, ringback**).

TrFO Statistics for Asymmetric Preconditions

The **show sipd preconditions-trfo** command shows Asymmetric Preconditions TrFO statistics:

- Initiated: number of initiated TRFO reINVITE transactions
- Success: number of successfully completed TRFO reINVITE transactions
- Failure: number of failed TRFO reINVITE transactions (either error returned or timed out)

```
ORACLE# show sipd preconditions-trfo
 Asymmetric Preconditions TrFO statistics (2011-09-24 12:03:37.051)
             ---- Lifetime ----
            Recent Total PerMax
 Initiated    0      3      2
 Success      0      3      2
 Failure      0      0      0
```

You can reset this data back to zero using the **reset sipd** command.

Asymmetric Preconditions and EVS using Super Wide-band

The SBC supports transcoding the EVS codec, but not when the bandwidth presented is SWB, NB-SWB, or WB-SWB. When presented with these within asymmetric preconditions call flows, the SBC performs an "internal transcode" using the EVS WB instead of the EVS-SWB codec. This works because a UE that supports EVS-SWB also supports EVS-WB. The SBC performs this function for asymmetric preconditions call flows only.

To support EVS-SWB for within an asymmetric precondition call flow, the SBC monitors initial INVITEs for the EVS codec with SWB in the offer/answer SDP. If present, the system maps the bandwidth parameter from SWB to WB/NB and updates the media flows. Once media flows are updated, and before sending out the request/response, the SBC uses the original offer to compare and revert the bandwidth parameter back to support the caller or callee.

The SBC performs this mapping when triggered by the caller or callee. This could be the initial INVITE from the caller as well as the 200 OK from the callee. Internally, the SBC maps these to evs-wb and, before sending out the request or response, replaces them with evs-swb, in accordance with the stored offer.

Supported methods include INVITE, UPDATE and PRACK within the context of asymmetric preconditions call flow. The system maps EVS-SWB bandwidth as follows:

- bw=nb-swb mapped to bw=nb-wb
- bw=wb-swb mapped to bw=wb
- bw=swb mapped to bw=wb

You configure this behavior with the following, in addition to the TrFo configuration.

```
ORACLE(sip-config)# asymm-preconditions-evs-swb-support enabled
```

Important considerations while deploying this feature include:

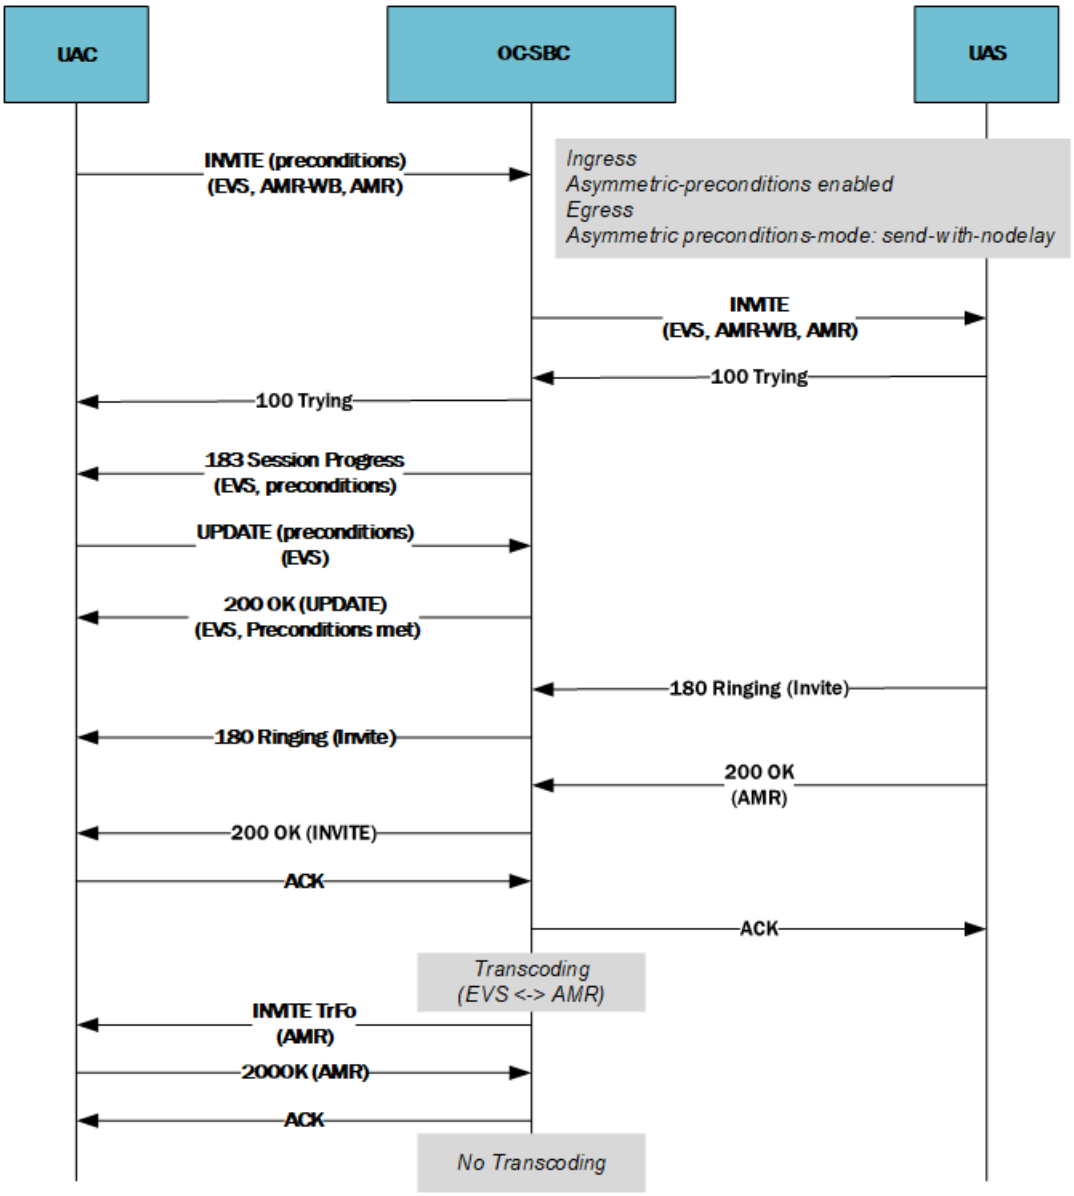
- The SBC does not support EVS-SWB within codec policy, because it does not encode EVS-SWB packets.
- If the environment changes the codec's payload type before forwarding the request, the SBC still tries to negotiate using wideband bandwidth. This is because , while reverting the bw parameter, the SBC continues to use the original SDP, performing the inherent operation by referring to the payload type.
- If and end-station issues EVS-SWB within a re-INVITE, such as when the caller rejects the TrFO re-INVITE, the SBC does not perform this mapping function. The SBC only negotiates preconditions before the call is established, and clears them after it receives the final response for the INVITE.

Call Flows for Asymmetric Preconditions TrFo

The image below depicts the SBC performing TrFo with asymmetric preconditions, wherein the egress mode is **send-with-nodelay**.

1. The UAC issues an invite with SDP that offers EVS, AMR-WB and AMR.
2. The SBC, supporting asymmetric preconditions, forwards this list to the UAS, per SBC configuration. Note the use of the**send-with-nodelay** mode causes the SBC to immediately send the INVITE.
3. The SBC proceeds with confirming preconditions with the UAC.

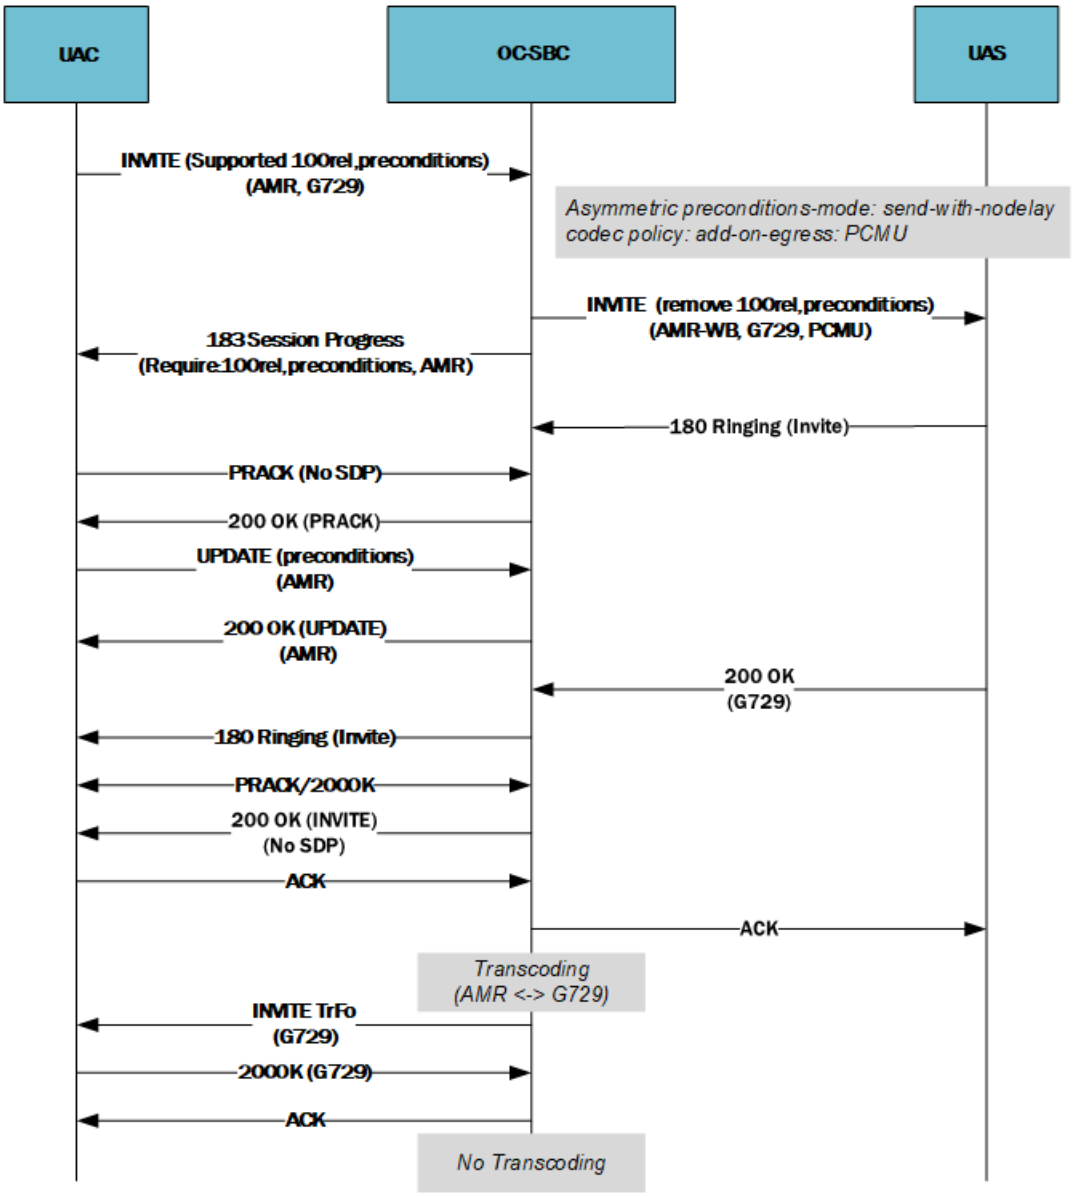
4. In the meantime, the UAS proceeds with agreeing to the call using AMR.
5. The UAC and SBC confirm the call with transcoding.
6. Immediately after confirming the call, the SBC triggers its TrFO function, changing the agreed upon codec to AMR with the UAC.
7. The call proceeds without transcoding (TrFo).



The image below depicts the SBC performing TrFo with asymmetric preconditions and PRACK interworking, wherein the egress mode is **send-with-nodelay**.

1. The UAC issues an invite with SDP that offers AMR and G729.
2. The SBC, supporting asymmetric preconditions, forwards this list to the UAS, per SBC configuration. Note the use of the **send-with-nodelay** mode causes the SBC to immediately send the INVITE.
3. The SBC proceeds with confirming preconditions with the UAC. This process specifies AMR as the codec agreed upon by the UAC and the SBC.
4. In the meantime, the UAS proceeds with agreeing to the call using G729.

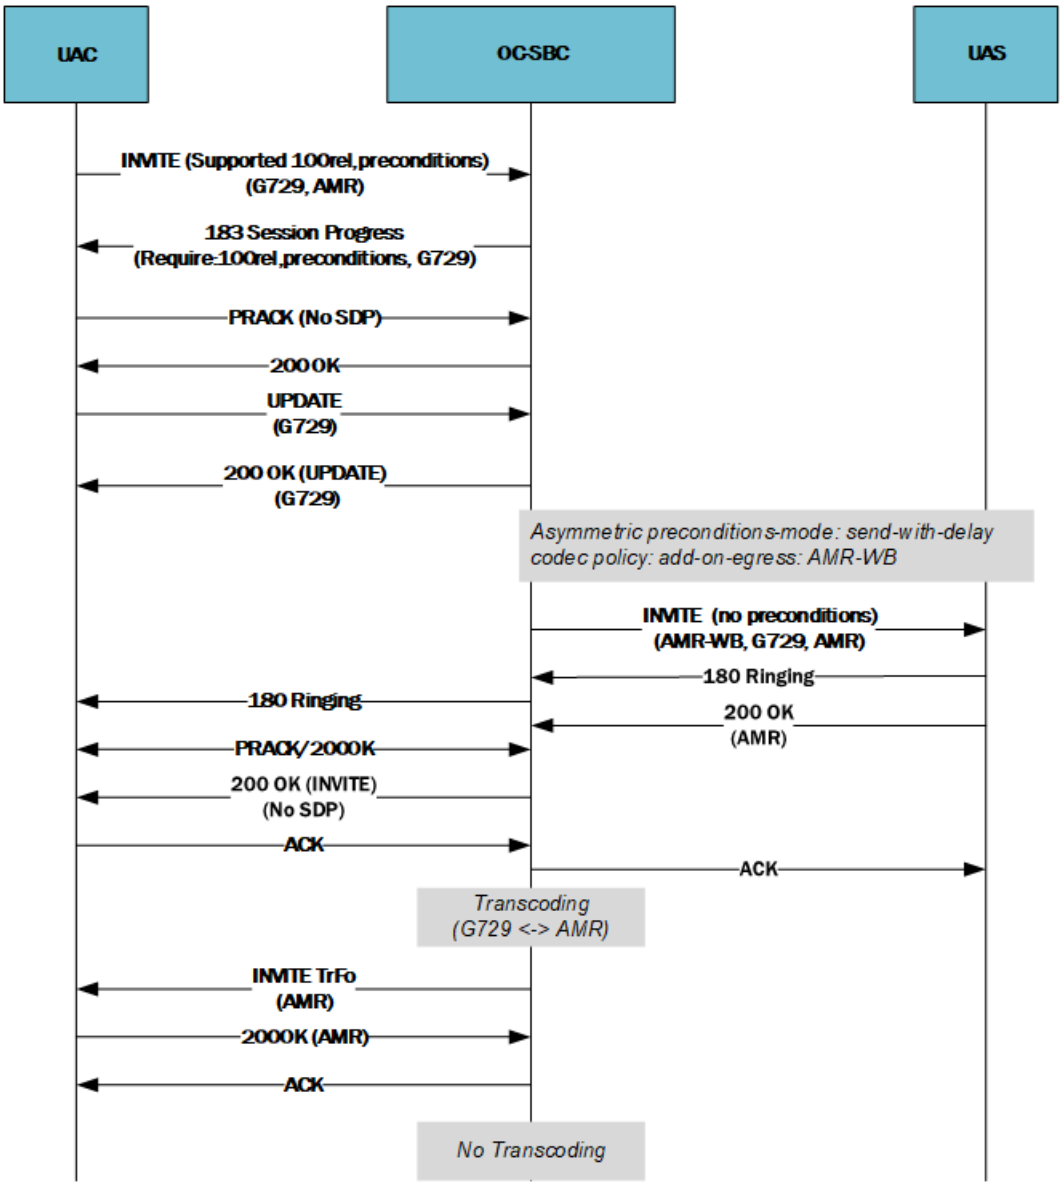
5. The UAC and SBC confirm the call with transcoding.
6. Immediately after confirming the call, the SBC triggers its TrFO function, changing the agreed upon codec to G729 with the UAC.
7. The call proceeds without transcoding (TrFo).



The image below depicts the SBC performing TrFo with asymmetric preconditions, wherein the egress mode is **send-with-delay**.

1. The UAC issues an invite with SDP that offers AMR and G729.
2. The SBC, supporting asymmetric preconditions, forwards this list to the UAS, per SBC configuration. Note the use of the **send-with-delay** mode causes the SBC to hold the INVITE.
3. The SBC proceeds with confirming preconditions with the UAC. This process specifies G729 as the codec agreed upon by the UAC and the SBC.
4. After establishing preconditions and agreeing the G729 with the UAC, the SBC forwards the INVITE.

5. The UAS proceeds with agreeing to the call using AMR.
6. The UAC and SBC confirm the call with transcoding.
7. Immediately after confirming the call, the SBC triggers its TrFO function, changing the agreed upon codec to AMR with the UAC.
8. The call proceeds without transcoding (TrFo).

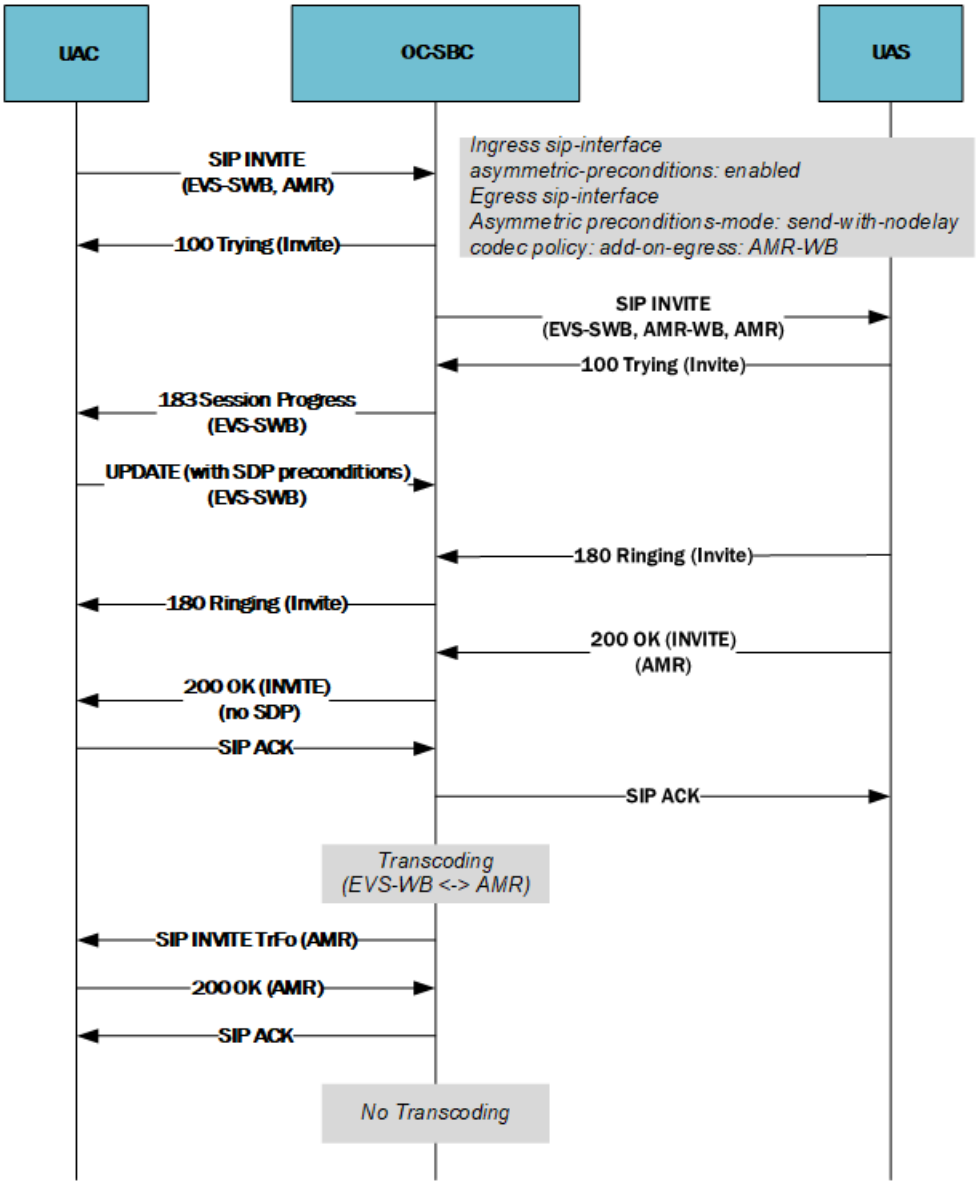


The image below depicts the SBC performing a simple TrFo process for a call flow with asymmetric preconditions. In addition, you have enabled the **asymm-preconditions-evs-swb-support** parameter in the **sip-config**.

1. The UAC issues an invite with SDP that offers EVS-SWB and AMR. The SBC, supporting asymmetric preconditions, forwards to the UAS adding AMR-WB to the offered list, per SBC configuration.
2. The UAS continues with the call while the SBC exchanges an UPDATE with the UAC.
3. As the UAS proceeds with accepting the call using AMR, the SBC reverts from EVS-SWB to EVS-WB and proceeds with the call using transcoding. Note the enabled **asymm-**

preconditions-evs-swb-support parameter allows the SBC to use EVS wideband instead of super-wideband without transcoding.

4. The SBC recognizes AMS as an option and issues a re-INVITE, as described, the establish the leg using AMR.
5. Once the leg is confirmed for AMR, the call proceeds without transcoding (TrFo).



Dynamic Preconditions

You can configure the SBC to extend its support of preconditions with dynamic preconditions, which allows the SBC to determine whether and where to support preconditions for a given call. Assuming proper configuration, the SBC refers to the INVITE from the caller and the 18x response to the initial INVITE from the callee. The INVITE informs the system on preconditions support within the caller's network. The 183 response informs the SBC whether the callee supports preconditions. The information in these messages trigger the system to support end-to-end, asymmetric, or no preconditions for a given call.

You configure the system to support dynamic preconditions by:

- Enabling the **precondition-enhancement** parameter within the **sip-config**
- Setting the **asymmetric-preconditions-mode** parameter on the called side **sip-interface** to **send-without-delay**
- Enabling **asymmetric-preconditions** on the **sip-interface** for both call legs
- Enabling the **100rel-interworking** option on the **sip-interface** for both call legs

With dynamic preconditions configured, the system is able to establish:

- End-to-end preconditions support, wherein the SBC transparently passes preconditions values between the caller and callee. In this case, the end stations perform preconditions negotiation with each other.
- Leg-by-leg preconditions, wherein one side of the call requests preconditions and the other side does not. In this case, the SBC performs preconditions negotiation with the side that supports it, and performs preconditions interworking for the call. This effectively establishes an asymmetric preconditions call flow.
  For asymmetric preconditions, the SBC performs preconditions interworking by stripping out preconditions information before forwarding the applicable message(s) to the unsupported side.

The SBC recognizes the attempt to establish preconditions by:

- The caller - based on the presence or absence of the preconditions tag in the initial INVITE.
- The callee - based on the presence or absence of the preconditions tag in the 183 Progress message.

The SBC always supports any preconditions requested by an end station. This means that preconditions negotiation within asymmetric preconditions call flows between the SBC and an end station consists of the SBC agreeing to all preconditions.

> **Note:**
>
> For cases involving an offer-less INVITE from the caller, meaning the INVITE includes the 100rel and preconditions option tags but no SDP, the system relays preconditions to the caller if the callee supports them and adds preconditions towards the caller if the callee does not support them.

Whenever the calling party (UAC) supports preconditions, it includes a preconditions tag in the INVITE to the SBC. If not, there is no tag. Regardless of the calling party's preconditions status, the SBC forwards the INVITE to the called party (UAS) with a preconditions tag in all cases where you have configured dynamic preconditions:

- When the Called party (UAS) supports preconditions, and:
  - The Calling party supports preconditions, then after the SBC forwards its INVITE:
    1. The UAS send 18x with preconditions to the SBC
    2. The SBC PROXIES the received messages
  - The Calling party does not support preconditions, then after the SBC forwards its INVITE:
    1. The UAS sends a 18x with preconditions to the SBC
    2. The SBC performs precondition negotiation towards the UAS
- When the Called party (UAS) does not support preconditions, and:

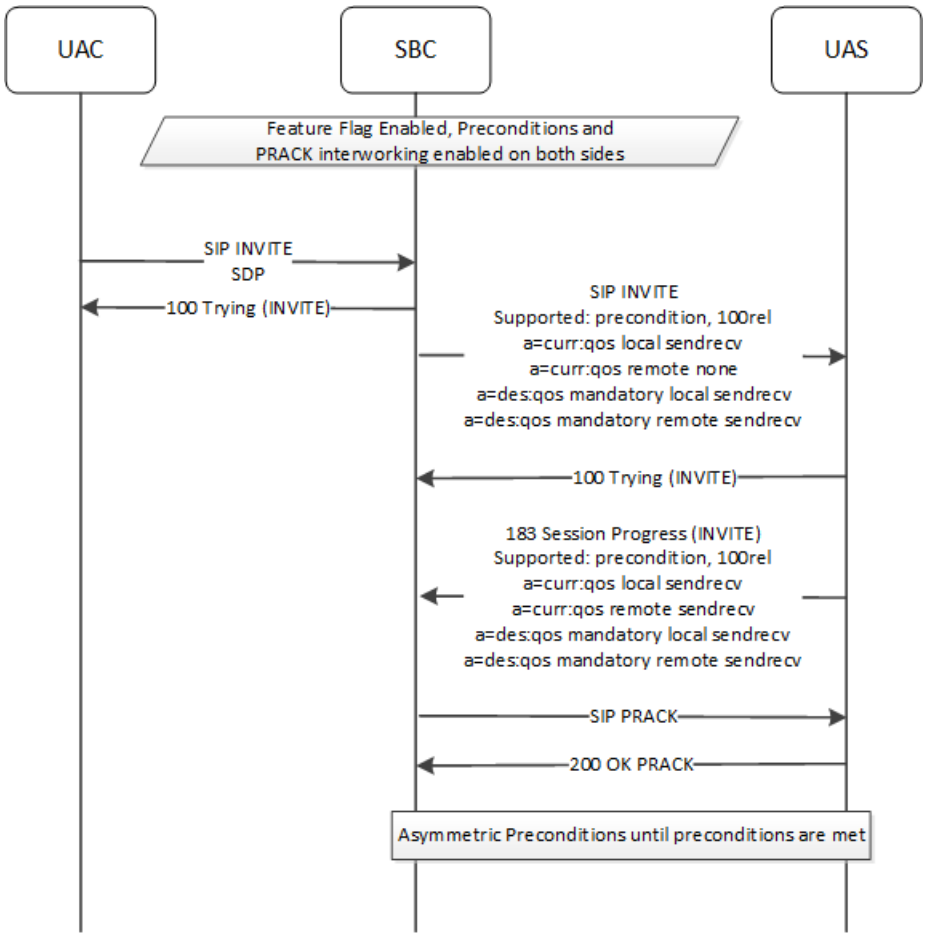
- The Calling party supports preconditions, then after the SBC sends its INVITE:
  1. The UAS sends a 18x without preconditions to the SBC
  2. The SBC performs precondition negotiation towards the UAC
- The Calling party does not support preconditions, then after the SBC adds preconditions attributes and forwards its INVITE:
  1. The UAS sends a 18x without preconditions to the SBC
  2. The SBC PROXIES the received messages

Dynamic Preconditions Call Flows

Key call flows for understanding SBC operation within dynamic preconditions contexts include depicting the calling and called network either supporting or not supporting preconditions. For all flows, the SBC has the required configuration for dynamic preconditions set on both sides of the call.

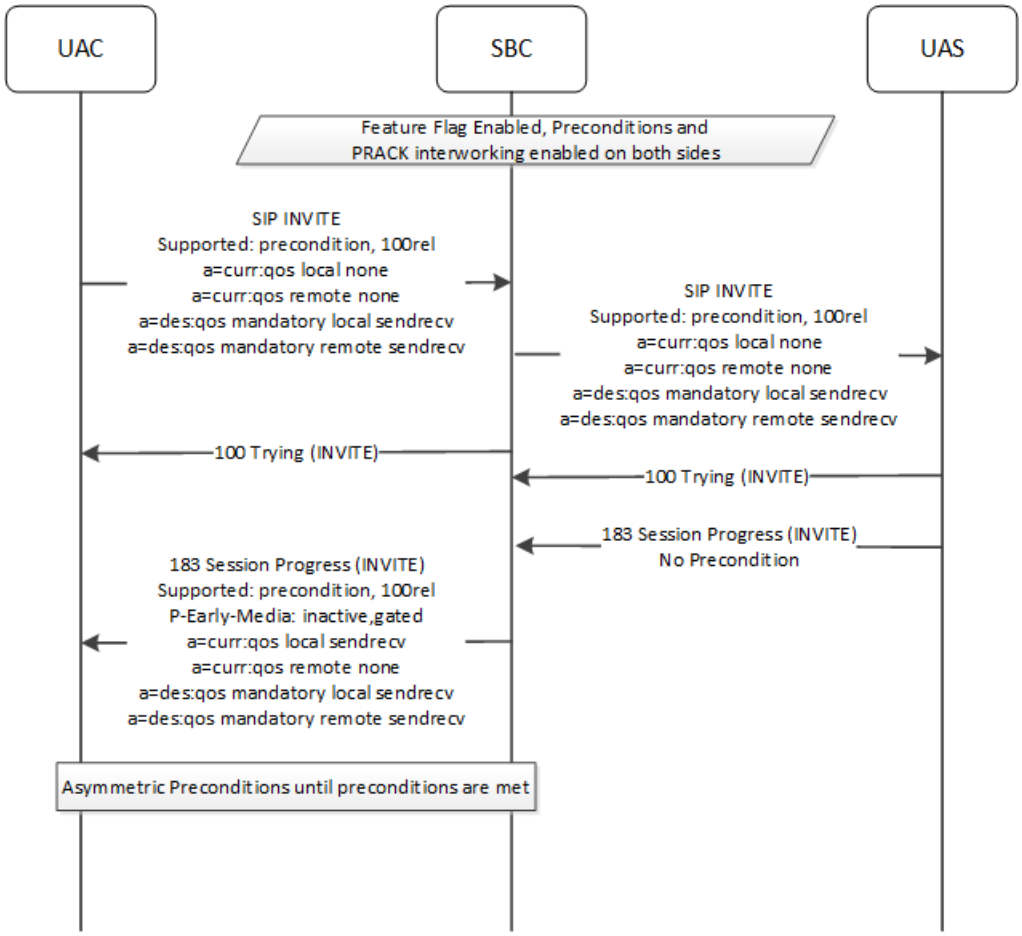
Calling Network Does Not Support Preconditions - Called Network Does

In this flow, the UAC sends an INVITE towards the SBC that does not specify preconditions. Because the system has dynamic preconditions configured on both sides, it offers preconditions to the UAS. The UAS accepts and the system establishes asymmetric preconditions for the flow.



Called Network Does Not Support Preconditions - Calling Network Does

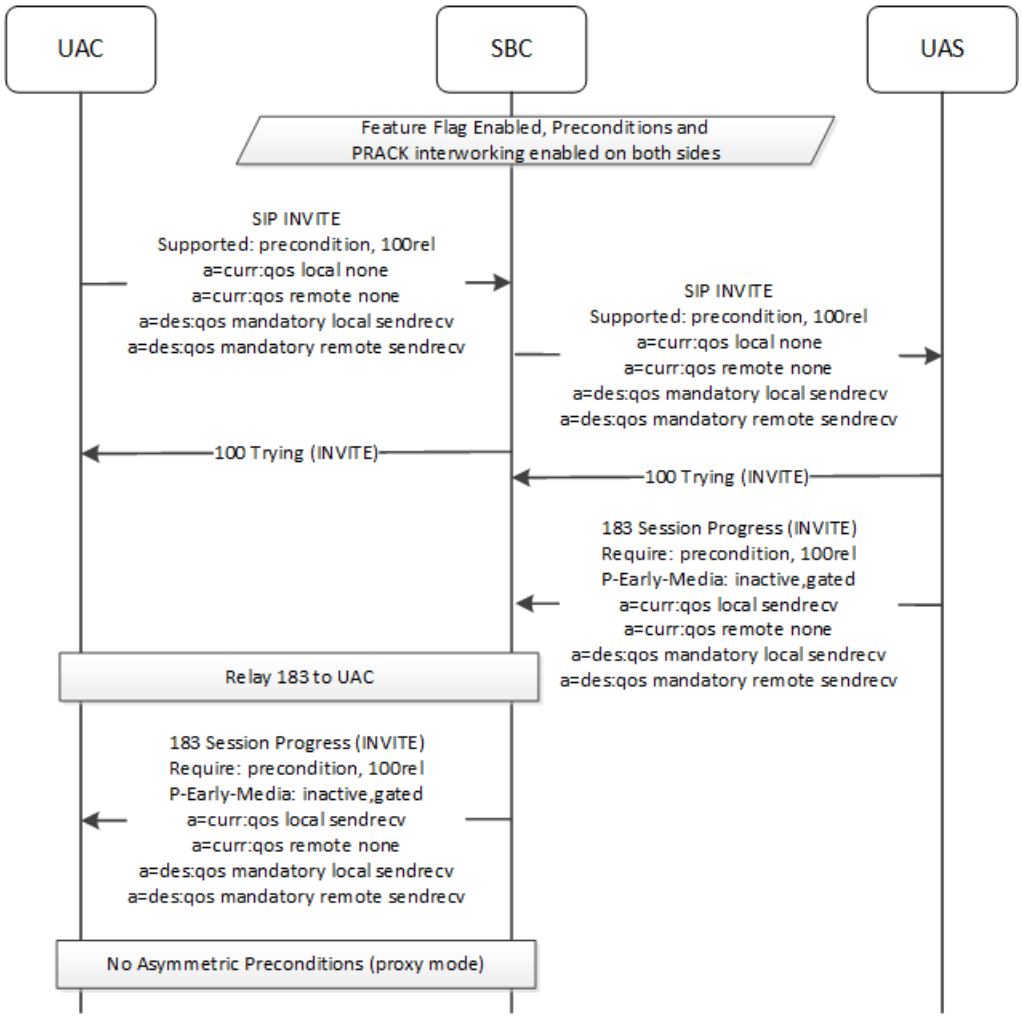
In this flow, the caller's network supports preconditions, so the caller presents its preconditions request within the initial INVITE. Because the UAC's side includes dynamic preconditions, the SBC sends an INVITE specifying the desired parameters. The UAS responds with a 183 that does not include preconditions, which signals to the SBC that there is no support in that network. Given the UAC has requested preconditions, the SBC complies and sets up the flow for asymmetric preconditions.



> **Note:**
>
> Notice that the SBC includes early media gated. This is a result of the behavior wherein the SBC inserts the inactive early media direction attribute, as described below.

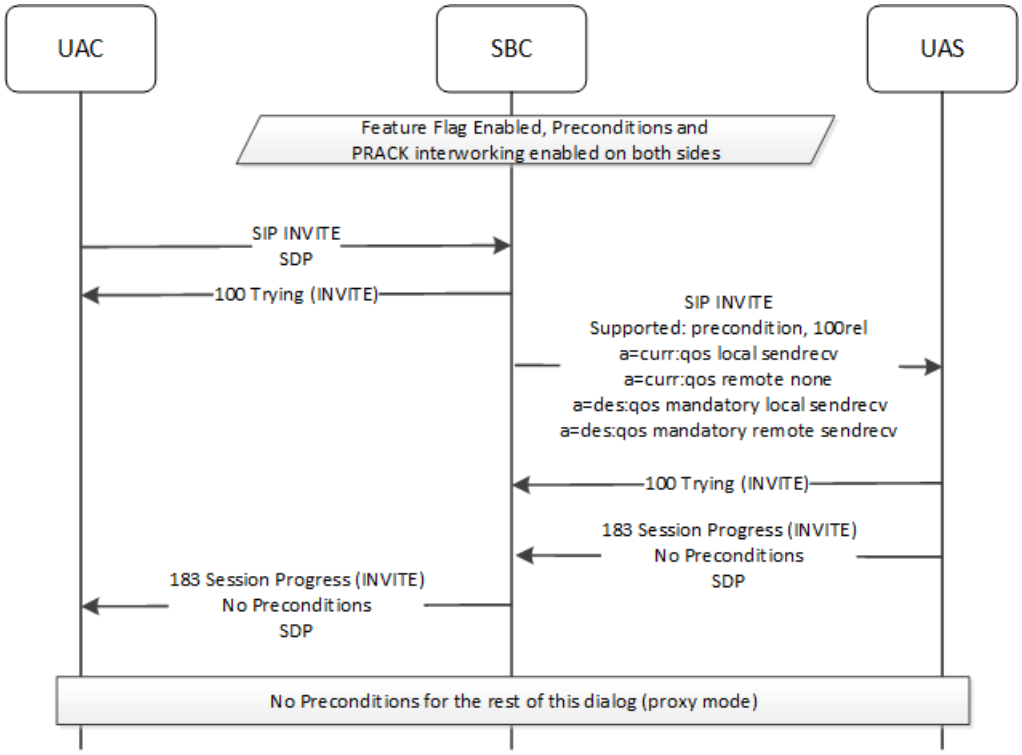
Both Calling and Called Network Supports Preconditions

Both networks in this next flow support preconditions. As described earlier, the SBC recognizes this by the presence of preconditions in the INVITE from the UAC and the 183 from the UAS. As described above, when both network sides of a call support preconditions, the SBC acts as proxy for preconditions, in the case below, by simply forwarding the 183 from the UAS to the UAC (proxy mode).



Neither Calling or Called Network Supports Preconditions

In this flow, the UAC sends an INVITE towards the SBC that does not specify preconditions. Because the system has dynamic preconditions configured on both sides, it offers preconditions to the UAS. The UAS network, however also does not support preconditions, so the system establishes the flow without preconditions on either side.



Early Media Gating using Locally Generated 183

When you enable the **precondition-enhancement** parameter within the **sip-config**, the SBC can manipulate the PEM header within both static asymmetric and dynamic preconditions call flows to change the direction attributes.

Within asymmetric preconditions flows, the SBC by default replies to the calling party's initial INVITE with a "183 Session Progress" response that includes SDP with preconditions and a PEM header set to sendrecv. This can be mistakenly interpreted by the calling party and intermediary nodes as an indication of early media. When you enable the **precondition-enhancement** parameter, the SBC sets the level of early-media authorization in the PEM header in this and other responses to a value less likely to be misinterpreted.

This behavior differs if the preconditions flows are static asymmetric or dynamic:

- When static, the SBC generates the applicable 183 message to the caller independently.
- When dynamic, the SBC refers to the callee's 183 response before it generates its own, applicable 183 to the caller.

In addition to requiring the **precondition-enhancement** configuration, this feature also refers to **p-early-media-direction** parameter on the **sip-interface** facing the calling party.

Applicable preconditions configurations include:

- Static Asymmetric Preconditions—when the calling party supports preconditions, the SBC sets the PEM header in the 183 response it generates towards the calling party to:
  - “inactive”, if **p-early-media-direction** is not configured
  - The configured value, if **p-early-media-direction** is configured
- Dynamic Preconditions—When the calling party supports preconditions but the called party does not, the SBC sets the PEM header in its 183 response to the calling party based on whether the response from the called party includes a PEM header:

- If not, the SBC sets the PEM value in its 183 response towards the calling party to:
  - “inactive”, if **p-early-media-direction** is not configured
  - The configured value, if **p-early-media-direction** is configured
- If so, the SBC sets the PEM value its 183 response towards the calling party as described in the tables below.

The tables below present the logic the SBC uses to set the PEM header in locally generated 183 based on various configurations.

The table below maps PEM with preconditions settings within flows from a trusted caller to a trusted callee.

Message Parameters configured on egress interface	**Precondition Ingress Interface**	**Precondition Egress Interface**	**Response (18x) w/o PEM header**	**Response (18x) with PEM header with one or more direction parameters where each has one of the values: "sendrecv", "sendonly", “recvonly", or "inactive"**
p-early-media-header: "add/ modify" **p-early-media-direction**: "sendonly"	Enabled	Enabled	modify or add: Populate PEM Header with configured PEM direction at egress interface. Changing the Media Direction Attribute

When you enable the **precondition-enhancement** parameter within the **sip-config**, system behavior changes for certain preconditions call flows wherein the SBC changes the direction value of the SDP media attribute to prevent issues.

Direction value changes, based on scenario include:

- For static asymmetric preconditions flows with mode set to **send-without-delay** or dynamic preconditions flows, the SBC sets the SDP direction attribute to sendrecv in the outgoing initial INVITE if the initial INVITE from the calling party has the direction attribute set to inactive.
  This ensures that the call does not remain inactive on the callee side.
- For dynamic preconditions flows where the calling party supports preconditions but the called party does not, the SBC sets the direction attribute to “inactive” when it generates a 183 response locally towards the calling party.

These behaviors allow you to avoid the use of HMR to change the direction attribute in the SDP at both the media and session level.

Strength Tag Support

By default, the SBC rejects calls that include optional preconditions tags, and it does not insert strength tags under any conditions. When you enable the **precondition-enhancement** parameter within the **sip-config** however, the SBC supports all of the strength tag values within all preconditions attributes. In addition, the SBC inserts strength tags under certain conditions.

The strength tag is a preconditions attribute value that specifies how strictly an end-station requires the establishment of preconditions for a call. The strength tag has three values:

- None—where no resource reservation is needed
- Optional—where the user agents should try to provide the requested resources
- Mandatory—where the call is terminated if the resources cannot be provided

This value is included in an end-station's status table to further define qos attributes. Ultimately, end-stations can use the strength tag's value in conjunction with the status-type and direction tag values to determine whether or not to proceed from preconditions negotiation to ringing.

When you enable the **precondition-enhancement** parameter, the SBC adds the following behaviors to its preconditions processing:

- If the SBC receives an optional strength tag while performing preconditions interworking, it treats the precondition as if it is mandatory.
- Whenever it generates a strength tag, the SBC generates and inserts mandatory strength tags to process:
  - Static or dynamic preconditions flows wherein the calling party supports preconditions and has provided optional strength tags in the initial INVITE, but the called party does not support preconditions. In this case, the SBC inserts mandatory strength tags into its locally generated 183 toward the calling party.
  - Dynamic preconditions flows wherein the calling party does not support preconditions in the initial INVITE. In this case, the SBC inserts mandatory strength tags into the INVITE it forwards to the called party.
- When processing dynamic preconditions flows wherein the calling party supports preconditions but has provided strength tags in the initial INVITE, the SBC:
  - Relays the preconditions with strength tags unchanged in messages back to the calling party
  - If the called party also supports preconditions, relays the preconditions with strength tags unchanged in messages to the called party

Enhanced Preconditions Configuration

You can configure the SBC with additional preconditions functionality by enabling the **precondition-enhancement** parameter within the **sip-config**, including:

- Dynamic Preconditions
- PEM Gating using Locally Generated 183
- Changing the Media Direction Attribute
- Supporting the Optional Strength Tag

To configure the SBC to perform the functions listed above:

1. From superuser mode, use the following command sequence to access sip-config configuration mode. While in this mode, you enable enhanced preconditions functions.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

2. Use the **precondition-enhancement** parameter to enable enhanced preconditions functions.

```
ORACLE(sip-config)#precondition-enhancement enabled
```

3. Use **done**, **exit**, and **verify-config** to complete SAG-based address resolution.

Preconditions and Multiple Early Dialogs

You can configure the SBC with the enhancement described here to overcome limitations in call flows that use the Multiple Early Dialogs (MED) function in conjunction with multiple early dialog merging, preconditions, preconditions interworking and/or transcoding free operation (TrFO). To support the use of MED with preconditions, the SBC implements preconditions processing at the dialog level.

This functionality is based on the *Early Media Support for Multiple Early Dialog Scenarios* and *Asymmetric Preconditions* features, described in this ACLI Configuration Guide. Refer to that documentation for further, applicable background. This documentation includes multiple call flows that depict the key enhancements.

An example of these enhancements includes support for static or dynamic preconditions in conjunction with multiple early dialogs generated by call forking towards multiple devices on the call termination side.

You configure this support by enabling the **precondition-med-enhancement** parameter within the **sip-config**. When enabled, the SBC supports:

- Preconditions with MED merge
- Dynamic Asymmetric Preconditions with TrFO

This support addresses specific precondition with MED merge scenarios, including:

- Static Asymmetric Preconditions with MED merge, with and without delay
- Static Asymmetric Preconditions with MED and TrFO, with and without delay
- Dynamic Preconditions with MED merge
- Dynamic Preconditions with TrFO

In addition, the SBC also includes preconditions in the offer of the resulting INVITE when it receives a 3xx, 4xx, or 5xx error message on the side supporting preconditions for all the scenarios above.

The SBC provides confirmation for dialogs requesting confirmation in the following scenarios:

- Multiple devices on the terminating side resulting into multiple early dialogs from a forking proxy
- Sequential forking initiated by the SBC

Related Configuration

In addition to enabling **preconditionMedEnhancement**, this feature is designed to operate with the following parameters enabled:

- **asymmetric-preconditions**, on the access and core **sip-interface**
- The **100-rel interworking** option, on the access and core **sip-interface**
- **asymmetric-precondition-mode**, on the core **sip-interface**

- **precondition-enhancement** in the **sip-config**
- **multiple-dialogs-enhancement** in the **sip-config**
- **merge-early-dialogs** on the access and core **realm-config**
- **hide-egress-media-update** on the access and core **realm-config**

In addition, you must configure transcoding for call flows using TrFO.

> **Note:**
>
> This MED precondition enhancement feature is not compatible with the **Drop-Additional-Provisional** SPL Option.

Precondition and MED merge Functional Overview

This section presents the SBC supporting call flows with preconditions signaling within the context of merged multiple early dialogs. Multiple dialog merging requires early dialog support in addition to enabling the **merge-early-dialogs** parameter in the caller's realm.

If you do not enable **precondition-med-enhancement** with static or dynamic preconditions, the SBC uses the first dialog it receives to perform preconditions negotiation. It does not include any subsequent forked dialogs in preconditions IWF.

Consider a SIP dialog with early media that proceeds by establishing call scenarios in which the final 200 OK does not include any SDP. This messaging may include multiple 183 (Session Progress) messages with SDP that differ from each other and include different To tags, establishing multiple early dialogs. In these scenarios, the SBC uses the saved SDP from the dialog that matches the dialog indicated in the 200 OK's To tag to anchor the media.

For both static and dynamic preconditions with MED flows, the SBC uses this feature to enhance support by:

- Forwarding calls and accepting multiple 18x messages with different To tags. Based on the To tags, the SBC recognizes a multiple early dialog scenario, which may or may not be established by multiple endstations that could be the first callee. These 18xs may also include different SDP.
- Saving information on all dialogs. This allows the SBC to proceed with the call under a variety of conditions, including when the final 200 OK does not include SDP.
- Generating PRACKs locally for all forked responses to 18x message that include 100rel.
- Updating MBCD when it receives SDP from each forked terminal.
- Generating UPDATEs locally towards all the dialogs requesting confirmation to complete the preconditions negotiation between all subsequent forked destination and itself.

When you enable **precondition-med-enhancement**, the SBC modifies its behavior for call flows with dynamic preconditions and MED merge mode to include:

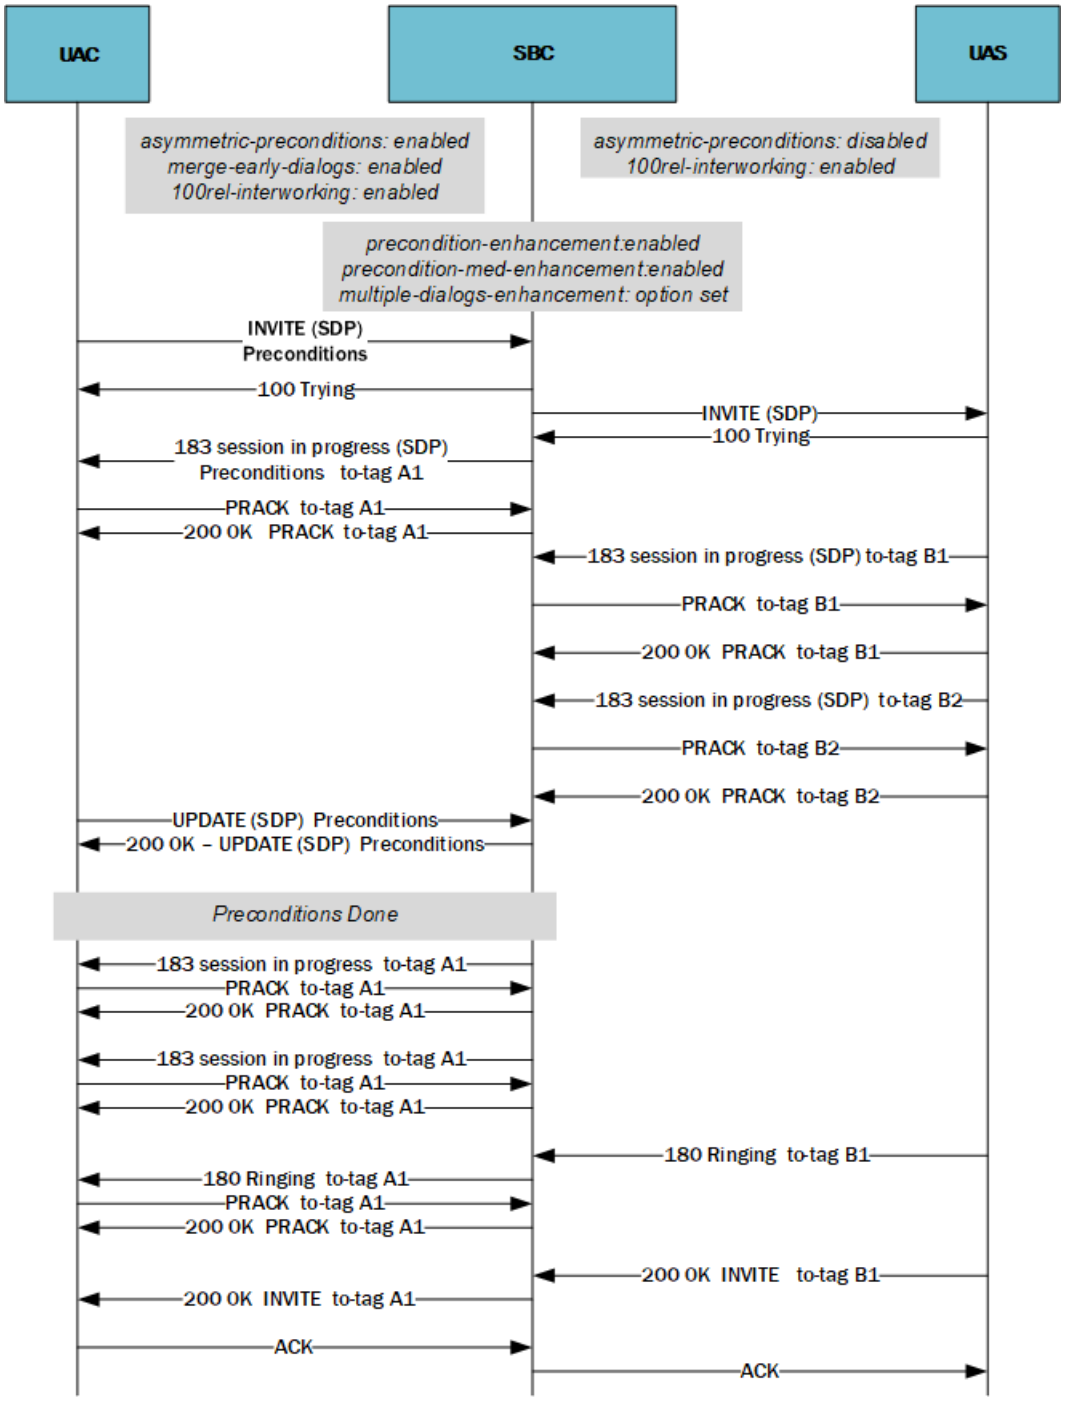
- In the case of dynamic asymmetric preconditions where the calling party supports preconditions and the first terminating called party does not, the SBC uses the locally generated to-tag that was generated for the first 183 and starts preconditioning IWF towards the UAC in merge mode.
- In the case of dynamic preconditions, where both the calling and first terminating called parties support the precondition, the SBC transparently passes the first 183 to the calling side and conducts end-to-end precondition negotiation.

- Also, in this end-to-end precondition case, the SBC never maintains the precondition state machine. Instead, it passes all 18x and 2xx responses without changes towards the calling side on the single merge dialog before precondition completion. This may result in undesirable behavior in cases where a forked UAS, for example B2, sends 18x/2xx before precondition completion between the caller and B1, and when resource reservation is mandatory.

The next table presents a composite overview of these principles when you enable asymmetric preconditions on both the ingress and egress interfaces.

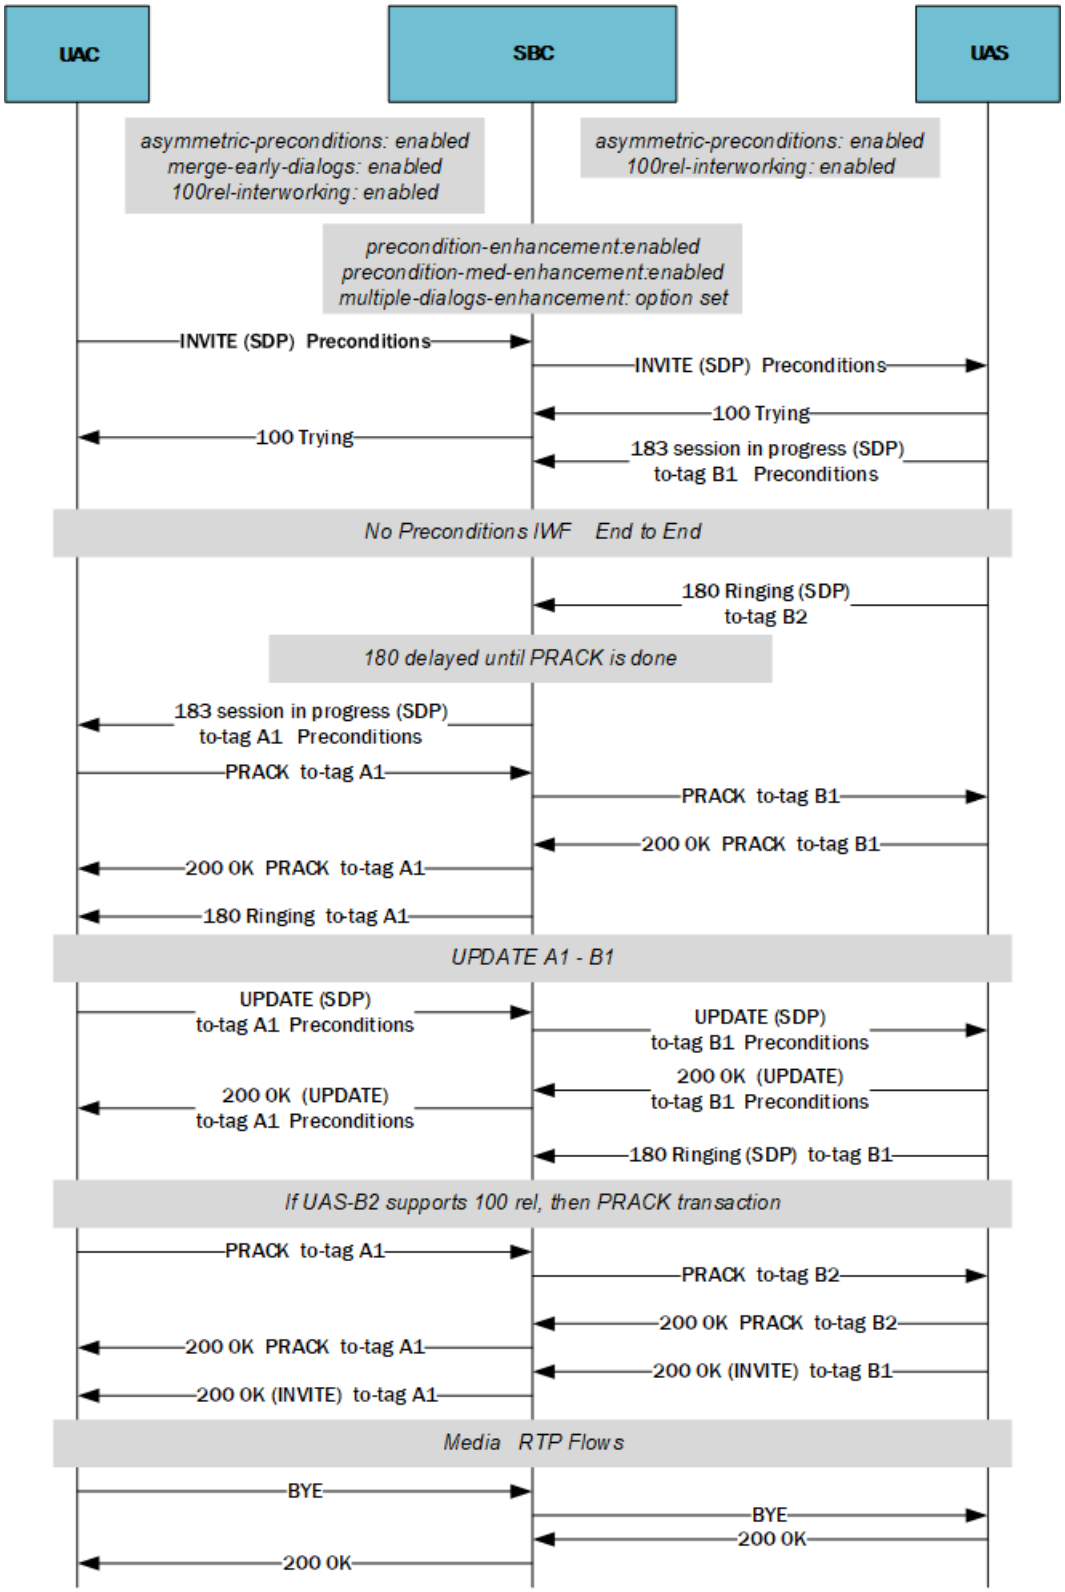
First terminating 18x received	Calling party doesn't support preconditions	Calling party supports preconditions
Without precondition support	Incoming INVITE received without preconditions tag, SBC sends INVITE with preconditions tag towards UAS UAS send 18x without preconditions	Incoming INVITE received with preconditions tag, SBC sends INVITE with preconditions tag towards UAS UAS side sends 1st 18x without preconditions
	SBC will simply PROXY received messages from B1.	SBC will perform precondition IWF negotiation towards UAC.
	SBC will do precondition IWF complete it locally towards all subsequent forked destinations if precondition required in 18x.	SBC will do precondition IWF and complete it locally towards all subsequent forked destinations if precondition required in 18x.
With precondition support	Incoming INVITE received without preconditions tag, SBC sends INVITE with preconditions tag towards UAS UAS send 18x with preconditions	Incoming INVITE received with preconditions tag, SBC sends INVITE with preconditions tag towards UAS UAS sends 1st 18x with preconditions
		SBC will simply PROXY received messages from first terminating dialog.
	SBC will perform precondition IWF negotiation towards UAS and send UPDATE to confirm precondition to each forked dialog.	SBC will do precondition IWF and complete it locally towards all subsequent forked destinations if precondition required in 18x.

The call flow below shows the basic signaling required for the SBC to support static preconditions in conjunction with MED while initiating the call to the UAS. Note that the SBC supports preconditions below in no delay mode. The UAS responds with two early dialogs, which the SBC supports using PRACKs. Having completed preconditions negotiation with the UAC, the SBC merges the two dialogs, presenting them to the UAC, which provides PRACK acknowledgments. Finally, the B1 dialog from the UAS signals ringing and 200 OK to the SBC, which conveys the call setup to the UAC.



This next call flow shows the signaling required for the SBC to support dynamic preconditions in conjunction with MED. Again, the SBC imposes no delay during with the call setup while it performs preconditions negotiation. In this case, the UAS supports preconditions allowing the SBC to proxy end-to-end preconditions setup.

The SBC supports preconditions negotiation with the UAC while initiating the call to the UAS. The UAS responds with two early dialogs which the SBC supports using PRACKs. Dialog B1 supports preconditions, but B2 does not. The SBC ignores a 180 ringing from B2, instead proceeding with support for end-to-end preconditions with B1. Once the preconditions negotiation between the UAC and the UAS (B1) is complete, the SBC accepts a 180 ringing from dialog B1 and sets up the call.



Static and Dynamic Preconditions with TrFO

This section presents the SBC supporting call flows using the TrFO function within the context of multiple early dialogs scenarios that also support preconditions. This feature also requires

that you set the **trfo-feature** parameter on the ingress realm to **asymmetric-preconditions**. Note that this excludes TrFO for ringback on that realm.

For static preconditions flows, when you enable preconditions on the caller side and disable it on the other side, the SBC triggers its preconditions IWF. Within these contexts the SBC stores provisional and final responses from all callees until the preconditions are met. Similarly, when you enable dynamic preconditions, the SBC triggers preconditions IWF towards the caller if the first 18x from a forked response does not include preconditions support.

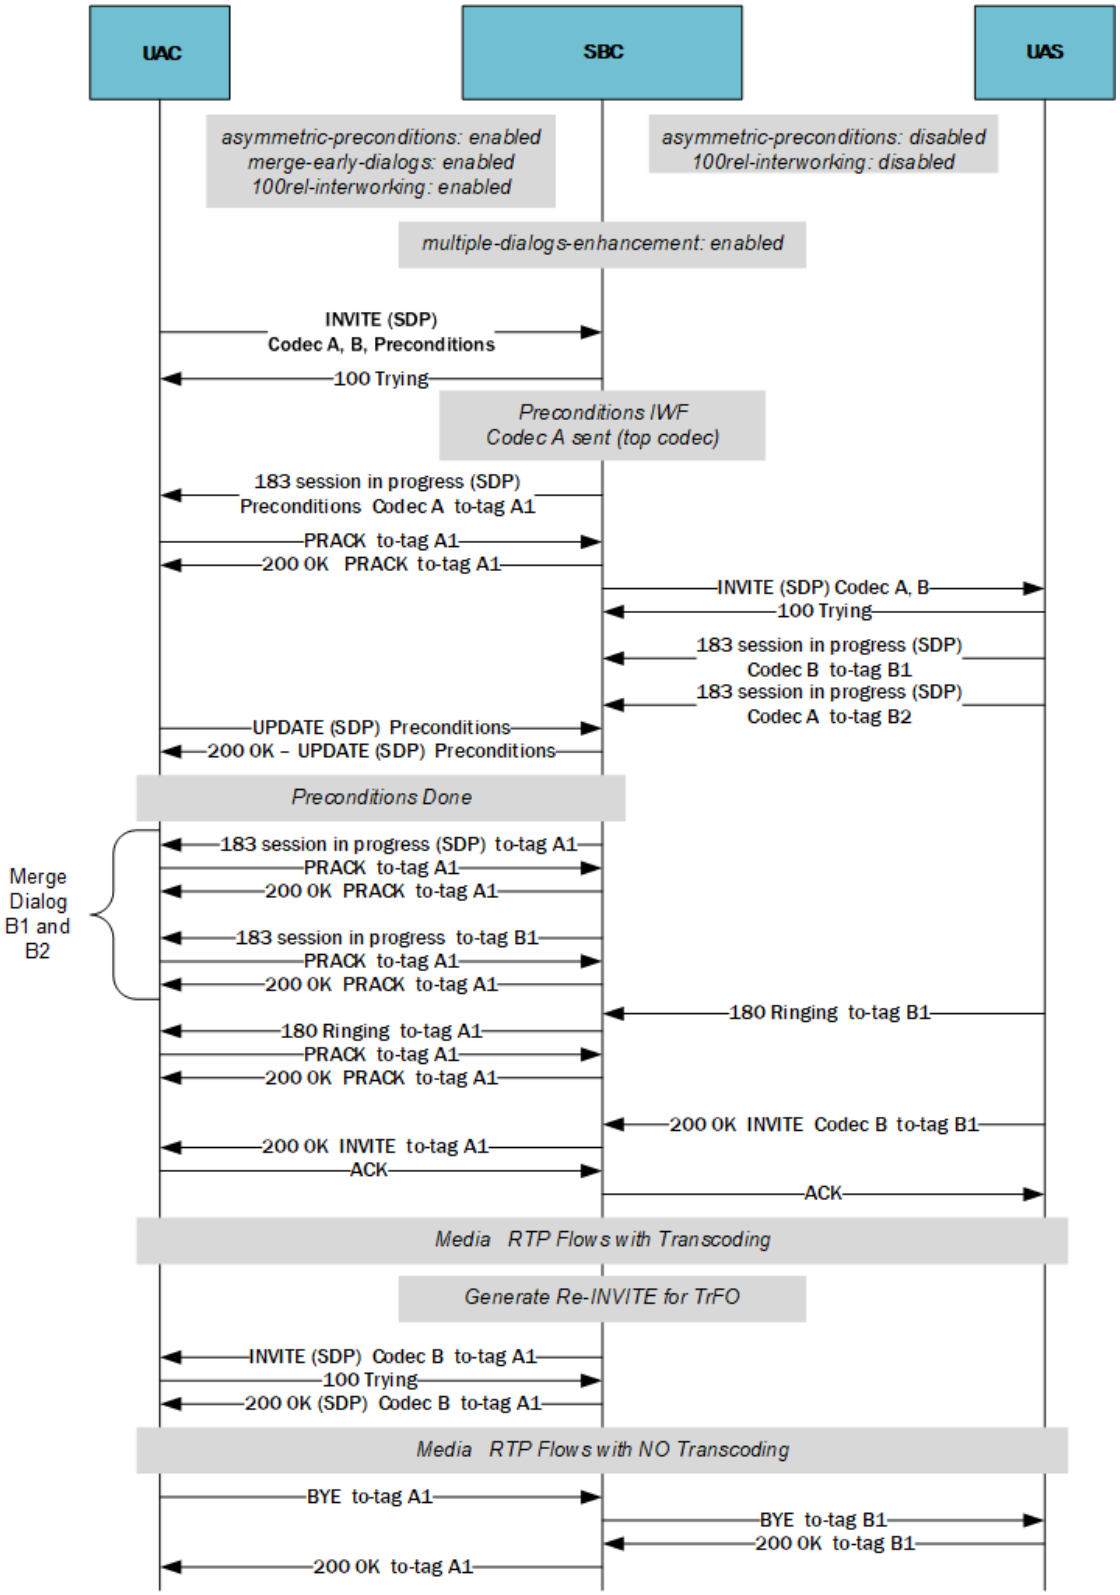
These call flows can also include a negotiated codec in the final answer (200 OK) that is different from that of the calling side. If so, the SBC triggers transcoding upon call establishment, consuming the associated resources. To avoid this, the SBC can use its TrFO function to determine whether the callee's codec is available at the caller based on the stored responses. If so, the SBC can send a re-INVITE to the caller with the negotiated codec on the called side.

Scenarios wherein the SBC can identify a codec that allows it to avoid transcoding include:

- It has received the first 18x with SDP, but the final response from the same callee has a different SDP.
- It has received the first 18x with SDP, but the final response, from a different, forked callee has a different codec.
- It has received the first 18x with no SDP, but the negotiated codec by the callee is in the list of initial offer of ingress INVITE.

In these cases, the codecs negotiated by the SBC and the callee are available. Once the preconditions are met and the SBC has identified a codec available, it sends the re-INVITE to the caller with the callee's negotiated codec. The called side simply agrees and the call proceeds without transcoding.

The example call flows below contrast the system operating with MED and needing to consider TrFO support within dynamic preconditions and static preconditions scenarios. For all flows, you have enabled MED facing the UAC.



This next flow depicts the system setting up asynchronous preconditions because, although you have enabled both realms for asymmetric preconditions, none of the dialogs returned from the UAS include preconditions. In addition, you have configured the UAC realm for preconditions to send without delay mode.

> **Note:**
>
> The SBC supports TrFO in both send with, and send without delay mode.

The system determines that the UAC has specified Codec A and the UAS has specified Codec B after the preconditions and merge dialog functions are complete. This is because the B1 session is the first dialog to present a 200 OK to the INVITE. The SBC determines that the UAC can support Codec B, so it performs its TrFO function by issuing a re-INVITE to the UAC with Codec B.

200 OK

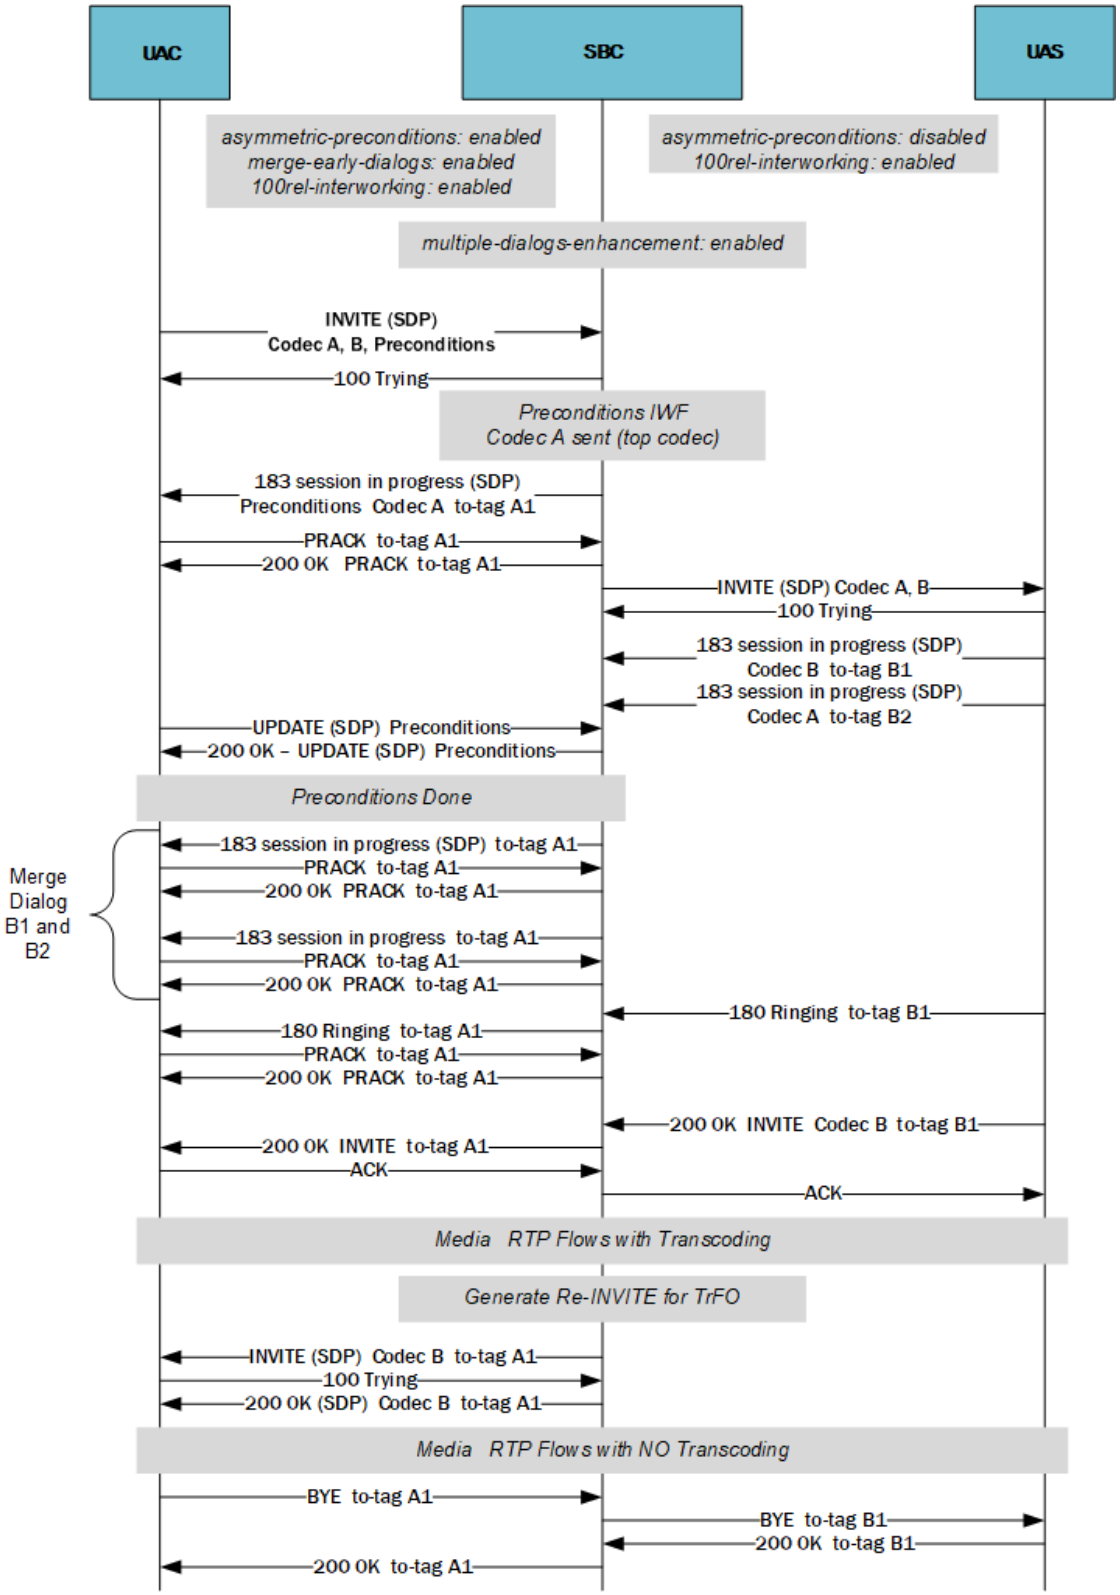
This last TrFO flow depicts the system setting up static, asymmetric preconditions because the UAS realm has asymmetric preconditions disabled. In addition, the system determines that both stations agree to Codec A after the preconditions and merge dialog functions are complete, so there is no need for TrFO.

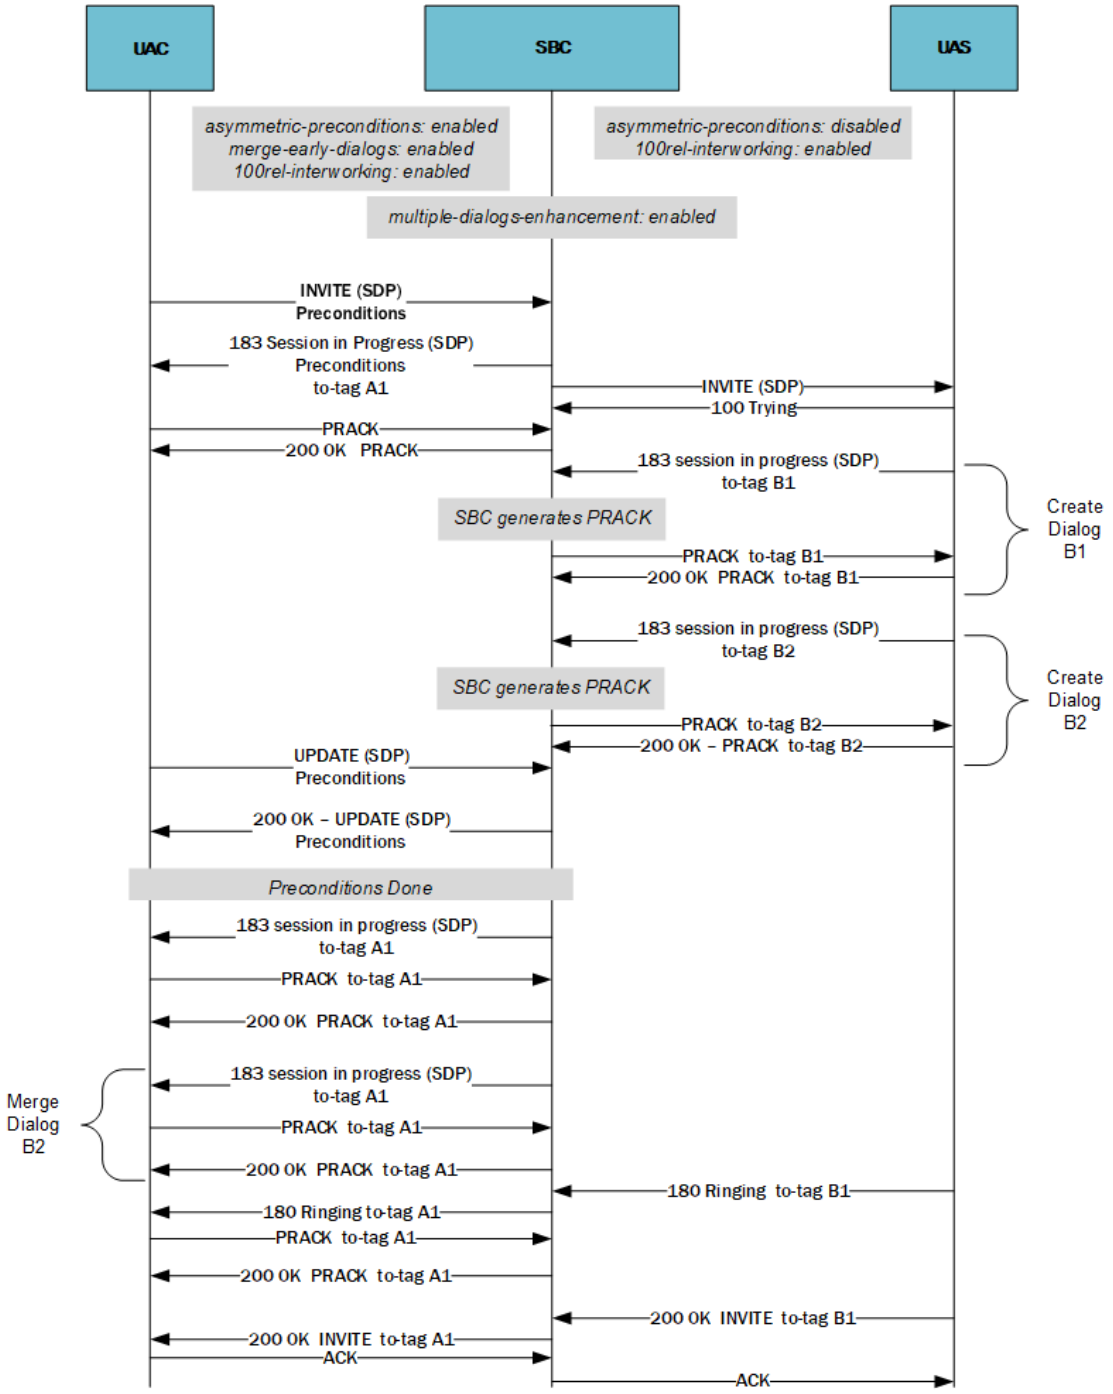
Note that, if the 200 OK came from dialog B2, the SBC would have triggered transcoding, and then TrFO.



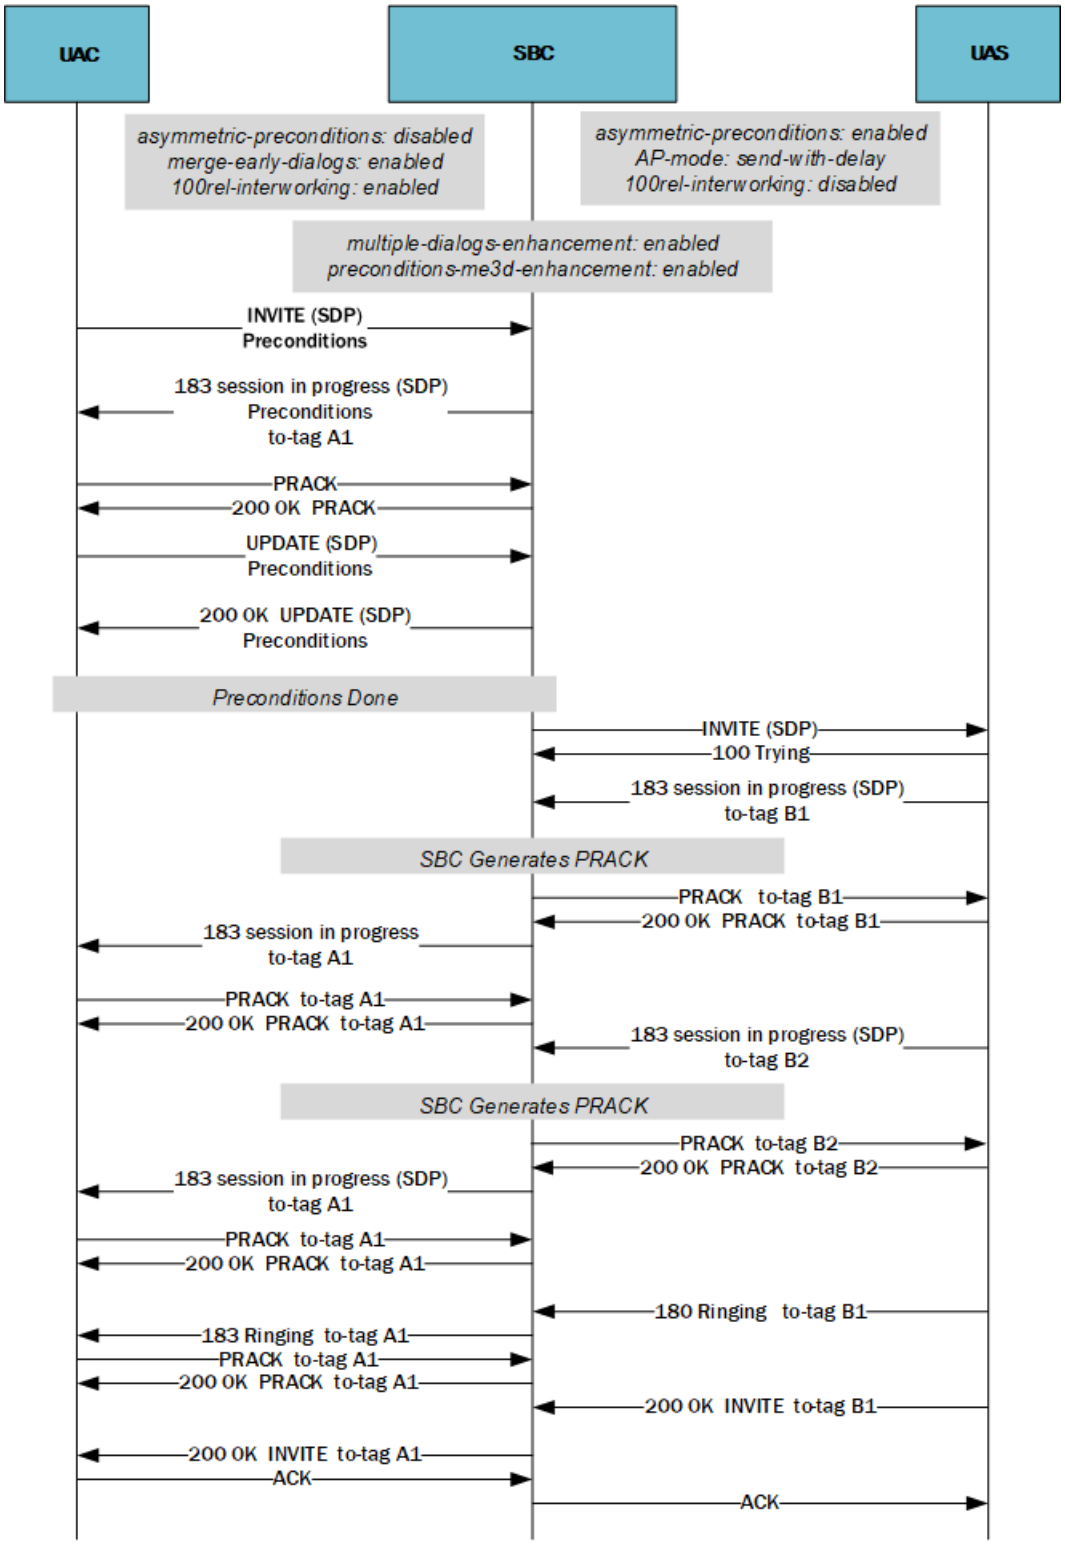
Preconditions and MED with and without Delay

This section presents the SBC supporting call flows with preconditions in conjunction with MED, including when configured to merge mode. In addition, you can set preconditions to operate under the 'send with delay' or 'send with no delay' mode.

The call flow below shows the SBC supporting asymmetric preconditions signaling sending the egress INVITE without delay in conjunction with multiple early dialogs. The system has invited the UAS without waiting for preconditions confirmation with the UAC (without delay). The system instantiates each client dialog, based on the 183s. In the meantime, the system confirms preconditions with the UAC and merges the multiple dialogs to a single dialog for the UAC. Ultimately, the system supports the call using dialog B1 from the UAS.



Similar to the above, the next call flow shows the system supporting preconditions with delay. Notice that the preconditions negotiation happens on the UAC side. In this case, the system needs to confirm preconditions for the dialog prior to proceeding with the call. The system merges the dialogs and ultimately supports the call using dialog B1 from the UAS.



Related Preconditions and MED Call Flows

This section presents call flows related to precondition support in conjunction with multiple early dialogs within sequential forking/recursion scenarios.

When you enable this feature, the SBC also provides precondition support, with or without simultaneous MED support, in redirected, recursive, or sequential forking calls. To achieve this

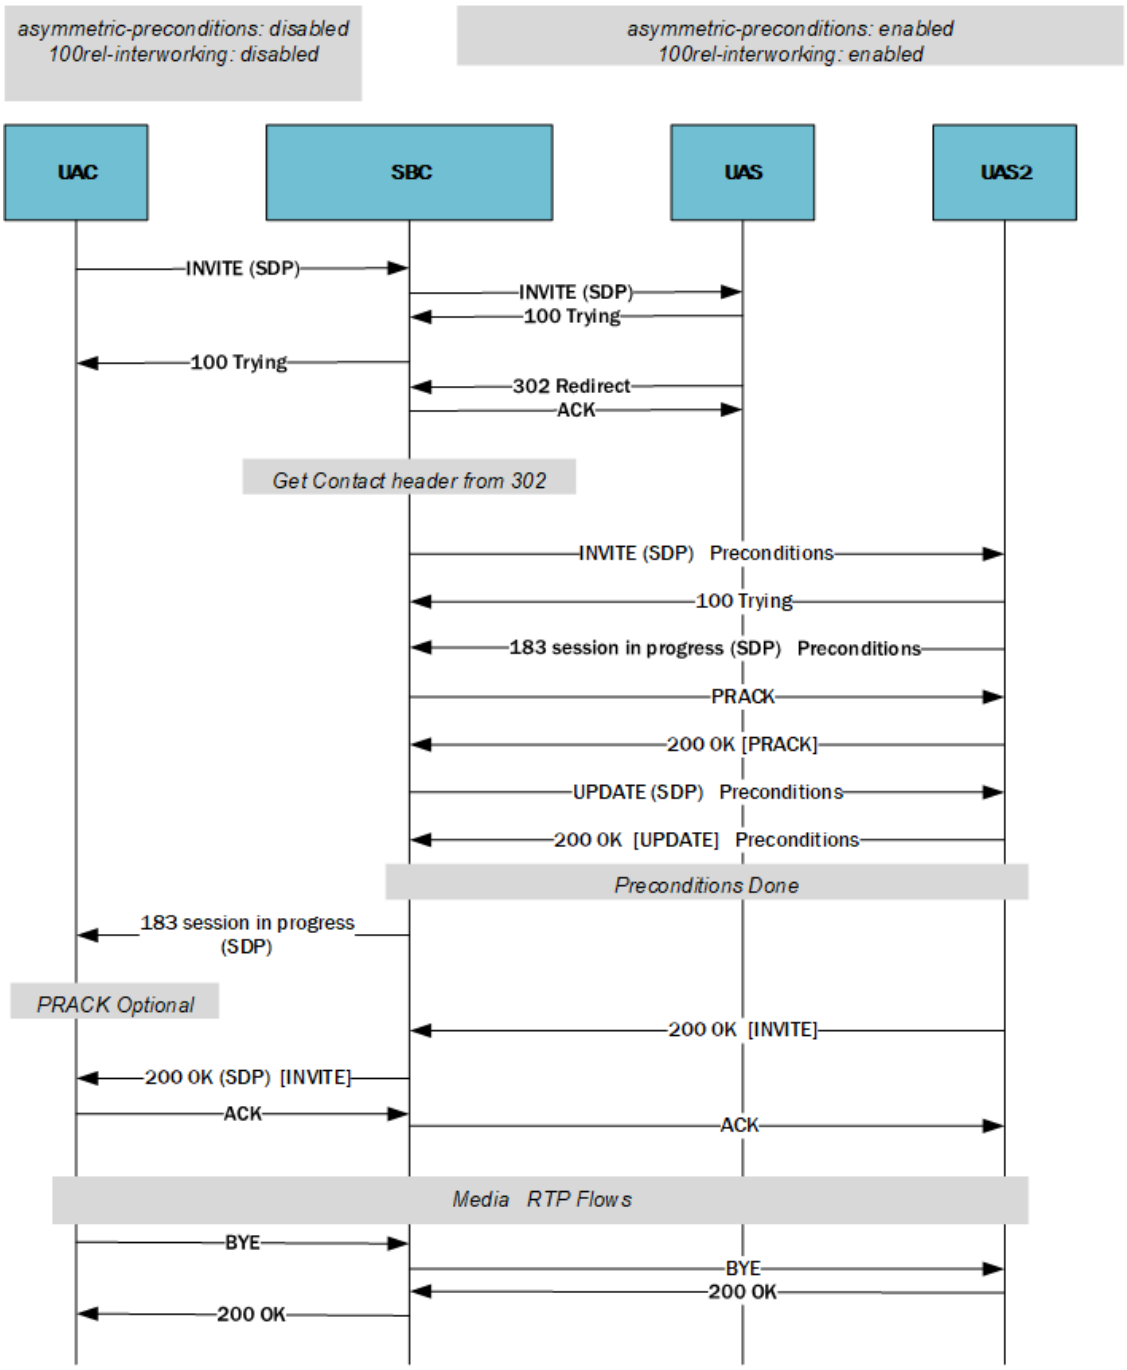
functionality, the SBC offers preconditions, in the context of both the supported header and SDP attributes in the egress INVITE used for the next destination. This assume proper **sip-interface** configuration. To accommodate this scenario, the SBC sends UPDATEs that provide confirmation for all serial forked users, and dialogs requesting confirmation within multiple early dialogs.

Message specific recursion and sequential forking considerations also include:

- If an endstation responds with a 6xx global failure, the SBC forwards it towards the UAC without changes. There is no serial or sequential forking applicable to 6xx error cases.
- If an endstation responds with a 491 request pending message in response to an initial INVITE, the SBC proxies the 491 error and does not retry that endstation after a timeout. If a new INVITE arrives, the SBC generates its own new INVITE towards its destinations, including that endstation, and continues to support recursion/sequential forking.

Static Preconditions Flows with 302 and 4xx Responses

The call flow below presents the SBC fielding a redirect within a multiple early dialog scenario. The flow also includes static preconditions negotiation with the endstation to which the first UAS redirected the call. The call includes the preconditions UPDATE prior to successful call setup.



This next call flow shows the SBC supporting 4xx or 5xx responses, which generate multiple early dialogs with two alternative endstations, which the SBC merges to A1. In this case, an error message generates the contact to the second UAS. Preconditions are supported on the egress realm, and the SBC issues an INVITE with preconditions based on the 183 from the first UAS. UAS2 generates an UPDATE to confirm preconditions.

Ultimately, the first UAS sends a 200 OK to the initial INVITE without preconditions, so the SBC proceeds with the call to the first UAS.

You must have enabled the **preconditions-med-enhancement** for the SBC to support preconditions with UAS2 despite the error. In addition, this parameter is also supporting MED merge in this call flow.

Dynamic Preconditions Flows with 302 and 4xx Responses

This next call flow shows the SBC supporting a 302 redirect within a dynamic preconditions scenario. (This generates multiple early dialogs with two alternative endstations.) The SBC offers preconditions to both the first and second UAS. The UPDATE exchange verifies the preconditions between the UAC and UAS2. Having completed preconditions negotiation, UAS2 answers the call, supported by the SBC.

You must have enabled the **preconditions-med-enhancement** for the SBC to support preconditions across the redirect.

SIP Interface Configuration

To configure a SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

   From this point, you can configure SIP interface parameters. To view all sip-interface parameters, enter a **?** at the system prompt.

4. **state**—Enable or disable the SIP interface. The default is **enabled**. The valid values are:
   - enabled | disabled

   > **Note:**
   >
   > Oracle does not recommend disabling and re-enabling a sip-interface operating with TCP ports. Depending on conditions and circumstances, you may not be able to re-enable this sip-interface without rebooting the system. If you need to disable, then re-enable a sip-interface, ensure that:
   >
   > – There are no ESTABLISHED in-bound sockets
   >
   > – The access-control-trust-level of the realm must not be configured to low or medium

5. **realm-id**—Enter the name of the realm to which the SIP interface is connected.
6. **sip-ports**—Access the **sip-ports** subelement.
7. **carriers**—Enter the list of carriers related to the SIP interface.

   Entries in this field can be from 1 to 24 characters in length and can consist of any alphabetical character (Aa-Zz), numerical character (0-9), or punctuation mark (! ”$ % ^ & * ( ) + - = < > ? ‘ | { } [ ] @ / \ ‘ ~ , . _ : ;) or any combination of alphabetical characters, numerical characters, or punctuation marks. For example, both 1-0288 and acme_carrier are valid carrier field formats

8. **proxy-mode**—Enter an option for the proxy mode parameter. Valid values are:
   - **Proxy**—Forward all SIP requests to selected targets.
   - **Redirect**—Send a SIP 3xx redirect response with the selected target(s) in the Contact header.
   - **Record-Route**—Forward requests to selected target(s) and insert a Record-Route header with the SBC’s address. For stateless and transaction mode only.

9. **redirect-action**—Enter the value for the redirect action. Valid values are:
   - **Proxy**—Send the SIP request back to the previous hop.
   - **Recurse**—Recurses on the Contacts in the response.

     The designated proxy action will apply to SIP 3xx responses received from non-session agents and to 3xx responses received from session agents without configured SIP Redirect message actions (for example, session agents without values for the redirect action field).
   - **Recurse-305-only**—Recurses on the Contacts only in a 305 response.
10. **contact-mode**—Set the Contact header routing mode, which determines how the contact address from a private network is formatted.

    For example, whether a maddr parameter equal to the Oracle Communications Session Border Controller's SIP proxy needs to be added to a URI present in a Contact header.

    The default is **none**. The valid values are:
    - **none**—The address portion of the header becomes the public address of that private realm.
    - **maddr**—The address portion of the header will be set to the IP address of the Oracle Communications Session Border Controller's B2BUA.
    - **strict**—The contents of the Request-URI is destroyed when a Record-Route header is present.
    - **loose**—The Record-Route header is included in a Request, which means the destination of the request is separated from the set of proxies that need to be visited along the way.
11. **nat-traversal**—Define the type of HNT enabled for SIP. The default is **none**. Valid values are:
    - **none**—HNT function is disabled for SIP.
    - **rport**—SIP HNT function only applies to endpoints that include the rport parameter in the Via header. HNT applies when the sent-by of the topmost VIA matches the Contact-URI host address, both of which must be different from the received Layer 3 address.
    - **always**—SIP HNT applies to requests when the sent-by of the topmost VIA matches the Contact-URI host address, both of which must be different from the received Layer 3 address. (Even when the rport parameter is not present.)
12. **nat-interval**—Set the expiration time in seconds for the Oracle Communications Session Border Controller's cached registration entry for an HNT endpoint. The default is **30**. The valid range is:
    - Minimum—0
    - Maximum—4294967295

      Oracle recommends setting the NAT interval to one-third of the NAT binding lifetime. A NAT binding lifetime is the network connection inactivity timeout. The value is configured (or hardwired) in the NAT device (firewall). This timer is used to cause the UA to send REGISTER messages frequently enough to retain the port binding in the NAT. Retaining the binding lets inbound requests to be sent through the NAT.
13. **tcp-nat-interval**—Set the registration cache expiration time in seconds to use for endpoints behind a NAT device that register using TCP. On upgrade, the Oracle Communications Session Border Controller assigns this parameter the same value as the existing NAT interval. The default is **90**. The valid range is:

- Minimum—0
- Maximum—999999999

The Oracle Communications Session Border Controller uses the value you set for the TCP NAT interval as the expiration value passed back in SIP REGISTER (200 OK) responses to endpoints behind a NAT that register over TCP. The NAT interval value with which you are familiar from previous releases is used for endpoints behind a NAT that register over UDP. Requiring endpoints that register over TCP to send refresh requests as frequently as those registering over UDP puts unnecessary load on the Oracle Communications Session Border Controller. By adding a separate configuration for the TCP NAT interval, the load is reduced.

For upgrade and backward compatibility with Oracle Communications Session Border Controller releases prior to Release 4.1, when the tcpNatInterval is not present in the XML for a SIP interface configuration, the value of the NAT interval (natInterval) is used for the TCP NAT interval as well.

14. **registration-caching**—Enable for use with all UAs, not just those that are behind NATs. The default is **disabled**. The valid values are:

- enabled | disabled

If enabled, the Oracle Communications Session Border Controller caches the Contact header in the UA's REGISTER request when it is addressed to one of the following:

- Oracle Communications Session Border Controller
- registrar domain value
- registrar host value

The Oracle Communications Session Border Controller then generates a Contact header with the Oracle Communications Session Border Controller's address as the host part of the URI and sends the REGISTER to the destination defined by the registrar host value.

Whether or not SIP HNT functionality is enabled affects the value of the user part of the URI sent in the Contact header:

- HNT enabled: the Oracle Communications Session Border Controller takes the user part of the URI in the From header of the request and appends a cookie to make the user unique. A cookie is information that the server stores on the client side of a client-server communication so that the information can be used in the future.
- HNT disabled: the user part of the Contact header is taken from the URI in the From header and no cookie is appended. This is the default behavior of the Oracle Communications Session Border Controller.

When the registrar receives a request that matches the address-of-record (the To header in the REGISTER message), it sends the matching request to the Oracle Communications Session Border Controller, which is the Contact address. Then, the Oracle Communications Session Border Controller forwards the request to the Contact-URI it cached from the original REGISTER message.

15. **min-reg-expire**—Set the time in seconds for the SIP interface. The value you enter here sets the minimum registration expiration time in seconds for HNT registration caching. The default is **300**. The valid range is:

- Minimum—0
- Maximum—999999999

This value defines the minimum expiration value the Oracle Communications Session Border Controller places in each REGISTER message it sends to the real registrar. In

HNT, the Oracle Communications Session Border Controller caches the registration after receiving a response from the real registrar and sets the expiration time to the NAT interval value.

Some UAs might change the registration expiration value they use in subsequent requests to the value specified in this field. This change causes the Oracle Communications Session Border Controller to send frequent registrations on to the real registrar.

16. **registration-interval**—Set the Oracle Communications Session Border Controller's cached registration entry interval for a non-HNT endpoint. Enter the expiration time in seconds that you want the Oracle Communications Session Border Controller to use in the REGISTER response message sent back to the UA. The UA then refreshes its registration by sending another REGISTER message before that time expires. The default is **3600**. The valid range is:

    - Minimum—0

      A registration interval of zero causes the Oracle Communications Session Border Controller to pass back the expiration time set by and returned in the registration response from the registrar.

    - Maximum—999999999

      If the expiration time you set is less than the expiration time set by and returned from the real registrar, the Oracle Communications Session Border Controller responds to the refresh request directly rather than forwarding it to the registrar.

      Although the registration interval applies to non-HNT registration cache entries, and the loosely related NAT interval applies to HNT registration cache entries, you can use the two in combination. Using a combination of the two means you can implement HNT and non-HNT architectures on the same Oracle Communications Session Border Controller. You can then define a longer interval time in the registration interval field to reduce the network traffic and load caused by excess REGISTER messages because there is no NAT binding to maintain.

17. **route-to-registrar**—Enable routing to the registrar to send all requests that match a cached registration to the destination defined for the registrar host; used when the Request-URI matches the registrar host value or the registrar domain value, not the Oracle Communications Session Border Controller's address. Because the registrar host is the real registrar, it should send the requests back to the Oracle Communications Session Border Controller with the Oracle Communications Session Border Controller's address in the Request-URI. The default is **disabled**. The valid values are:

    - enabled | disabled

      For example, you should enable routing to the registrar if your network uses a N Oracle Communications Session Border Controller and needs requests to go through its service proxy, which is defined in the registrar host field.

18. **teluri-scheme**—Enable to convert SIP URIs to tel (resources identified by telephone numbers) URIs.

    If enabled, the requests generated on this SIP interface by the Oracle Communications Session Border Controller will have a tel URI scheme instead of the SIP URI scheme. Only the Request, From, and To URIs are changed to the tel scheme. After the dialog is established, the URIs are not changed. The default is **disabled**. The valid values are:

    - enabled | disabled

19. **uri-fqdn-domain**—Change the host part of the URIs to the FQDN value set here. If set to enabled, and used with an FQDN domain/host, the requests generated by the Oracle Communications Session Border Controller on this SIP interface will have the host part of

the URI set to this FQDN value. Only the Request, To, and From URIs are changed. After the dialog is established, the URIs are not changed.

20. **trust-mode**—Set the trust mode for the SIP interface, which is checked by the Oracle Communications Session Border Controller when it receives a message to determine whether the message source is trusted. The default is **all**. Available options are:

    - **all**—Trust all SIP elements (sources and destinations) in the realm(s), except untrusted session agents. Untrusted session agents are those that have the **trust-me** parameter set to **disabled**.
    - **agents-only**—Trust only trusted session agents. Trusted session agents are those that have the **trust-me** parameter set to **enabled**.
    - **realm-prefix**—Trust only trusted session agents, and source and destination IP addresses that match the IP interface's realm (or subrealm) address prefix. Only realms with non-zero address prefixes are considered.
    - **registered**—Trust only trusted session agents and registered endpoints. Registered endpoints are those with an entry in the Oracle Communications Session Border Controller's registration cache.
    - **none**—Trust nothing.

      Session agents must have one or more of the following:

    - global realm
    - same realm as the SIP interface
    - realm that is a subrealm of the SIP interface's realm

21. **trans-expire**—Set the TTL expiration timer in seconds for SIP transactions. This timer controls the following timers specified in RFC 3261:

    - Timer B—SIP INVITE transaction timeout
    - Timer F—non-INVITE transaction timeout
    - Timer H—Wait time for ACK receipt
    - Timer TEE—Used to transmit final responses before receiving an ACK

      The default is **0**. If you leave this parameter set to the default, then the Oracle Communications Session Border Controller uses the timer value from the global SIP configuration. The valid range is:

    - Minimum—0
    - Maximum—999999999

22. **invite-expire**—Set the TTL expiration timer in seconds for a SIP client/server transaction after receiving a provisional response.

    You set this timer for the client and the sever by configuring it on the SIP interface corresponding to the core or access side.

    The default is **0**. If you leave this parameter set to the default, then the Oracle Communications Session Border Controller uses the timer value from the global SIP configuration. The valid range is:

    - Minimum—0
    - Maximum—999999999

23. **max-redirect-contacts**—Set the maximum number of contacts or routes for the Oracle Communications Session Border Controller to attempt in when it receives a SIP Redirect (3xx Response). The default is **0**. If you leave this parameter set to the default, then the

Oracle Communications Session Border Controllerwill exercise no restrictions on the number of contacts or routes. The valid range is:

- Minimum—0
- Maximum—10

24. **response-map**—Enter the name of the SIP response map configuration that you want to apply to this SIP interfaces for outgoing responses. This parameter is blank by default.
25. **local-response-map**—Enter the name of the SIP response map configuration that you want to apply to this SIP interfaces for locally-generated SIP responses. This parameter is blank by default.
26. **options**—Optional.

Configuring SIP Ports

To configure SIP ports:

1. From sip-interface, type **sip-ports** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(sip-interface)# sip-ports
ORACLE(sip-port)#
```

2. **address**—Enter the IP address of the host associated with the sip-port entry on which to listen. For example:

```
192.168.11.101
```

3. **port**—Enter the port number you want to use for this sip-port. The default is **5060**. The valid range is:
   - Minimum—1
   - Maximum—65535
4. **transport-protocol**—Indicate the transport protocol you want to associate with the SIP port. The default is **UDP**. The valid values are:
   - **TCP**—Provides a reliable stream delivery and virtual connection service to applications through the use of sequenced acknowledgment with the retransmission of packets when necessary.
   - **UDP**—Provides a simple message service for transaction-oriented services. Each UDP header carries both a source port identifier and destination port identifier, allowing high-level protocols to target specific applications and services among hosts.
   - **TLS**—See the Security chapter for more information about configuring TLS.
5. **allow-anonymous**—Define the allow anonymous criteria for accepting and processing a SIP request from another SIP element.

   The anonymous connection mode criteria includes admission control based on whether an endpoint has successfully registered. Requests from an existing SIP dialog are always accepted and processed. The default is **all**.

   The following table lists the available options.

   - **all**—All requests from any SIP element are allowed.
   - **agents-only**—Only requests from configured session agents are allowed. The session agent must fit one of the following criteria:

  - Have a global realm.
  - Have the same realm as the SIP interface
  - Be a sub-realm of the SIP interface's realm.
    When an agent that is not configured on the system sends an INVITE to a SIP interface, the Oracle Communications Session Border Controller:
  - Refuses the connection in the case of TCP.
  - Responds with a 403 Forbidden in the case of UDP.

- **realm-prefix**—The source IP address of the request must fall within the realm's address prefix or a SIP interface sub-realm. A sub-realm is a realm that falls within a realm-group tree. The sub-realm is a child (or grandchild, and so on) of the SIP interface realm.

  Only realms with non-zero address prefixes are considered. Requests from session agents (as described in the **agents-only** option) are also allowed.

- **registered**—Only requests from user agents that have an entry in the registration cache (regular or HNT) are allowed; with the exception of a REGISTER request. A REGISTER request is allowed from any user agent.

  The registration cache entry is only added if the REGISTER is successful. Requests from configured session agents (as described in the **agents-only** option) are also allowed.

- **register-prefix**—Only requests from user agents that have an entry in the Registration Cache (regular or HNT) are allowed; with the exception of a REGISTER request. A REGISTER request is allowed only when the source IP address of the request falls within the realm address-prefix or a SIP interface sub-realm. Only realms with non-zero address prefixes are considered.

  The Registration Cache entry is only added if the REGISTER is successful. Requests from configured session agents (as described in the **agents-only** option) are also allowed.

Asymmetric Preconditions Configuration

1. Access the **sip-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

2. Select the **sip-interface** object to edit.

```
ORACLE(sip-interface)# select
<RealmID>:
1: realm01 172.172.30.31:5060

selection: 1
ORACLE(sip-interface)#
```

3. **asymmetric-preconditions** — identifies whether to enable preconditions interworking on the interface. Allowable values are **enabled** and **disabled**. The default is **disabled**. You cannot enable asymmetric preconditions unless you have first set the value of **sip-interface**, **options** to **100rel-interworking**.

4. **asymmetric-preconditions-mode** — identifies, when the value of **asymmetric-preconditions** is **enabled**, whether to send egress INVITEs immediately or to delay them until preconditions have been met. Allowable values are **send-with-delay** and **send-with-nodelay**. The value **send-with-delay** delays INVITEs on the egress interface until preconditions are met on the ingress interface. The value **send-with-nodelay** forwards INVITEs to the egress interface immediately, but holds the responses until preconditions are met on the ingress interface. The default is **send-with-nodelay**.
5. **add-sdp-in-msg** — identifies the messages in which to insert SDP offers or answers. The only allowable value is **18xresp** which, for an offerless INVITE that needs preconditions, causes the SBC to insert the SDP, as configured in the media profile names listed in **add-sdp-profiles-in-msg**, in the 18x (183) response towards the UE. The default is null (no value).
6. **add-sdp-profiles-in-msg** — identifies a list of media profiles that contain, based on the codec, the SDP to insert in the 18x response when **add-sdp-in-msg** is configured. The default is null (no value).
7. Type **done** to save your configuration.

Diversion Info and History-Info Header Mapping

History-Info and Diversion are two headers commonly used in SIP signaling to convey information related to call transfer and call diversion. The Oracle Communications Session Border Controller (SBC) supports mapping and interworking between networks that support the History-Info versus the Diversion header. You implement this interworking on the SBC using the **diversion-info-mapping-mode** parameter on egress **sip-interface** configuration elements. This interworking, and the subsequent header behaviors, comply with RFC 7544. When configured, the SBC monitors signaling for the presence of History-info headers that comply with RFC 7044 and Diversion headers that comply with RFC 5806 to trigger the interworking. The SBC also provides support for RFC 8119, with respect to the cause URI parameter.

The History-Info header is the standard solution adopted by the Internet Engineering Task Force (IETF) for storing re-targeting information. The non-standard Diversion header is also used in many existing network implementations. Individual networks typically use one or the other. As both headers address call forwarding needs but have different syntaxes, having both present in a signaling request can cause diverting information to be misinterpreted, thereby making an interworking solution necessary. In addition to using different syntaxes, these methods also use different reason codes for the diversions, different security flags, and list events using opposite chronology. The diversion header lists the last diversion first; the History-Info header lists the first diversion first.

The SBC applies the configuration at the egress interface. You can configure the following header interworking modes:

- Diversion to History-Info
- History-info to Diversion
- A combination of Diversion to History-Info interworking and a forced insertion of the History-info header if the INVITE contains neither

When interworking from a History-Info header to a Diversion header, the SBC initializes the new Diversion header with the value of the History-Info header.

History-Info and Diversion Header Interworking Operations

The Oracle Communications Session Border Controller (SBC) performs this interworking on the information provided in the initial INVITE. History-Info and Diversion header entries may arrive in any order and can be mixed. The SBC supports interworking for interleaved entries and mixed input. History-Info has a much broader scope than Diversion header (not limited to call forwarding) so not all information can be interworked. The SBC manages History-Info headers with or without cause parameter per RFC 7544.

At a high level, the SBC performs the following tasks:

- When interworking History-Info to Diversion headers:
  - Supports the mp parameters in History-Info received and generated to the hi-targeted-to-URI to change the user. Examples include forwarding to a different call center technician.
  - If received in the INVITE, the SBC stores the rc and np parameters:
    * rc—Changes Request-URI, while the target user does not. Examples include forwarding to a user's voice mail.
    * np—No change in the Request-URI. Examples include a proxy forwarding a request to a next-hop proxy when you are using loose routing.
  - Interworks the History-Info 380 cause parameter to the Diversion header (cause=unknown), as described below.
- When interworking Diversion headers to History-Info:
  - Creates placeholder History-Info headers when the Diversion counter is greater than 1.
  - Converts TEL-URIs to SIP-URIs.
  - Forwards History-Info not related to call forwarding without change.

For both directions:

- Preserves unknown elements of History-Info and Diversion headers, such as display name, parameters, and enclosed headers adhering to the HI or DIV syntax. Specifically:
  - If there are any unknown parameters/elements present in the URI part (in between "<" and ">") of HI/Diversion headers, the SBC preserves those values in the converted entries.
  - If there is any extra/unknown supplementary information outside the URI of an HI entry, the SBC maps that HI entry, including the EXTRA info.
  - If there is any extra/unknown supplementary information outside the URI of the Diversion entry, the SBC maps that Diversion entry, but ignores the EXTRA information.
- Based on **sip-config** configuration, makes the Diversion and History-Info headers anonymous if the egress peer is untrusted.

> **Note:**
>
> If there is any information outside of the HI/DIV header syntax, the SBC treats that information as unknown or supplementary information.

You configure the SBC for this interworking support at the egress interface. The applicable parameter, **diversion-info-mapping-mode**, assumes traffic egressing the interface supports either History-Info or Diversion. There are three modes of operation:

- History-Info to Diversion Header Interworking (**hist2div**)
  - If Diversion headers are already present, the SBC considers them when building the egress request.
  - The SBC adds the unknown elements of History-Info headers to the generated Diversion headers (display-name, SIP parameters, SIP headers). See the specific functions presented above.
  - The SBC optionally converts History-Info with a "380" cause to a Diversion header (cause=unknown). By default, it forwards the History-Info cause=380 transparently.
  - Existing Diversion headers received in the input appear at the end of the Diversion list.
  - Converted History-Info entry with cause = 380, shall be at the top of newly created div headers. The SBC adds other HI entries with different cause (other than 380) per the conversion.
  - The SBC retains HI entries if they don't have a cause parameter, and if that entry is not a target entry to any diverting entry.
  - When configured, the SBC inserts the cause 380 History-Info as the topmost Diversion header, because it assumes the applicable events happened before the call forwarding History-Info.
    - When converting hist2div, the SBC removes the last History-Info with a cause parameter if used to build a diversion header.
    - If this cause parameter is 380 and option hist380todiv (hist-to-div-for-cause-380) is not present, then this History-Info header is not taken into account to build a Diversion because it is not recognized as a call forward. This results in the SBC keeping the last History-Info header.
    - If this cause parameter is 380 and option hist380todiv (hist-to-div-for-cause-380) is present, then this History-Info header is taken into account to build a Diversion because it is recognized as a call forward. In that case, the History-Info header removes the last History-Info header.
- Diversion Header to History-Info Interworking (**div2hist**)
  - The SBC generates the mp-param parameter for History-Info headers.
  - If the SBC is adding converted History-Info headers to existing History-Info headers it manages both index and mp-param continuation.
  - The SBC integrates any existing History-Info headers to the top of the list in the resulting request.
  - The SBC adds the unknown R-URI elements of Diversion headers to the generated History-Info headers (display-name, SIP parameters, SIP headers). If there is any other extra info that cannot be mapped to History-Info header, the SBC ignores it.
  - If a Diversion header contains a TEL-URI, the SBC converts it into a SIP-URI and inserts it into the resulting History-Info header.
  - Tel-URI with additional parameters to SIP-URI. If a Diversion header contains a TEL-URI, the SBC converts it into a SIP-URI and inserts it into the resulting History-Info header along with any additional Tel-URI parameters.

  - The SBC adds newly converted History-Info headers to the existing History-Info headers. If the last old/existing HI entry has cause 380, the SBC removes the mp-param from the first HI entry in the list of converted HI entries that it is going to add.
  - All Diversion headers are always converted to HI headers because information in diversion headers can always be converted.
- Forced Mode (**force**)
  - This mode is similar to **div2hist**, but invokes additional actions by the SBC.
  - If History-Info headers are already present, the SBC adds new History-Info header(s) to the existing set.
  - The SBC retargeting feature adds a History-Info entry as well as the expected Index and mp to an outgoing INVITE when certain conditions are met:
    * When **force** mode is set on the realm from which the 3xx or ENUM response came.
    * When the SBC gets a redirect response (3xx) or an ENUM response.
    * When this response also contains the new URI and cause-param.
    * When it receives a cause parameter in a SIP redirect reply.
  - The SBC extracts parameters for creating a History-Info header from the Contact header of the incoming SIP redirect reply. This Contact header must contain the URI and cause. The SBC copies all this information for use in the History-Info it generates.
  - Adds History-Info headers to a SIP INVITE if it has been re-targeted.
  - For repeated re-targeting the SBC keeps adding History-Info headers to each INVITE it sends out.
  - The SBC extracts information from a received Contact header from incoming re-direct replies. For this feature SBC only uses the URI and cause.
  - The SBC ignores a hi-target-param if it is received as the Contact of a 3xx or via an ENUM response. The SBC can not rely on that information.

The SBC retains any added History-Info entry it adds to an outgoing retargeting request for ensuing retargeting requests.

History-Info to Diversion Header Interworking

When configured for this interworking, the SBC performs the following steps for all History-Info headers except the last in the incoming initial INVITE:

1. Create a new diversion header.
2. If there is a subsequent HI header, extract the cause parameter, map it to the corresponding reason parameter, and add this reason parameter to the interworked Diversion header, using the following conversion table.

History-Info Cause	Diversion Reason
404	Unknown (default value)
302	unconditional
486	user-busy
408	no-answer
480	deflection

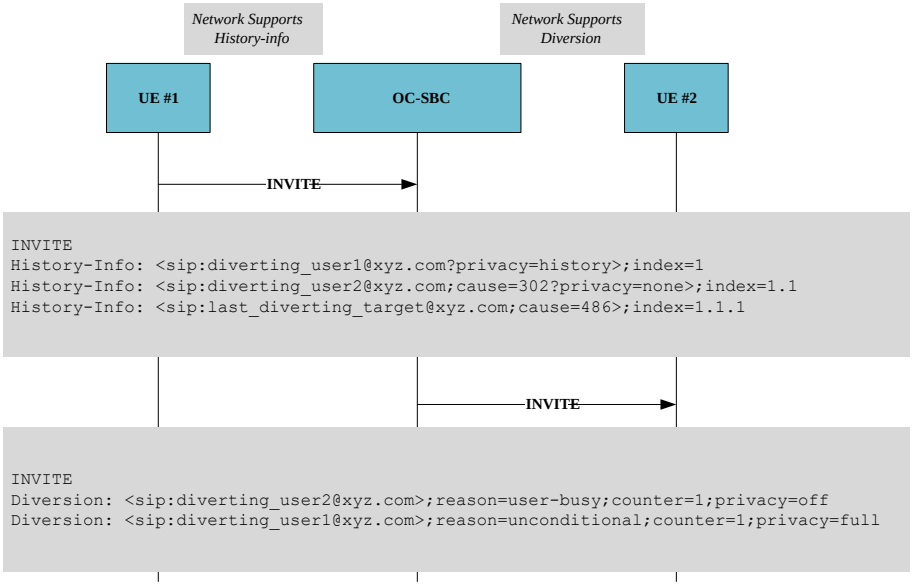
History-Info Cause	Diversion Reason
487	deflection
503	unavailable

3. If an HI entry includes a cause that is not in the list of valid causes, per RFC 7544, use the default value **Unknown** for the reason parameter.
4. If the History-Info header contains a privacy parameter, add a Privacy parameter to the Diversion header, using the following conversion table.

History-Info Privacy	Diversion Privacy
history	full
Field absent or none	Off (default value)

5. If there is no privacy parameter, use the default value **Off** in the Diversion header.
6. Add a counter parameter with the value **1**.
7. Delete the History-Info header.

The diagram below provides an example flow and the header text used for this example.



Diversion to History-Info Header Interworking

When configured for this interworking, the SBC takes the following steps for all Diversion headers in the incoming initial INVITE:

1. Create a new History-Info header.
2. Add the **index** header parameter.
3. Set the value for the first header to **1**. Append **.1** to the value of the last_index_value for the subsequent headers.
4. If the Diversion header contains a privacy parameter, add the Privacy header parameter to the History-Info header using the following conversion table.

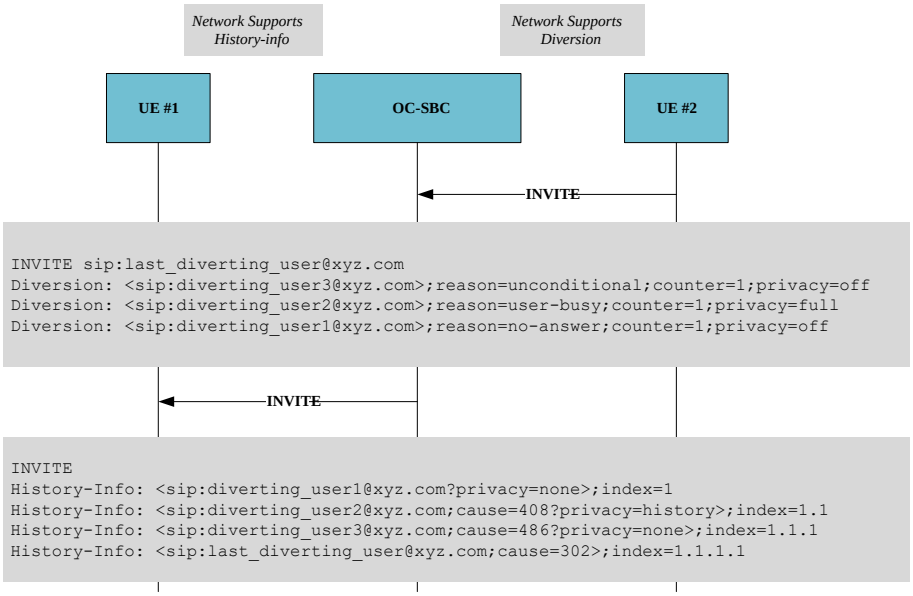
Diversion Privacy	History-Info Privacy
full	history
name	history
uri	history
off	none

5. If the previous Diversion header contains a reason parameter, add the **cause** header parameter to the History-Info header using the following conversion table. The SBC does not add a cause parameter to the first History-info entry.

Diversion Reason	History-Info Cause
unknown	404 (default value)
unconditional	302
user-busy	486
no-answer	408
deflection	480
unavailable	404
time-of-day	404
do-not-disturb	404
follow-me	404
out-of-service	404
away	404

6. If the presented reason parameter is not in the table above, set the parameter to the default value of **404**.
7. Remove the diversion header from the outgoing INVITE.

The diagram below provides an example flow and the header text used for this example.



Mapping the History-Info Cause Parameter

You can configure SBC to map the History-Info's cause 380 parameter to the Diversion header's reason=unknown parameter. You can configure the applicable parameter, **hist-to-div-**

for-cause-380, in both the **sip-config** and **sip-interface**, with the egress **sip-interface** setting taking precedence. This parameter only applies when you set the applicable **sip-interface** interworking mode to **hist2div**. The verify-config command informs you if there is a **hist-to-div-for-cause-380** without a corresponding **hist2div**.

By default, the **hist-to-div-for-cause-380** parameter is disabled, which causes the SBC to transparently forward the Hisory-Info entry with cause 380. Enabling the parameter makes the SBC interwork the parameter, allowing it to be understood by devices that support Diversion headers.

When using **hist-to-div-for-cause-380** for 380 cause mapping, the SBC places those headers at the top of the Diversion header list. This is true regardless of how many History-Info entries are present.

Anonymization of History and Diversion Information

The SBC supports anonymization of entries for both History-Info and Diversion, independent of the interworking function. You configure this function separately from the interworking function. The SBC applies anonymization rules as long as the circumstances meet all anonymization criteria. This anonymization configuration is global. For untrusted peers, the SBC changes input header addresses to the anonymous SIP URI syntax **sip:anonymous@anonymous.invalid**.

This feature uses functionality independent of the IWF to confirm whether or not the remote target is trusted. The SBC checks the **session-agent** trust mode. If the **session-agent** reports "trust-me", then assuming nothing else conflicts, the system trusts the agent. This functionality also refers to the IWF state.

If IWF is configured, the SBC performs anonymization on the output generated after conversion per RFC 7544.

If IWF is not configured:

- Remote peer trusted - The SBC does not anonymize the History-Info header or Diversion header. The Privacy header field values in incoming History-Info or Diversion header of INVITE shall be used likewise in outgoing header.
- Remote peer untrusted - The SBC checks **sip-config**, **anonymize-history-for-untrusted** setting, introduced by this feature, to determine whether it should anonymize the entries in History-Info or Diversion headers with Privacy fields set to full/history. If **anonymize-history-for-untrusted** is configured, the SBC anonymizes the input received in the initial INVITE.

The SBC uses the following steps when it is sending messages to untrusted peer.

1. Based on the mode set, do the conversion between headers.
2. If mode is not set, check for History-Info and Diversion headers entries in outgoing message.
3. For the entries where privacy value is other than "none" in History-Info and "off" in Diversion, anonymize the entries if **anonymize-history-for-untrusted** is set.
4. For HI entries with a privacy value other than "none", and for diversion entries that have a privacy value other than "off", the SBC does not anonymize entries if is not set.
5. In case the entries have Privacy settings as "none" in History-Info or "off" in Diversion, do not anonymize the entries even if **anonymize-history-for-untrusted** is set.

If a privacy header is present in INVITE with value as "history" or "header" or "full" and the outgoing INVITE is going to untrusted remote side, then all the History-Info and Diversion

entries shall be anonymized as per above section, given **anonymize-history-for-untrusted** is set.

The SBC anonymizes all History-Info and Diversion entries regardless of the value of the privacy header of each History-Info or Diversion entry. If a privacy header with above values appears in incoming INVITE, every History-Info and Diversion entry will be anonymized.

Diversion and History-Info Headers Interworking Configuration

You can configure Oracle Communications Session Border Controllers to map call transfer and call diversion information between Diversion and History-Info headers.

To configure interworking between the Diversion and History-Info headers:

1. Access the **sip-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

2. Select the **sip-interface** object to edit.

```
ORACLE(sip-interface)# select
<RealmID>:
1: realm01 172.172.30.31:5060

selection: 1
ORACLE(sip-interface)#
```

3. **diversion-info-mapping-mode**— Configure this parameter to specify how the Diversion and History-Info headers map to and work with each other on the interface. The default value is **none**.
   - **div2hist** — any Diversion headers in the initial INVITEs going out of this sip-interface will be converted to History-Info headers before sending
   - **force** — behavior is the same as **div2hist** when a Diversion header is present in the incoming INVITE. If there are no Diversion headers, a History-Info header for the current URI is added in the outgoing INVITE.
   - **hist2div** — any History-Info headers in the initial INVITEs going out of this sip-interface will be converted to Diversion headers before sending
   - **none** — no conversion applied (default)
4. Type **done** to save your configuration.

History-Info Cause 380 Parameter Interworking Configuration

You can configure Oracle Communications Session Border Controllers to map the History-Info cause 380 parameter information to Diversion headers.

To configure cause parameter interworking on a sip-interface:

1. Access the **sip-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
```

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

2. Select the **sip-interface** object to edit.

```
ORACLE(sip-interface)# select
<RealmID>:
1: realm01 172.172.30.31:5060

selection: 1
ORACLE(sip-interface)#
```

3. **hist-to-div-for-cause-380**— Configure this parameter to specify whether or not the system should perform cause parameter interworking. The default value is **disabled**.
   - **enabled**—Perform cause parameter interworking.
   - **disabled**—Do not perform cause parameter interworking.
   - **inherit**—Use the setting specified in the sip-config.
4. Type **done** to save your configuration.

Anonymize History Configuration

You can configure Oracle Communications Session Border Controllers to 'anonymize' History-Info and Diversion headers.

You configure History-Info and Diversion header anonymization globally at the sip-config.

1. Access the **sip-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

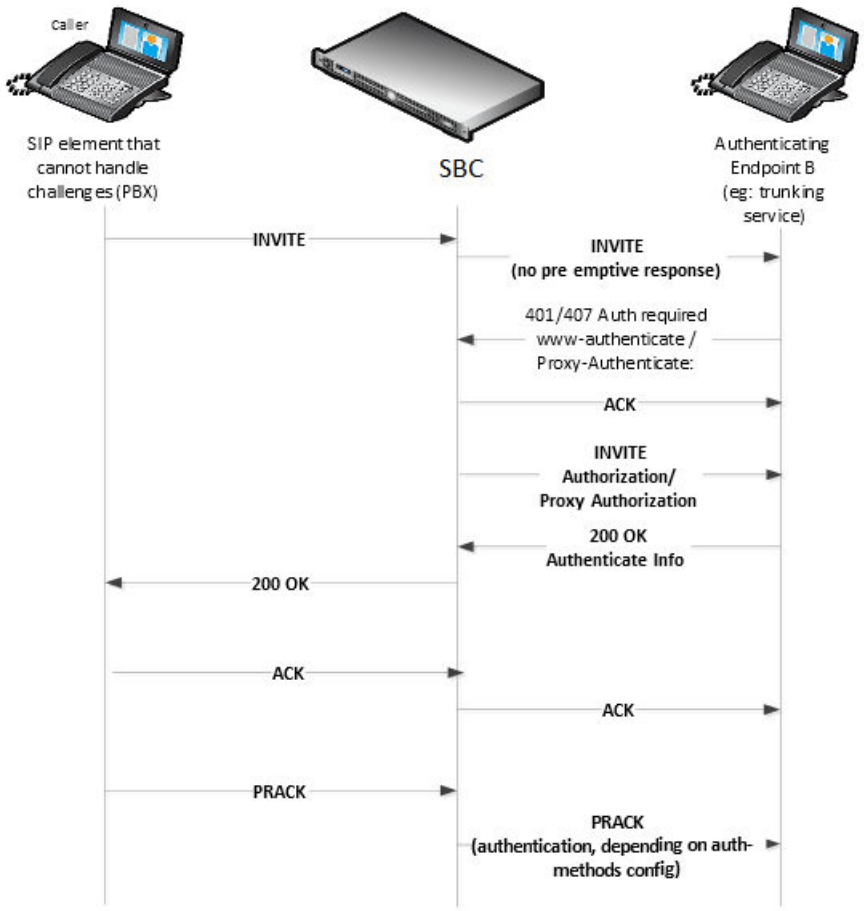
2. **anonymize-history-for-untrusted**— Configure this parameter to specify whether or not the system should anonymize parameter interworking. The default value is **disabled**.
   - **enabled**—Anonymize history interworking.
   - **disabled**—Do not anonymize history interworking.
3. Type **done** to save your configuration.

Digest Authentication with SIP

Digest authentication for Session Initiation Protocol (SIP) is a type of security feature on the SBC that provides a minimum level of security for basic Transport Control Protocol (TCP) and User Datagram Protocol (UDP) connections. Digest authentication verifies that both parties on a connection (host and endpoint client) know a shared secret (a password). This verification can be done without sending the password in the clear.

Digest authentication is disabled by default on the SBC. When digest authentication is enabled, the SBC (host) responds to authentication challenges from SIP trunking Service Providers (endpoint client). The SBC performs authentication for each IP-PBX initiating the call. However, the authentication challenge process takes place between the host and the

client only since the IP-PBX cannot handle authentication challenges. The following illustration shows the digest authentication process.



The digest authentication scheme is based on a simple challenge-response paradigm. A valid response contains a checksum of the “username” and password. In this way, the password is never sent in the clear.

By default, the SBC uses cached credentials for all requests within the same dialog, once the authentication session is established with a 200OK from the authenticating SIP element. If the in-dialog-methods attribute contains a value, it specifies the requests that have challenge-responses inserted within a dialog.

In digest authentication with SIP, the following can happen:

- More than one authenticating SIP element (IP-PBX) may be the destination of requests.
- More than one authentication challenge can occur in a SIP message. This can occur when there are additional authenticating SIP elements behind the first authenticating SIP element.
- The SBC distinguishes whether the IP-PBX is capable of handling the challenge. If Digest Authentication is disabled (no auth-attributes configured) on the Session Agent, the challenge is passed back to the IP-PBX.

> **Note:**
>
> If there are multiple challenges in the request, and if the SBC has only some of the cached credentials configured, the SBC adds challenge-responses for the requests it can handle, and does not pass the challenge back to the IP-PBX.

Challenge-Responses in Requests not in the Dialog

A digest authentication session starts from the client response to a www-authenticate/proxy-authenticate challenge and lasts until the client receives another challenge in the protection space defined by the auth-realm. Credentials are not cached across dialogs; however, if a User Agent (UA) is configured with the auth-realm of its outbound proxy, when one exists, the UA may cache credentials for that auth-realm across dialogs.

> **Note:**
>
> Existing Oracle Communications Session Border Controller behavior with surrogate-agents is that they cache credentials from REGISTER for INVITE sessions only if the Oracle Communications Session Border Controller is considered a UA sending to its outbound proxy.

Configuring Digest Authentication

In the Oracle Communications Session Border Controller ACLI, you can access the Digest Authentication object at the path **session-router**, **session-agent**, **auth-attribute**. If enabled, the Digest Authentication process uses the attributes and values listed in this table.

> **Note:**
>
> If enabling Digest Authentication, all attributes listed below are required except for the in-dialog-methods attribute which is optional.

The following table lists the digest authentication object

```
ORACLE(auth-attribute)# show
        auth-attribute
                auth-realm                      realm01
                username                        user
                password                        ********
                in-dialog-methods               ACK INVITE SUBSCRIBE
```

To configure digest authentication on the Oracle Communications Session Border Controller:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type session-router and press Enter to access the session router-related objects.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type session-agent and press Enter to access the session agent-related attributes.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

4. Type auth-attribute and press Enter to access the digest authentication-related attributes.

```
ORACLE(session-agent)# auth-attribute
ORACLE(auth-attribute)#
```

5. auth-realm — Enter the name (realm ID) of the host realm initiating the authentication challenge. This value defines the protected space in which the digest authentication is performed. Valid value is an alpha-numeric character string. Default is blank.

```
ORACLE(auth-attribute)# auth-realm realm01
```

6. username — Enter the username of the client. Valid value is an alpha-numeric character string. Default is blank.

```
ORACLE(auth-attribute)# username user
```

7. password — Enter the password associated with the username of the client. This is required for all LOGIN attempts. Password displays while typing but is saved in clear-text (i.e., *****). Valid value is an alpha-numeric character string. Default is blank.

```
ORACLE(auth-attribute)# password *******
```

8. in-dialog-methods — Enter the in-dialog request method(s) that digest authentication uses from the cached credentials. Specify request methods in a list form separated by a space enclosed in parentheses. Valid values are:

- INVITE | BYE | ACK | CANCEL | OPTIONS | SUBSCRIBE | PRACK | NOTIFY | UPDATE | REFER

```
ORACLE(auth-attribute)# in-dialog-methods (ack invite subscribe)
```

> **Note:**
>
> The methods not in this list are still resubmitted if a 401/407 response is received by the Oracle Communications Session Border Controller.

If you do not specify any in-dialog-method value(s), digest authentication does not add challenge-responses to in-dialog requests within a dialog.

This attribute setting applies to in-dialog requests only.

Additional Notes

The following are additional notes that describe the digest authentication process:

- The Oracle Communications Session Border Controller always challenges the first LOGIN request, and initial authentication begins with that request. The recalculated authorization key — the credentials — are then included in every subsequent request.
- If the Oracle Communications Session Border Controller does not receive any communication from the client within the expiration period, the Oracle Communications Session Border Controller logs the client out and tears down the transport connection. Faced with interface loss, the Oracle Communications Session Border Controller default behavior is to flush all warrant information from the target database. This response necessitates that the client first login/re-register with the Oracle Communications Session Border Controller, and then repopulate the empty database using a series of ADD requests. This behavior ensures that client and Oracle Communications Session Border Controller target databases are synchronized.

  Alternatively, when faced with interface loss, the Oracle Communications Session Border Controller can retain all warrant information within the target database. This response necessitates only that the client first login/re-register with the Oracle Communications Session Border Controller. After successful registration the client should, but is not required to, use a series of GET, ADD, and DELETE requests to ensure that the Oracle Communications Session Border Controller and client target databases are synchronized.
- The Oracle Communications Session Border Controller ignores the Authentication-Info header that comes in the 200OK response after digest authentication is complete. The Oracle Communications Session Border Controller receives a 401/407 response from the client. However, some surrogate-agents may process the Authentication-Info header in a single challenge.

Digest Authentication and High Availability

The Oracle Communications Session Border Controller supports digest authentication in high availability (HA) environments. The session-agent configuration, which includes the digest authentication parameters on the primary Oracle Communications Session Border Controller, are replicated on the HA Oracle Communications Session Border Controller. However, cached credentials on the primary device are not replicated on the HA device.

Surrogate Agents and the SBC

In the case where a surrogate-agent is configured for the IP-PBX, you do not have to configure digest authentication attributes in the session-agent object for the same IP-PBX. The surrogate-agent authentication configuration takes precedence over the session-agent authentication configuration and so it is ignored.

The following illustration shows an example of a surrogate-agent with a session-agent in the network.

Surrogate Registration

The Oracle Communications Session Border Controller surrogate registration feature lets the Oracle Communications Session Border Controller explicitly register on behalf of a Internet Protocol Private Branch Exchange (IP-PBX). After you configure a surrogate agent, the Oracle Communications Session Border Controller periodically generates a REGISTER request and authenticates itself using a locally configured username and password, with the Oracle Communications Session Border Controller as the contact address. Surrogate registration also manages the routing of class from the IP-PBX to the core and from the core to the IP-PBX.

Registration

The Oracle Communications Session Border Controller uses the configuration information of the surrogate agent that corresponds to a specific IP-PBX. After the surrogate agents are loaded, the Oracle Communications Session Border Controller starts sending the REGISTER requests on their behalf. (You can configure how many requests are sent.)

The SIP surrogate agent supports the ability to cache authorization or proxy-authorization header values from a REGISTER 401, 407, and 200 OK messages and reuse it in subsequent requests, such as in an INVITE. This allows the Oracle Communications Session Delivery Manager to support authorization of subsequent requests in cases such as, when a customer PBX doesn't support registration and authentication. It also supports the generation of authorization/proxy-authorization header if subsequent requests get challenged with a 401/407 response.

If the Oracle Communications Session Border Controller receives 401 or 407 responses to REGISTER, requests, it will use the Message Digest algorithm 5 (MD5) digest authentication to generate the authentication information. You need to specify the password. The Oracle Communications Session Border Controller also supports authentication challenge responses with the quality of protection code set to auth (qop=auth), by supporting the client nonce (cnonce) and nonce count parameters.

The Oracle Communications Session Border Controller creates a registration cache entry for each of the AoRs for which it is sending the REGISTER requests. When the Oracle Communications Session Border Controller receives the associated URIs, it checks whether the customer host parameter is configured. If it is configured, the Oracle Communications Session Border Controller changes the host in the received Associated-URI to the customer host. If it is not configured, the Oracle Communications Session Border Controller does not change the Associated-URI. It makes the registration cache entries that correspond to each of the Associated-URIs. The From header in the INVITE for calls coming from the IP-PBX should have one of the Associated-URIs (URI for a specific phone). If the Oracle Communications Session Border Controller receives a Service-Route in the 200 (OK) response, it stores that as well.

The Oracle Communications Session Border Controller uses the expire value configured for the REGISTER requests. When it receives a different expire value in the 200 OK response to the registration, it stores the value and continues sending the REGISTER requests once half the expiry time has elapsed.

REGISTER requests are routed to the registrar based on the configuration. The Oracle Communications Session Border Controller can use the local policy, registrar host and the SIP configuration’s registrar port for routing.

If the Oracle Communications Session Border Controller is generating more than one register on behalf of the IP-PBX, the user part of the AoR is incremented by 1 and the register contact-user parameter will also be incremented by 1. For example, if you configure the register-user

parameter as caller, the Oracle Communications Session Border Controller uses caller, caller1, caller2 and so on as the AoR user.

Authenticating Registrations

There are two ways to configure the SBC to authenticate a registration using a surrogate agent. These include defining authentication criteria within a realm configuration and within the surrogate agent itself. Surrogate agent authentication, for both register requests and for call methods, are applications of digest authentication.

The first method uses **surrogate-agent** and **realm-config** configuration. This method is considered more robust, supporting multi-tenant, diverse IP-IPXs, and intra-realm registration support. The second method refers to the **surrogate-agent** configuration alone, applying to simpler deployments that, for example, do not request registration from a registrar outside of the IP-PBX's realm. The first method takes precedence, if configured, and also works when registrars and IP-IPXs reside on the same realm. The second method is considered a legacy configuration maintained for SBC deployments that have been using it. These methods are considered exclusive and the SBC throws a configuration verification error when it finds you have set up both methods on a surrogate agent.

When confronted with an authentication challenge to a surrogate agent's registration request, the SBC:

1. Checks whether you have configured the **auth-user-lookup** attribute in the **surrogate-agent**. If so, the SBC :
   a. Searches for a **realm-config** that contains an **auth-attribute** object with an **auth-user-lookup** value that is the same as the **auth-user-lookup** value in the **surrogate-agent**. An example **auth-user-lookup** setting is shown below.

      ```
      ORACLE(surrogate-agent)# auth-user-lookup TargetRealmAuthUser
      ```

   b. If found, the SBC issues a response to the challenge using the **username** and **password** values in the **auth-attribute** presented within the **realm-config**.
   c. If not found, the registration fails.
2. If the **auth-user-lookup** is empty, the SBC:
   a. Refers to the **auth-user** and **password** parameters in the surrogate configuration.
   b. If found, Issues a response to the challenge using those **auth-user** and **password** values.
   c. If not found, the registration fails.

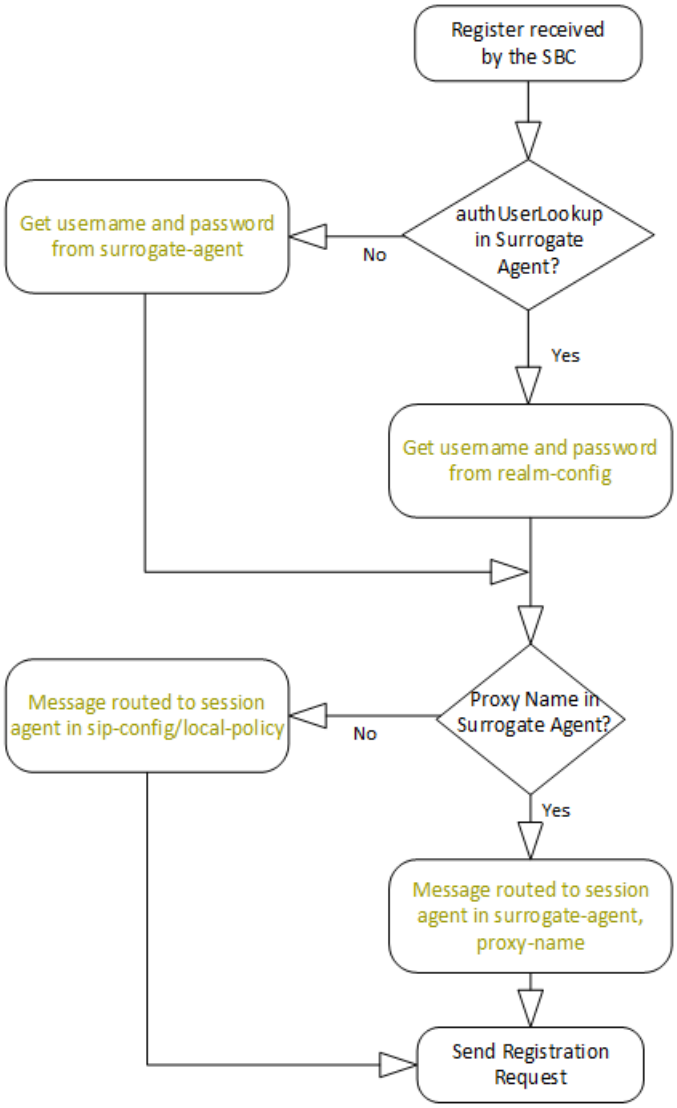
The SBC also has multiple means of routing the response to the correct registrar. The SBC follows this process to route the registration as well as the challenge response. To route to the correct registrar, the SBC:

1. Checks to see if you have configured the **proxy-name** parameter in the **surrogate-agent**. This **proxy-name** setting must match the **name** parameter in a **session-agent** you have configured for the registrar. An example **proxy-name** setting is shown below.

   ```
   ORACLE(surrogate-agent)# proxy-name MyProxyName
   ```

   If you have configured this parameter correctly, the SBC routes to that proxy.
2. If you not have configured the **proxy-name** parameter, the SBC routes the REGISTER using the **registrar-host** and **registrar-port** parameters in the **sip-config**.

3. If the system cannot route using the **sip-config**, the SBC attempts to route the response to the **next-hop** in a matching **local-policy** attribute.
4. If there is no match in any **local-policy**, the SBC replies to the source that the registration has failed.



Setting the un-register Parameter

Additional applicable **surrogate-agent** configuration allows you to enable the **un-register** parameter. Enabling this parameter causes the SBC to send the all REGISTER requests generated from this surrogate agent with Expires: 0 to the REGISTRAR, and remove all associated entries from the SBC registration-cache upon each registration.

```
ORACLE(surrogate-agent)# un-register enabled
```

Surrogate Agent Authentication Across Realms

The SBC uses an authentication attribute element in realms to support surrogate agent authentication requests initiated from other realms. This is a multi-instance element that supports the authentication of non-REGISTER traffic to surrogate agents with different authentication detail. The key for these lookups is the combination of the authentication realm

and the authentication user lookup configurations. If you do not configure authentication attribute element in the realm, the SBC handles surrogate agent authentication using the authentication table setup on the IP-PBX session agent, which supports this traffic in a single realm only.

This feature resolves two key surrogate agent authentication issues:

- In a multi-tenanted environment, there might be multiple IP-PBX systems or realms trying to use the same surrogate agent function. Therefore, there is a need to authenticate traffic to surrogate agents by the SBC on the SIP Trunk Realm with no association or relation to the IP-PBX system or realm.
- In addition, some SIP Trunk providers send 401/407 challenges to all outbound calls. The SBC utilizes the authentication table setup on the **session-agent** for username/password to response to the 401/407 challenge. However, if the **auth-realm** value is the same for all customers, then the SBC cannot provide the correct username/password in response to the 401/407 challenge. When this feature is not set up, the SBC always uses the first entry on the **auth-attributes** in the session agent's table for all outbound calls.

You configure the SBC to populate the authentication headers using your configuration from either the softswitch's surrogate agent or realm during a 401/407 authentication challenge. The SBC uses these tables to look up the authentication realm and obtain the username and password. The SBC uses the username and password to authenticate the request.

> **Note:**
>
> The device initiating the authentication challenge to the surrogate agent does not need to be a softswitch.

The SBC chooses the table based on your configuration:

- If you have configured the **auth-user-lookup** parameter in the **local-policy** attribute, then the SBC builds the authentication headers from the **realm-config** configuration.
- If the **auth-user-lookup** parameter in the **local-policy** attribute is empty, then the SBC builds the authentication headers from the IP-PBX **session-agent** configuration.

The SBC uses the following objects to perform this feature's function:

- A **local-policy** that forwards traffic to the target softswitch, which may or may not reside in a different realm from the source traffic. Further configuration supports intra-realm surrogate agent authentication.
- The **policy-attributes** within that **local-policy** that includes the target **auth-user-lookup** value and the target **realm** of the surrogate agent.
- An **auth-attributes** sub-element in the target **realm-config**. This sub-element includes:
  - The **realm** of the surrogate agent. This is the host realm initiating the authentication challenge. This value defines the protected space in which the digest authentication is performed.
  - An **auth-user-lookup** value that matches the **auth-user-lookup** in the **local-policy**.
  - The **username** and **password** that provide access to the target surrogate agent.

Cross Realm Surrogate Agent Authentication Operation

After configuration, the SBC authenticates applicable cross-realm surrogate agent authentication, allowing registration and call traffic.

When the SBC receives traffic that triggers your **local-policy**, it uses the policy's **auth-user-lookup** value in combination with the target realm of the **local-policy** to prepare for authentication.

The key used for these lookups is a combination of the authentication realm and the user lookup. Typical behavior during operation includes:

- If the **auth-user-lookup** in the **policy-attribute** is empty, the SBC gets the configured **password** for authorization from the softswitch **session-agent** configuration.
- If the **auth-user-lookup** in the **policy-attribute** is not empty, the SBC selects the AuthAttributes (username/password) for the matching **auth-user-lookup** in the **realm-config**.
- If the **auth-user-lookup** in **policy-attribute** is not empty, but there is no corresponding entry in **realm-config**, then the call fails as unauthorized. Additionally, the SBC displays a warning during **verify-config**.

When operating with the **auth-user-lookup** from the **local-policy** attributes, the SBC uses the returned value of **username** and **password** for authenticating the request. During the processing of the INVITE request, a reference to the selected local policy route is stored along with the route.

Additional Notes on Operation

The following are additional notes that describe the digest authentication process:

- The SBC always challenges the first LOGIN request, and initial authentication begins with that request. The selected authorization key — the credentials — are then included in every subsequent request.
- If the SBC does not receive any communication from the client within the expiration period, the SBC logs the client out and tears down the transport connection. Faced with interface loss, the SBC default behavior is to flush all warrant information from the target database. This response necessitates that the client first login/re-register with the SBC, and then repopulate the empty database using a series of ADD requests. This behavior ensures that client and SBC target databases are synchronized.

  Alternatively, when faced with interface loss, the SBC can retain all warrant information within the target database. This response necessitates only that the client first login/re-register with the SBC. After successful registration the client should, but is not required to, use a series of GET, ADD, and DELETE requests to ensure that the SBC and client target databases are synchronized.
- The SBC ignores the Authentication-Info header that comes in the 200OK response after digest authentication is complete. The SBC receives a 401/407 response from the client. However, some surrogate-agents may process the Authentication-Info header in a single challenge.

Routing Calls from an IP-PBX

When it receives a call from an IP-PBX configured as a surrogate agent, the SBC attempts to route, and if challenged, perform authentication on behalf of the IP-PBX to authorize the call. It does this by validating the request with your configuration. After routing the call to its destination, the callee may challenge the call, in which case the SBC has an opportunity to authenticate the call. If the SBC cannot authenticate the call, it leaves authentication procedures to other devices, such as the IP-PBX itself.

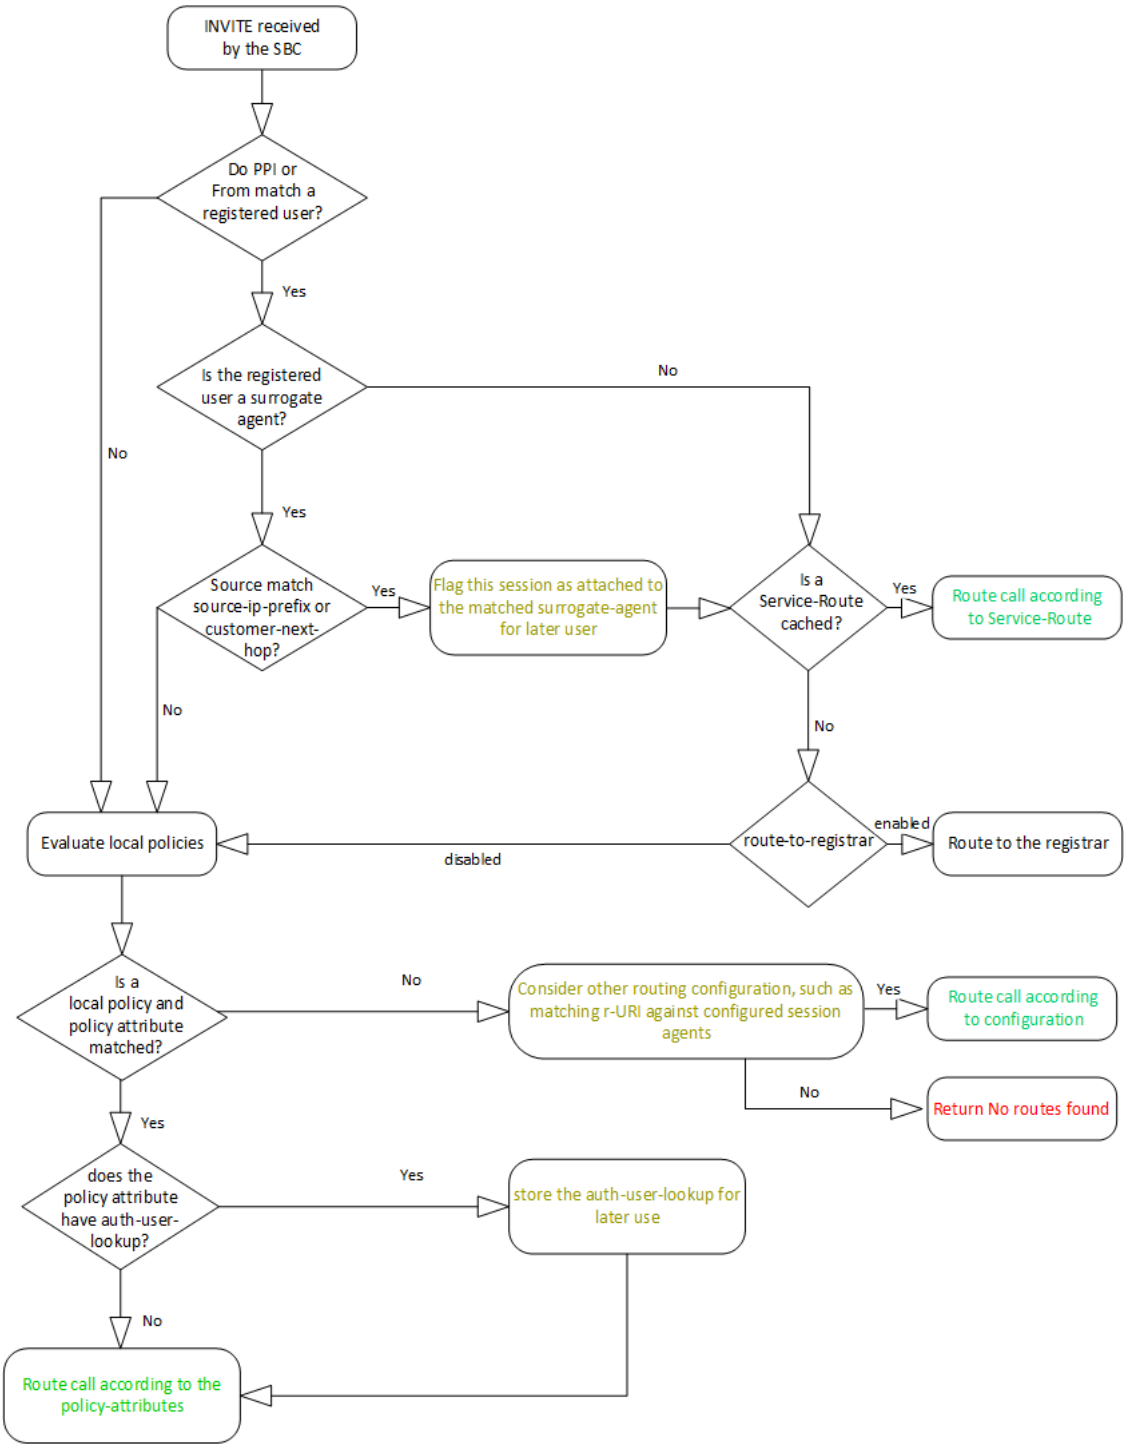
The process of routing a call from an IP-PBX using a Surrogate Agent fits within the overall routing process, as shown in the following diagram. While determining a route, the SBC also

determines whether the call may be authenticated using the SBC as a surrogate. The call may be routed by multiple processes, each of which can include a **surrogate-agent** match and specifying that the SBC can trust the caller.

To route the call, the SBC looks for a service route. After finding the corresponding registration Service-Route entry, the SBC uses the Service-Route for this endpoint to route the call, if it exists.

If no Service-Route exists, but the **route-to-registrar** parameter is enabled on the **sip-interface**, the SBC tries to route the call to the registrar. If **route-to-registrar** is disabled, the SBC refers to **local-policy** for routing.

At this point, the SBC routes the call, and is prepared if it needs to respond to an authentication challenge.



Having received a challenge, the SBC matches the challenge with source and SIP information presented by the caller and stored by the SBC. This matching process is explained below. If the match is successful, the SBC authenticates the call on behalf of the IP-PBX. After authentication succeeds, media between the caller and callee may proceed.

> **Note:**
>
> You can configure the **surrogate-agent** to override the **sip-interface**, **route-to-register** setting. If the surrogate agent's **route-to-registrar** parameter is set to disable, it takes precedence over the **sip-interface** setting. In this case, the SBC does not try to route the call to the registrar.

Matching an INVITE to a Surrogate Agent

You can configure the SBC to perform authentication for an end station sending an INVITE through its surrogate agent in two ways. These methods match information in your **surrogate-agent**, and in some cases **session-agent** configurations, with source information in the request. The SBC uses this function for requests needing authentication, except REGISTERs. This processing is not relevant to calls sent to a **surrogate-agent**.

Assuming configuration, to confirm and authenticate requests originating from a surrogate agent, the SBC matches:

1. Information in the P-Preferred-Identity (PPI) or the FROM header in the request to a registered user, and then your **register-user** and **register-host** configuration in your **surrogate-agent**. These matches confirm the **surrogate-agent** from which the request came. If these do not match, the SBC does not continue with authentication.

   > **Note:**
   >
   > The PPI or FROM header should contain the user portion of one of the Associated-URIs that it received from the registrar in the 200 (OK) responses to REGISTER requests. It should also have a hostname.

   > **Note:**
   >
   > Should the **register-host** match fail, the SBC tries to match the host portion with your **customer-host** configuration.

2. IP source addressing to the **source-ip-prefix** parameter within the **surrogate-agent** element. This confirms that the SBC can perform the authentication. If you have configured this parameter and there is no match, the SBC does not authenticate the request.
3. If there is no **source-ip-prefix** configuration, the SBC tries to match the **customer-next-hop** configuration in the **surrogate-agent** with the source of the incoming request. This can also confirm that the SBC can perform the authentication.

To perform this step, the SBC compares the source IP of the request with the **customer-next-hop** parameter. You can configure the **customer-next-hop** parameter with a **session-agent** name, a **session-agent-group** or any IP address. That value must match:

- The **hostname** Session Agent, or the **group-name** of the Session Agent Group.
- If configured with an IP address, your value must match the source IP of the request.

The **source-ip-prefix** configuration provides the SBC with the flexibility to perform the authentication against specific IP addresses, multiple prefixes and/or IP ranges. The **customer-next-hop** configuration allows for only a single entry, attempting to match to a single

address, a **hostname** configuration on a corresponding **session-agent** or the **group name** of the SAG to which the session agent belongs.

> **Note:**
>
> If **source-ip-prefix** is not configured and the **customer-next-hop** matches a **session-agent-group**, the SBC uses that group to choose a specific **session-agent**.

Process Detail

The steps below present SBC behavior when it receives a request from a **surrogate-agent** that needs authentication, other than a REGISTER. The steps use an INVITE as an example. To support these calls the SBC:

1. Determines if there is a **surrogate-agent** match by ensuring the PPI or FROM matches the **register-user** and the **register-host** or **customer-host** in the **surrogate-agent** agent configuration.

   > **Note:**
   >
   > The SBC attempts to match to the PPI only if you have enabled the **sip-ims-feature** on the applicable **sip-interface**.

   > **Note:**
   >
   > If there is no match with the **register-host**, the SBC attempts to match the applicable host portion with the **customer-host** configuration.

   - If not, the SBC attempts to use other configuration to proceed with the call, such as local policy. If those processes do not find a route, the SBC sends the caller with a 480 - No routes found message.
   - If so, the SBC attempts to verify the source of the INVITE to determine whether or not it can perform the authentication on behalf of the IP-PBX.
2. To determine if it should perform the authentication, the SBC checks whether the **surrogate-agent** has a **source-ip-prefix** configuration:
   - If so, the SBC matches the source IP address with any of your **source-ip-prefix** settings in the **surrogate-agent**.
     - If there is a match, the SBC considers the INVITE as originated from a trusted source and it can perform authentication on behalf of the **surrogate-agent**.
     - If it does not match, the SBC does not perform authentication on behalf of the **surrogate-agent**, and forwards a 401 with challenge towards the IP-PBX.
3. If you have not configured the **source-ip-prefix**, the SBC can next refer to your **customer-next-hop** configuration and check for a match. to the **surrogate-agent**. Detail on matching criteria is above.
   - If there is a match, the SBC considers the INVITE as originated from a trusted source and performs authentication on behalf of **surrogate-agent**.

- If it does not match, the SBC does not perform authentication on behalf of **surrogate-agent**, and forwards 401 with challenge towards the endpoint.

4. If there is a match, the SBC generates an INVITE with authentication parameters and sends it to the REGISTRAR to confirm the authentication.
5. If the authentication is successful, the SBC sends a 200 OK to the IP-PBX, and routes the call to the callee.
6. If the authentication fails, the SBC sends a 401 with challenge to the IP-PBX.
7. At this point, the endpoint may or may not attempt to authenticate itself directly with the REGISTRAR.
   - If not, the call does not proceed.
   - If so, and the authentication is successful, media may proceed between the caller and callee.
   - If so, and the authentication fails, the REGISTRAR replies to the IP-PBX directly with (an authentication failed message), and the call does not proceed.

Configuration Detail on Verifying Source IP

You configure the **source-ip-prefix** and the **customer-next-hop** parameters on the applicable **surrogate-agent**. The **source-ip-prefix** accepts any number of IP addresses and IP address prefixes in the format <ip>/<subnet>. If you set multiple values, separate them with a space and enclose them with parenthesis (). Addressing can be IPv4, IPv6 or a combination of both. The SBC performs individual match checks in the same order as your configuration.

For example, to configure the agent to trust IPs 192.168.1.0, 172.16.10.10 and 172.168.x.x, you can configure the parameter as follows.

```
ORACLE(surrogate-agent)#source-ip-prefix (192.168.1.0 172.168.0.0/16
172.16.10.10)
```

In contrast, the **customer-next-hop** parameter accepts a single entry as an IP address, FQDN, Session Agent name, or Session Agent Group name.

```
ORACLE(surrogate-agent)#customer-next-hop 192.168.1.0
```

The SBC prevents you from configuring parameters using an incorrect format.

Related Configuration

Note the following configurations and their impact on this authentication process.

- This feature fully supports HA deployments.
- If you disable the **sip-ims-feature** on the ingress **sip-interface**, the SBC uses only the FROM header to determine the associated **surrogate-agent**, ignoring any PPI header.

Call Flow Examples

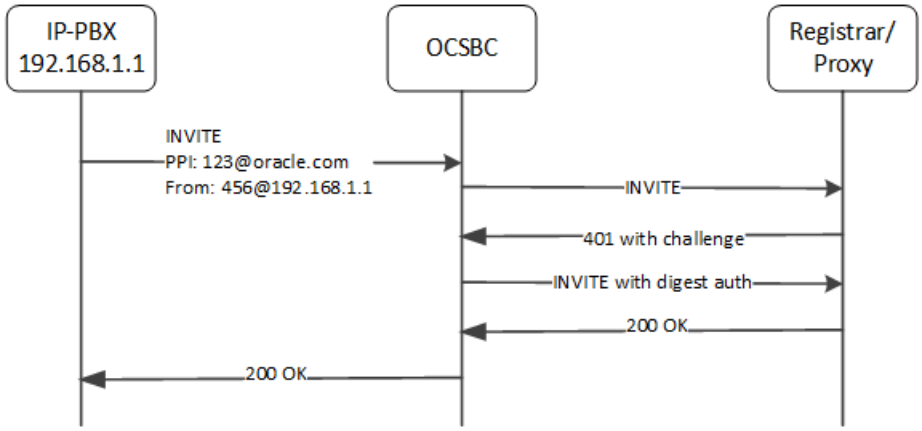
The call flows in this topic demonstrate how the SBC identifies the **surrogate-agent** for an incoming call for the purpose of authentication. Your **surrogate-agent**, **session-agent**, and **sip-interface** configuration are key to processing these calls.

Call Flow 1

This first call flow depicts the SBC successfully handling the end station authentication. In this case, the SBC identifies the **surrogate-agent** by matching PPI with the **register-user** and **register-host** parameters in the **surrogate-agent** configuration.

```
surrogate-agent:
      register-host: oracle.com
      register-user: 123
      source-ip-prefix: 192.168.0.0/16
```

Next, the SBC matches the source IP of the INVITE request with the **source-ip-prefix** parameter in the **surrogate-agent** configuration to determine if it should perform surrogate authentication. Note the source IP address, 192.168.1.1 falls in the range of the setting, 192.168.0.0/16.

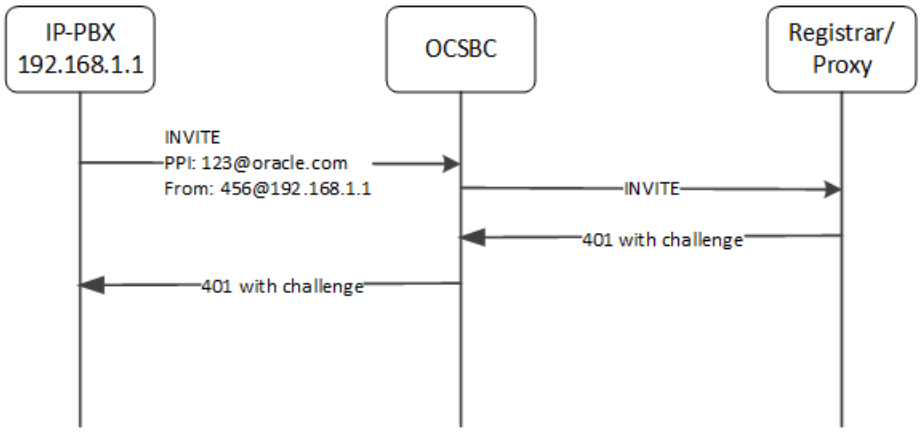


The SBC does not reference the **customer-next-hop** parameter because you have configured the **source-ip-prefix** with some value.

Call Flow 2

This next call flow depicts the SBC not handling an end station authentication. In this case, the **source-ip-prefix**, configured to 172.16.0.0/16, does not match the source IP address.

```
surrogate-agent:
      register-host: oracle.com
      register-user: 123
      source-ip-prefix: 172.16.0.0/16
```

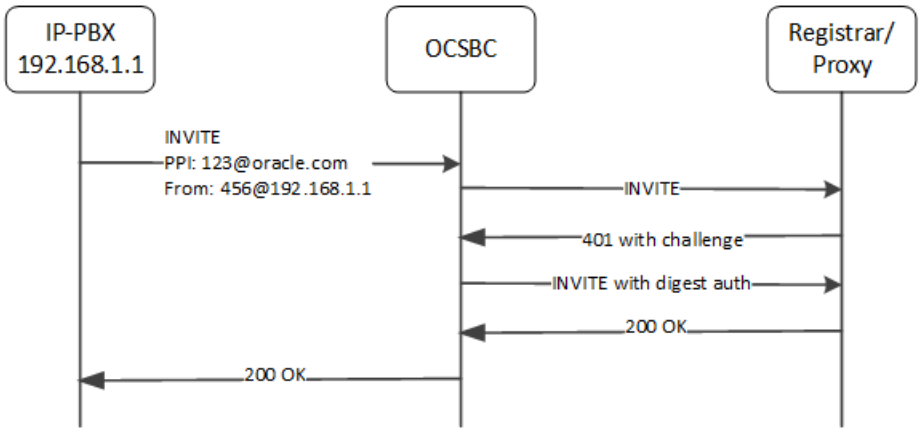


Again, the SBC does not reference the **customer-next-hop** parameter.

Call Flow 3

Consider this next case, wherein the **source-ip-prefix** is not configured. But the relevant configuration, shown below, includes a **customer-next-hop** configuration that provides a match.

```
surrogate-agent:
      register-host: oracle.com
      register-user: 123
      customer-next-hop: SA1
      source-ip-prefix: <empty>
session-agent:
      hostname: SA1
      ip-address: 192.168.1.1
```

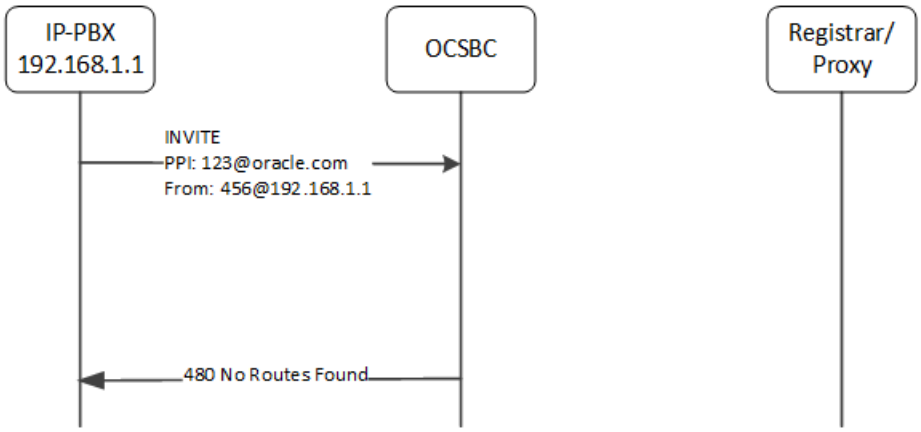


Call Flow 4

Consider this next case, wherein the **surrogate-agent** configuration fails to identify the source correctly. Because the **register-host** and **register-user** values do not match either the PPI or FROM presented in the INVITE, the SBC does not have a means of forwarding the INVITE, so it replies with '480 - No Routes Found' message.

```
surrogate-agent:
      register-host: acmepacket.com
      register-user: 486
```

```
customer-next-hop: <any value>
source-ip-prefix: <any value>
```



Separate from the feature, the SBC could use a **local-policy** or other routing configuration, to route this call.

Surrogate Agent Refresh on Invalidate

Surrogate agent registrations normally only re-register when nearing their expiration time. When a registrar fails, the surrogate agent will wait until the expiration time to refresh the registration with an in-service registrar.

You can configure your Oracle Communications Session Border Controller to immediately refresh the surrogate agent registrar with an in-service registrar by enabling the existing parameter **invalidate-registrations**.

Invalidate Registrations

An existing feature called **invalidate-registrations** located in the session agent keeps track of when surrogate agents go out of service. When REGISTER messages are received, registration entries that had out-of-service session agents since the last REGISTER will always allow the message through to the registrar (as opposed to responding directly from the cache).

The **invalidate-registrations** parameter in session agent configuration enables the Oracle Communications Session Border Controller to detect failed Registrar session agents.

If invalidate-registrations is enabled for the session agent, a response from a surrogate REGISTER that contains a service-route header that corresponds to a session-agent is installed to the registration cache entry.

The surrogate-agents are scanned. Surrogate agents with registration entries matching the out-of-service registrar have their timer reset to initiate a refresh. For an immediate refresh, the registration entry will only be considered when the service-route session agent goes out-of-service. The service-route session agent takes precedence and any previous registrar session agent w ill not be considered for an immediate refresh of the surrogate-agent registration.

Performance Impact

In cases with a large number of surrogate-agent registrations, there may be an impact to CPU usage when a session-agent goes out-of-service. All of the surrogate-agent registrations are scanned at that time. Refresh registrations are then sent out on timers.

Media Inactivity Timer Configuration

To disable the media inactivity timer for calls placed on hold:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-agent** and press Enter.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

   If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration you want to edit.

4. **invalidate-registration**—Set this parameter to **enabled** if you want to use the manual trigger to send this session agent offline (and therefore invalidate the registrations associated with it). The default is **disabled**.
5. Save and activate your configuration.

Surrogate Registration Configuration

Surrogate registration allows the SBC to explicitly register endstations on behalf of an IP-PBX. Surrogate registration also manages the routing of calls to and from the IP-PBX and core (registrar).

Configure multiple elements depending on your deployment's design for establishing IP-PBX proxies that you want the SBC to register. Elements include:

- surrogate-agent
- realm-config
- session-agent
- local-policy

Configuring Surrogate Registration

You can configure surrogate registration using the ACLI. You need to configure a surrogate agent for each IP-PBX proxy for which the SBC registers. Those parameters that are optional are marked, the rest are mandatory.

To configure the surrogate agent:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ACMEPACKET# configure terminal
```

2. Type **session-router** and press Enter to access the system-level configuration elements.

```
ACMEPACKET(configure)# session-router
```

3. Type **surrogate-agent** and press Enter. The prompt changes to indicate you can configure individual parameters.

```
ACMEPACKET(session-router)# surrogate-agent
ACMEPACKET(surrogate-agent)#
```

From this point, you can configure surrogate agent parameters. To view all surrogate agent configuration parameters, enter a **?** at the system prompt.

4. **register-host**—Enter the registrar's hostname to be used in the Request-URI of the REGISTER request. This name is also used as the host portion of the AoR To and From headers.
5. **register-user**— Enter the user portion of the AoR (Address of Record).
6. **state**—Set the state of the surrogate agent to indicate whether the surrogate agent is used by the application. The default value is **enabled**. The valid values are:
   - enabled | disabled
7. **realm-id**— Enter the name of realm where the surrogate agent resides (where the IP-PBX proxy resides). There is no default.
8. **description**—Optional. Enter a description of this surrogate agent.
9. **customer-host**—Optional. Enter the domain or IP address of the IP-PBX, which is used to determine whether it is different than the one used by the registrar.
10. **customer-next-hop**—Enter the next hop to this surrogate agent:
    - session agent group:

      ```
      SAG: <session agent group name>
      ```

    - session agent:

      ```
      <hostname> or <IPV4>
      ```

    - specific IP address:

      ```
      <IPV4> or <IPV4: port>
      ```

11. **register-contact-host**—Enter the hostname to be used in the Contact-URI sent in the REGISTER request. This should always point to the SBC. If specifying a IP address, use the egress interface's address. If there is a SIP NAT on the registrar's side, use the home address in the SIP NAT.
12. **register-contact-user**—Enter the user part of the Contact-URI that the SBC generates.
13. **password**—If you are configuring the auth-user parameter, you need to enter the password used in case the registrar sends the 401 or 407 response to the REGISTER request.
14. **register-expires**—Enter the expires in seconds to be used in the REGISTER requests. The default value is 600,000 (1 week). The valid range is:
    - Minimum—0

- Maximum—999999999

15. **replace-contact**—This specifies whether theSBC needs to replace the Contact in the requests coming from the surrogate agent. If this is enabled, Contact will be replaced with the Contact-URI the SBC sent in the REGISTER request. The default value is **disabled**. The valid values are:
    - enabled | disabled
16. **route-to-registrar**—This indicates whether requests coming from the surrogate agent should be routed to the registrar if they are not explicitly addressed to the SBC. The default value is **enabled**. The valid values are:
    - enabled | disabled
17. **aor-count**—Enter the number of registrations to do on behalf of this IP-PBX. If you enter a value greater than **1**, the SBC increments the register-user and the register-contact-user values by that number. For example, if this count is 3 and register-user is john then users for three different register messages will be john, john1, john2. It does the same for the register-contact-user values. The default value is **1**. The valid range is:
    - Minimum—0
    - Maximum—999999999
18. **auth-user**—Enter the authentication user name you want to use for the surrogate agent. This name is used when the SBC receives a 401 or 407 response to the REGISTER request and has to send the REGISTER request again with the Authorization or Proxy-Authorization header. The name you enter here is used in the Digest username parameter. If you do not enter a name, the SBC uses the value of the register-user parameter.
19. **max-register-attempts**—Enter the total number of times to attempt registration until success. The default value is **3**. The valid range is:
    - Minimum—0 (No Limit)
    - Maximum—10
20. **register-retry-time**—Enter the time to wait after an unsuccessful registration before re-attempting. The default value is **300**. The valid range is: Range 30-3600
    - Minimum—30
    - Maximum—3600
21. **count-start**—Enter the starting value for numbering when performing multiple registrations. The default value is **1**. The valid range is:
    - Minimum—0
    - Maximum—999999999
22. **register-mode**—Select automatic (default) or triggered (upon trigger from PBX).
    - automatic | triggered
23. **triggered-inactivity-interval**—Enter the maximum time with no traffic from the corresponding PBX. (Valid only with Triggered inactivity interval.) The default value is **30**. The valid range is:
    - Minimum—5
    - Maximum—300
24. **triggered-oos-response**—503 (Default. Send 503 response for core network failure) or drop response, which causes the system to not respond to PBX or core network failure.
    - 503 | dropresponse

25. **source-ip-prefix**—Contains a list of IP address/prefixes that specify the source addressing of endpoints the system can authenticate using this surrogate-agent. Valid entries include any number of IP addresses and IP address prefixes in the format <ip>/<subnet>. If you set multiple values, separate them with a space and enclose them with parenthesis (). Addressing can be IPv4, IPv6 or a combination of both. The default configuration is null (no entry).
26. **auth-user-lookup**—If you intend to authenticate register requests using a realm configuration, enter the name of the target Auth Attribute configuration in that realm. This name must match an Auth User Lookup name in the realm's Auth Attribute list. When configured, the SBC uses those credentials to authenticate challenged register requests.
27. **proxy-name**—If you have configured the Registrar that validates this surrogate agent's register requests as a session agent, enter the name of that session agent here.
28. **un-register**—Enable this parameter to cause the register requests from this surrogate agent to specify Expires:0 and to remove each of this surrogate agents entries from the registration cache. The default value is **disabled**. The valid values are:
    - enabled | disabled
29. Save and activate your configuration.

Example

The following example shows the surrogate agent configuration.

```
surrogate-agent
register-host    acmepacket.com
register-user    234567
state    enabled
realm-id    public
description
customer-host    acmepacket.com
customer-next-hop    111.222.33.44
register-contact-host    111.222.5.68
register-contact-user    eng
password
register-expires    600000
replace-contact    disabled
route-to-registrar    enabled
aor-count    1
source-ip-prefix
options
auth-user
max-register-attempts   10
register-retry-time   30
count-start   1
register-mode   automatic
triggered-inactivity-interval   30
triggered-oos-response   503
auth-user-lookup
proxy-name charlie
un-register disabled
last-modified-date    2006-05-04 16:01:35
```

Configure Authentication Attributes on a Realm

In the SBC ACLI, you can access authentication parameters applicable to surrogate agent operation using the path **media-manager**, **realm-config**, **auth-attributes**. If using this authentication method for register requests, this feature uses the attributes and values listed in this table. You perform this configuration to the **realm-config** on which the registrar resides.

> **Note:**
>
> If enabling this means of authentication, all the **auth-attributes** listed below are required except for the in-dialog-methods attribute, which is optional.

To configure authentication on the SBC:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type media-manager and press Enter to access the media manager-related objects.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type realm-config and press Enter.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Create or select the realm-config on which the softswitch resides.
5. Type auth-attributes and press Enter to access the authentication-related attributes.

   ```
   ORACLE(realm-config)# auth-attributes
   ORACLE(auth-attributes)#
   ```

6. auth-realm — Enter the identifier of this realm, which initiates the authentication challenge. This value defines the protected space in which the authentication is performed. Valid value is an alpha-numeric character string. Default is blank.

   ```
   ORACLE(auth-attributes)# auth-realm realm01
   ```

7. username — Enter the username of the client. Valid value is an alpha-numeric character string. Default is blank.

   ```
   ORACLE(auth-attributes)# username user
   ```

8. auth-user-lookup — Enter a name for this auth-user-lookup. You use this same name when configuring the **auth-user-lookup** within the attributes of a local-policy, and within the surrogate agent itself. Default is blank.

   ```
   ORACLE(auth-attributes)# auth-user-lookup reg1
   ```

9. password — Enter the password associated with the username of the client. This is required for all LOGIN attempts. Password displays while typing but is saved in clear-text (i.e., *****). Valid value is an alpha-numeric character string. Default is blank.

```
ORACLE(auth-attributes)# password *******
```

10. in-dialog-methods — Enter the in-dialog request method(s) that authentication uses from the cached credentials. Specify request methods in a list form separated by a space enclosed in parentheses. Valid values are:
    - INVITE
    - BYE
    - ACK
    - CANCEL
    - OPTIONS
    - SUBSCRIBE
    - PRACK
    - NOTIFY
    - UPDATE
    - REFER

```
ORACLE(auth-attributes)# in-dialog-methods (ack invite subscribe)
```

    If you do not specify any in-dialog-method value(s), authentication does not add challenge-responses to in-dialog requests within a dialog. This attribute setting applies to in-dialog requests only.

> **Note:**
>
> The methods not in this list are still resubmitted if a 401/407 response is received by the Oracle Communications Session Border Controller.

11. Type done to save changes to this realm-config.
12. Save and activate your configuration.

Configure the applicable **local-policy**. This configuration includes setting the **auth-user-lookup** parameter in the applicable **local-policy-attribute** with the same value as the **auth-user-lookup** above.

Configure a Local Policy for Authenticating Surrogate Agent Traffic

To configure a local policy to support intra-realm surrogate agent authentication, you configure the local policy that directs traffic from the surrogate agent to the softswitch, which initiates the authentication challenge for any traffic coming from the surrogate agent (usually a PBX without the ability to authenticate itself).

1. In Superuser mode, type **configure terminal** and press Enter.

```
ACMEPACKET# configure terminal
```

2. Type **session-router** and press Enter.

```
ACMEPACKET(configure)# session-router
```

3. Type **local-policy** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ACMEPACKET(session-router)# local-policy
ACMEPACKET(local-policy)#
```

4. **from-address**—Indicate the originating address information by entering a From address value. You can use the asterisk (*) as a wildcard to indicate this policy can be used with all originating addresses.

> **Note:**
>
> After entering the from-address value, the Oracle Communications Session Delivery Manager automatically saves it to the configuration when exiting from local policy.

5. **to-address**—Indicate the destination address by entering a To address value. You can use the asterisk (*) as a wildcard to indicate all this policy can be used for any destination address.

> **Note:**
>
> After entering the to-address value, the Oracle Communications Session Delivery Manager automatically saves it to the configuration when exiting from local policy.

6. **source-realm**—Enter the identifier of the realm on which the surrogate agent resides.
7. **state**—Indicate whether you want the local policy to be enabled or disabled on the system. The default value is **enabled**. The valid values are:
   - enabled | disabled
8. **policy-attribute**—Configure local policy attributes required for this feature. All other attributes are optional.
9. **next-hop**—Identify the next signaling host by entering the next hop value. For this feature, then next hop is the soft switch.
10. **realm**—Identify the egress realm (the realm used to reach the next hop) if the system must send requests out from a specific realm.
11. **lookup**—Set this parameter to single.
12. **auth-user-lookup**—Enter the name of the target auth-user-lookup you have configured for this surrogate agent on the Softswitch realm.
13. Type done twice to save changes to your policy-attributes and your local policy.
14. Save and activate your configuration.

Recurse 305 Only Redirect Action

The Oracle Communications Session Border Controller has a SIP feature called redirect action. This is a feature that allows the Oracle Communications Session Border Controller, acting as a SIP Proxy or a Session Agent, to redirect SIP messages after receiving a SIP redirect (3xx) response. Previously, for the ACLI objects of sip-interface and session-agent on the Oracle Communications Session Border Controller, you could set the redirect-action parameter to **proxy** or **recurse**. In Release 6.3 you can additionally set a value of **recurse-305-only** for the redirect-action parameter.

Redirect Action Process

When the redirect-action parameter is set to proxy, the Oracle Communications Session Border Controller sends SIP Redirect responses back to the previous hop (back to the User Agent Client (UAC)) when the User Agent Server (UAS) is not a session agent. The URI in the Contact of the response is changed from the URI that was in the original request.

> **Note:**
>
> If the target of the request is a session agent, the session agent's redirect action supercedes that of the SIP interface.

When the redirect-action parameter is set to recurse, if the Oracle Communications Session Border Controller receives a SIP redirect (3xx) response on the SIP interface, it automatically redirects all requests to the Contact URI specified in the 3xx response. The responses contain the same Contact URI that was in the original request sent to the UAS.

For example, if UAC X sends an INVITE to the Oracle Communications Session Border Controller set up as a SIP proxy, the Oracle Communications Session Border Controller forwards the INVITE to UAS Y (Y is not a session agent). Y then responds to the Oracle Communications Session Border Controller with a 3xx response (redirection message) with the same URI that was in the original request. This indicates to the Oracle Communications Session Border Controller that if it receives any future requests directed toward Y, that it should automatically redirect the request directly to Y. The Oracle Communications Session Border Controller then recurses, or repeatedly sends subsequent incoming messages to the Contact URI specified in the Header of the 3xx responses.

When the redirect-action parameter is set to recurse-305-only, if the Oracle Communications Session Border Controller receives a 305 SIP redirect response (Use Proxy) on the SIP interface, it automatically redirects all requests to the Contact URI specified in the 305 response. All other 3xx responses are sent back to the previous hop.

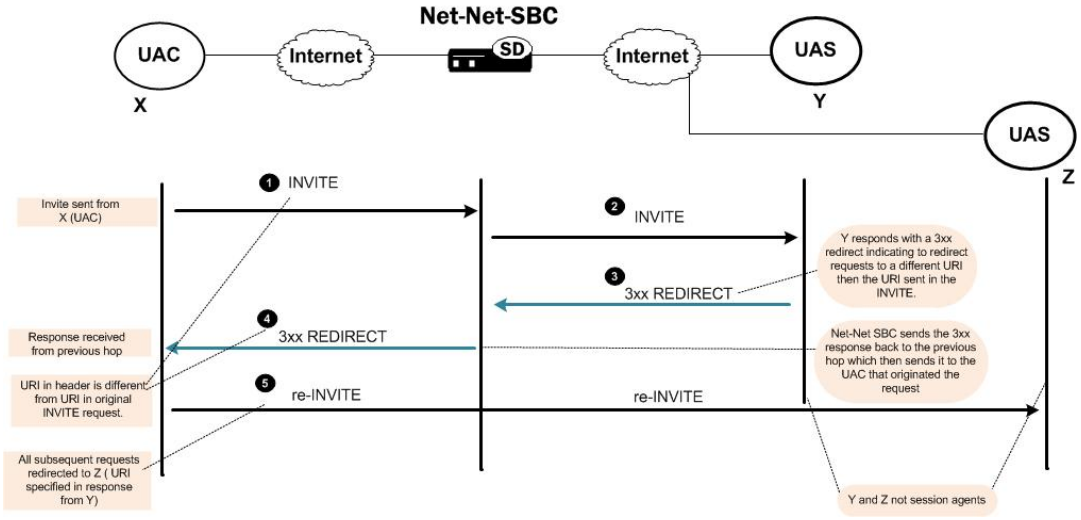
When the UAS is a session agent, the Oracle Communications Session Border Controller can send the SIP redirect response back to the UAC using the value in the session agent's redirect action field. If there are too many UASs to define as individual session agents, or if the UASs are Hosted NAT Traversal (HNT) endpoints, and SIP redirect responses need to be proxied for UASs that are not session agents, you can set the behavior at the SIP interface level.

Redirect-Action Set to Proxy

The following occurs if you set the **redirect-action** parameter to proxy on the Oracle Communications Session Border Controller:

1. X (UAC) sends an INVITE to the Oracle Communications Session Border Controller.
2. The Oracle Communications Session Border Controller forwards the INVITE to Y (UAS).
3. Y sends the 3xx REDIRECT response to the Oracle Communications Session Border Controller with a different URI in the message header.
4. The Oracle Communications Session Border Controller forwards the 3xx REDIRECT response to the previous hop. X receives the 3xx REDIRECT response from the previous hop.
5. X redirects all subsequent requests to the URI in the message header received from Y.

   The following illustration shows an example of a dialog between X, Y, Z, and the Oracle Communications Session Border Controller during a redirect-action session set to proxy.

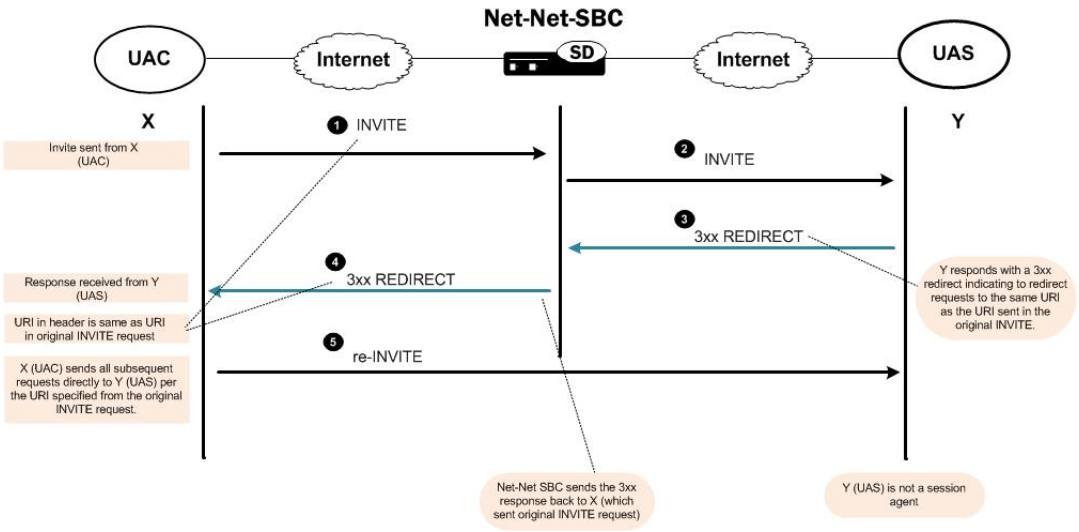


Redirect-Action Set to Recurse

The following occurs if you set the **redirect-action** parameter to recurse on the Oracle Communications Session Border Controller:

1. X (UAC) sends an INVITE to the Oracle Communications Session Border Controller.
2. The Oracle Communications Session Border Controller forwards the INVITE to Y (UAS).
3. Y sends the 3xx REDIRECT response to the Oracle Communications Session Border Controller with the same URI as the URI sent in the original request.
4. The Oracle Communications Session Border Controller forwards the 3xx REDIRECT response to X (UAC).
5. X (UAC) sends all subsequent requests directly to Y (UAS) per the URI specified from the original INVITE request.

   The following illustration shows an example of a dialog between X, Y, and the Oracle Communications Session Border Controller during a redirect-action session set to recurse.

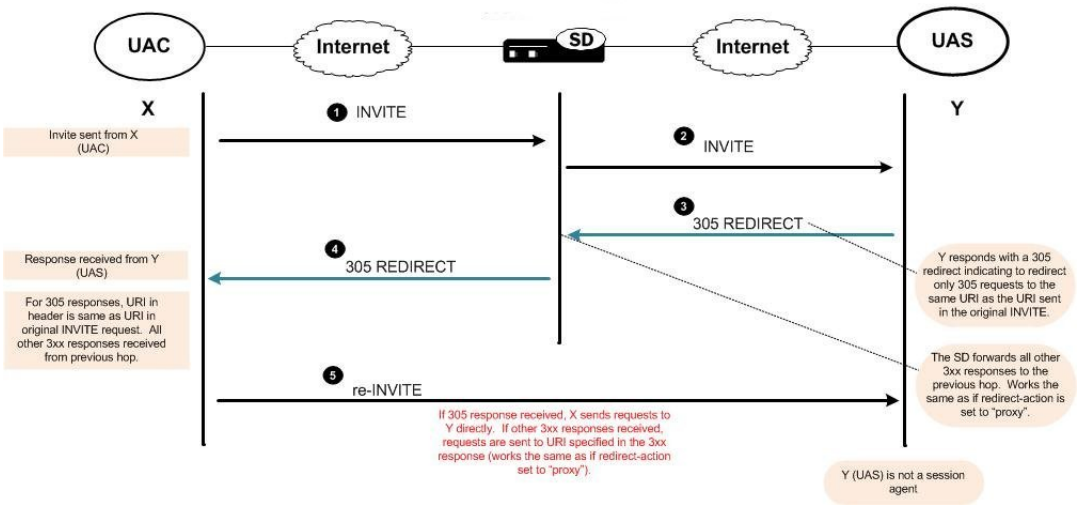


Redirect-Action Set to Recurse-305-Only

The following occurs if you set the **redirect-action** parameter to **recurse-305-only** on the Oracle Communications Session Border Controller:

1. X (UAC) sends an INVITE to the Oracle Communications Session Border Controller.
2. The Oracle Communications Session Border Controller forwards the INVITE to Y (UAS).
3. Y sends a 305 REDIRECT response to the Oracle Communications Session Border Controller with the same URI as the URI sent in the original request.
4. The Oracle Communications Session Border Controller forwards the 305 REDIRECT response to X (UAC).
5. If 305 response received, X sends requests to Y directly. If other 3xx responses received, requests are sent to URI specified in the 3xx response (works the same as if redirect-action set to proxy).

   The following illustration shows an example of a dialog between X, Y, and the Oracle Communications Session Border Controller during a redirect-action session set to recurse-305-only.



Redirect Configuration for SIP Interface

You can configure the Oracle Communications Session Border Controller to redirect requests from a UAC to a UAS using the URI in 305 responses only. You can use the ACLI at the paths **session-router**, **sip-interface** or **session-router**, **session-agent**.

To configure the redirect-action feature on the SIP interface on the Oracle Communications Session Border Controller:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session router-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter to access the SIP interface-related configurations. The system prompt changes to let you know that you can begin configuring individual parameters for this object.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. **Enter redirect-action followed by the following value:**

   - recurse-305-only

   ```
   ORACLE(sip-interface)# redirect-action recurse-305-only
   ```

   When the Oracle Communications Session Border Controller receives a 305 SIP redirect response (Use Proxy) on the SIP interface, it automatically redirects all requests to the Contact URI specified in the 305 response. All 3xx responses other than 305 responses are sent back to the previous hop.

   To disable this feature, enter **redirect-action** and press Enter without entering a value.

   ```
   ORACLE(sip-interface)# redirect-action
   ```

Redirect Configuration for Session Agent

To configure the redirect-action feature for a session agent on the Oracle Communications Session Border Controller:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ACMEPACKET# configure terminal
   ```

2. Type **session-router** and press Enter to access the session router-related configurations.

   ```
   ACMEPACKET(configure)# session-router
   ```

3. Type **session-agent** and press Enter to access the SIP session agent-related configurations. The system prompt changes to let you know that you can begin configuring individual parameters for this object.

```
ACMEPACKET(session-router)# session-agent
ACMEPACKET(session-agent)#
```

4. **Enter redirect-action followed by the following value:**
   - recurse-305-only

```
ACMEPACKET(session-agent)# redirect-action recurse-305-only
```

When the Oracle Communications Session Border Controller receives a 305 SIP redirect response (Use Proxy) on the SIP interface, it automatically redirects all requests to the Contact URI specified in the 305 response. All 3xx responses other than 305 responses are sent back to the previous hop.

To disable this feature, enter redirect-action and press Enter without entering a value.

```
ACMEPACKET(sip-interface)# redirect-action
```

Embedded Routes in Redirect Responses

When the Oracle Communications Session Border Controller recurses as the result of a redirect (3xx) response, the server might need to specify one or more intermediate hops. These hops are reflected in the Contact header for the 3xx response using embedded route headers and look like this:

```
Contact: <sip:touser@server.example.com?Route=%3Cproxy.example.com%Blr%3E>
```

The Contact header shows that the request should be sent to server.example.com using proxy.example.com.

You can configure your Oracle Communications Session Border Controller to specify that embedded headers in 3xx Contact headers are to be included in new requests such that they are tied to a session agent representing the new target (server.example.com). This behavior requires you to set the **request-uri-headers** parameter.

However, you can also use the **use-redirect-route** in global SIP configuration's options parameter so that the embedded Route header is used as the next hop to receive the new request.

When you configure this new option, the Oracle Communications Session Border Controller constructs a new request using the redirect Contact, and the SIP URI from the Contact becomes the Request-URI. Then, the system inserts the embedded routes as Route headers in the, using the same order in which they appeared in the redirect Contact. Afterward, the Oracle Communications Session Border Controller determines the next hop in the same way it does with any other request. If the first route is a loose route (i.e., it has the lr URI parameter), then the Oracle Communications Session Border Controller sends a request to host indicated in the first route. Otherwise, strict routing applies, and the Oracle Communications Session Border Controller sends the request to the host indicated in the Request-URI.

1. In Superuser mode, type configure terminal and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **options**—Set the options parameter by typing options, a Space, and then the option name.

```
ORACLE(sip-config)# options use-redirect-route
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

Selecting SDP within Multi-Dialog Call Scenarios

By default, the Oracle Communications Session Border Controller saves SDP presented in a series of early dialogs using To tags to differentiate between dialogs. If the session continues with a 200OK that does not include SDP, the Oracle Communications Session Border Controller refers to the To tag to identify the dialog from which the Oracle Communications Session Border Controller selects the SDP for the media flow. This complies with 3GPP TS 24.628, TS 24.182 and RFC 5009 behavior for sessions supporting early media.

Consider a SIP dialog with early media that proceeds by establishing call scenarios in which the final 200 OK does not include any SDP. This messaging may include multiple 183 (Session Progress) messages with SDP that differ from each other and include different To tags, establishing multiple early dialogs. In these scenarios, the Oracle Communications Session Border Controller uses the saved SDP from the dialog that matches the dialog indicated in the 200 OK's To tag to anchor the media. If the 200 OK includes SDP, the Oracle Communications Session Border Controller uses that SDP to anchor the media.

> **Note:**
>
> The user can disable this behavior, for example, to use the functional behavior in Oracle Communications Session Border Controller version S-CZ7.2.0 and below, which is to use the last SDP seen as the source for SDP. Deployments that rely on this behavior must revert to it using the **sip-config**'s **dont-save-early-dialog-sdp** option parameter.

```
ORACLE(sip-config)# options +dont-save-early-dialog-sdp
```

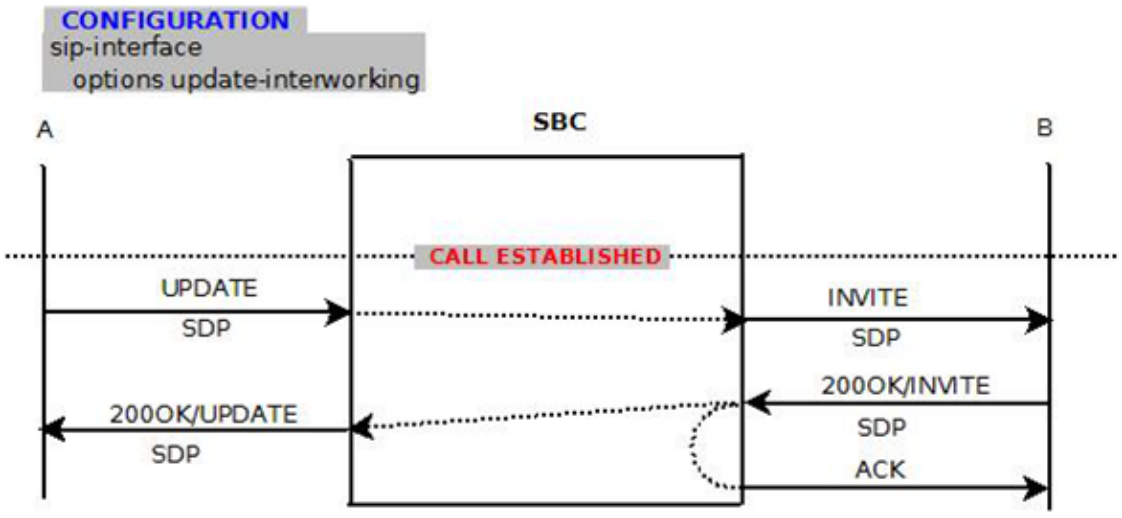
UPDATE Interworking

The Oracle Communications Session Border Controller can be configured to convert UPDATE methods (with or without SDP) to INVITE methods inside a dialog that has already been established. SDP is inserted when the UPDATE message doesn't have it. The method is modified from UPDATE to INVITE for the duration of an UPDATE based transaction and the SBC creates an ACK message to acknowledge the INVITE response.

You must specify the new **sip-interface** option **update-interworking** on the ingress SIP interface to enable the UPDATE Interworking feature. The three possible scenarios are described as follows:

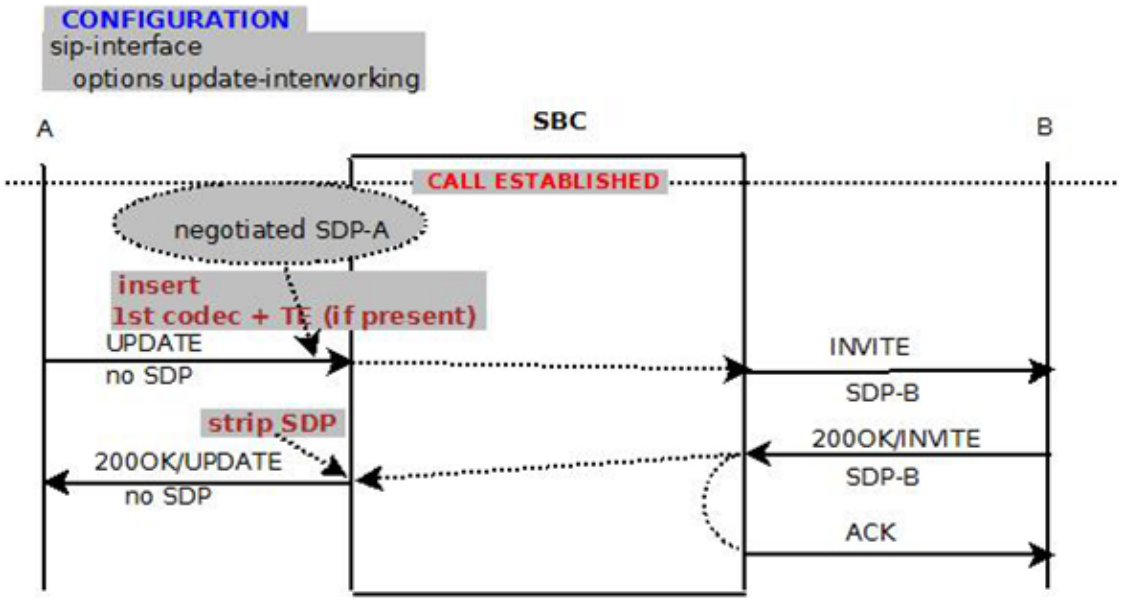
Successful UPDATE with SDP

In this example the original UPDATE contains SDP, and the INVITE is sent with SDP.



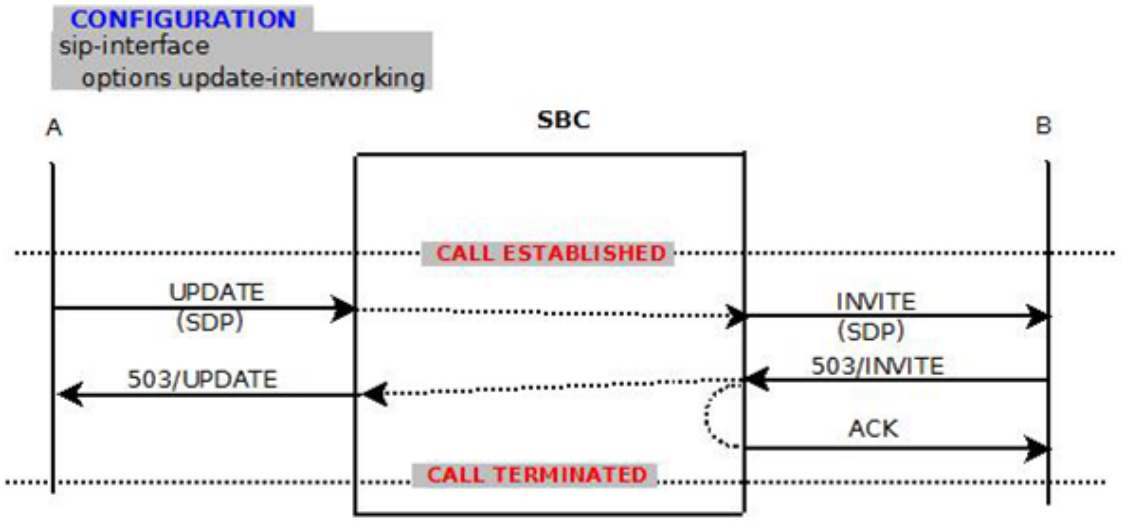
Successful UPDATE without SDP

In this example the original UPDATE does not contain SDP, SDP is inserted and the INVITE is sent with SDP. SDP is stripped from 200OK/UPDATE on the "A" (ingress) side.



UPDATE Failure

In this example the original UPDATE contains SDP, and the INVITE is sent with SDP.



UPDATE Interworking Configuration

1. Access the **sip-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

2. Select the **sip-interface** object to edit.

```
ORACLE(sip-interface)# select
<RealmID>:
1: realm01 172.172.30.31:5060
```

```
selection: 1
ORACLE(sip-interface)#
```

3. **options** — Set this parameter by typing **options**, a Space, the option name **update-interworking** with a plus sign in front of it, and then press Enter.

```
ORACLE(sip-interface)# options +update-interworking
```

   If you type options and then the option value without the plus sign, you will overwrite any previously configured options. In order to append the new option to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

4. Type **done** to save your configuration.

SIP PRACK Interworking

When you configure your Oracle Communications Session Border Controller with PRACK interworking for SIP, you enable it to interwork between endpoints that support RFC 3262, *Reliability of Provisional Responses in the Session Initiation Protocol*, and those that do not.

As its title indicates, RFC 3262 defines a reliable provisional response extension for SIP INVITEs, which is the 100rel extension tag. While some endpoints do not support the RFC, other SIP implementations require compliance with it. A session setup between two such endpoints fails. However, you can configure your Oracle Communications Session Border Controller to supply the provisional response on behalf of endpoints that do not support it—and thereby enable sessions between those endpoints and the ones requiring RFC 3262 compliance.

You need to configure PRACK interworking for a SIP interface associated with the endpoints that need RFC 3262 support. To enabled the feature, you set the **100rel-interworking** option. The Oracle Communications Session Border Controller applies PRACK interworking for either the UAC or the UAS. TheOracle Communications Session Border Controller checks to see whether or not it needs to apply PRACK interworking when an INVITE arrives at the ingress or egress SIP interface with the option enabled. First, it checks the Require header for the 100rel tag; if not found there, it checks the Supported header.

Since there is a slight difference in the application of this feature between the UAC and UAS, this section explains both.

> **Note:**
>
> If SDP is included in a PRACK request sent to a SIP interface where PRACK interworking is enabled, it will not be responded to, nor will any SDP be included in the locally-generated 200 OK to that PRACK.

UAC-Side PRACK Interworking

The Oracle Communications Session Border Controller applies PRACK interworking on the UAC side when:

- An incoming SIP INVITE contains the 100rel tag in a Require header
- The ingress SIP interface is enabled with the **100rel-interworking** option

- The UAS fails to send reliable provisional responses

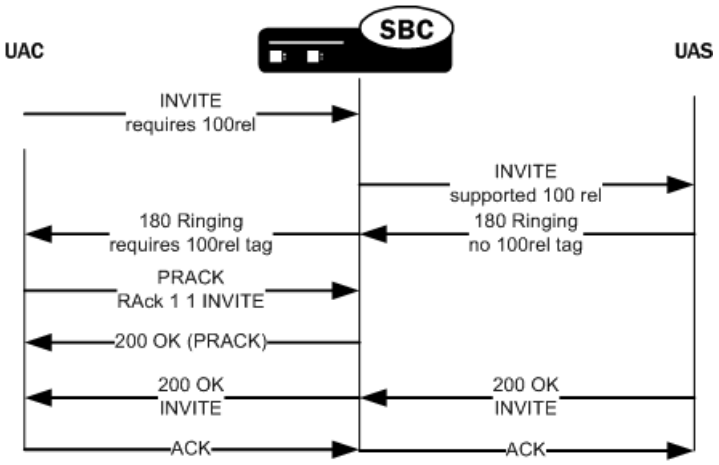
When it is to forward a non-reliable response to a UAC that requires RFC 3262 support, the Oracle Communications Session Border Controller converts the non-reliable response to a reliable one by adding the 100rel tag to the Require header and adding an Rseq header to the response. Further, the Oracle Communications Session Border Controller adds a Require header (complete with the100rel tag) if there is not one already in the response, and then also adds Rseq header.

Note that the Oracle Communications Session Border Controller sets the value of the Rseq header as 1 for the first provisional response, and then increments it by 1 for each subsequent provisional response. It also adds the PRACK method to the Allow header when that header appears.

The Oracle Communications Session Border Controller retransmits the converted reliable provisional response in accordance with RFC 3262, until it receives a PRACK request. For the initial timeout for retransmission, the Oracle Communications Session Border Controller uses the value you set in the **init-timer** parameter in the global SIP configuration. It stops retransmitting when either it receives a transmission, or when the ingress SIP interface's trans-expire timer elapses.

If it never receives a PRACK, the Oracle Communications Session Border Controller does not generate an error response to the INVITE, relying instead on the downstream UAS to produce a final response.

The call flow for this application looks like this:



UAS-Side PRACK Interworking

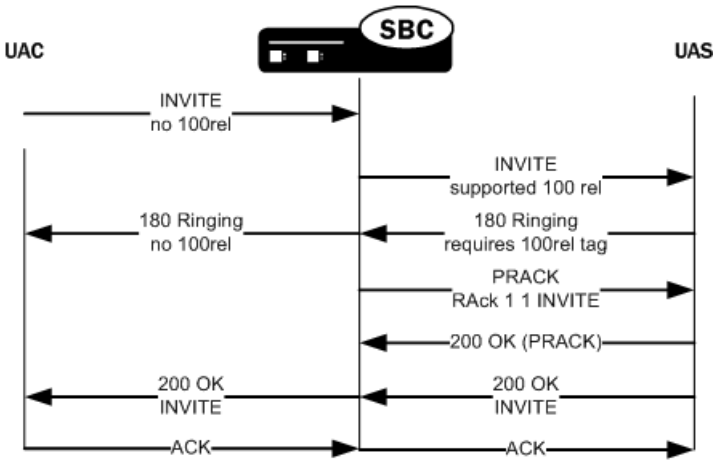
The Oracle Communications Session Border Controller applies PRACK interworking on the UAS side when:

- An incoming SIP INVITE does not contain the 100rel tag in a Require or Supported header
- The egress SIP interface is enabled with the **100rel-interworking** option
- The UAS does send reliable provisional responses

When the UAC does not support RFC 3262, the Oracle Communications Session Border Controller generates a PRACK request to acknowledge the response. It also converts the response to non-reliable by removing the 100 rel tag from the Require header and removing the RSeq header from the response.

In the case of the UAS, the Oracle Communications Session Border Controller matches the PRACK to a converted reliable provisional response using the PRACK's RAck header. If it finds a matching response, the Oracle Communications Session Border Controller generates a 200 OK to the PRACK. And if it finds no match, then it generates a 481 Call Leg/Transaction Does Not Exist response. The Oracle Communications Session Border Controller generates a 400 Bad Request response if either the RAck is not in the PRACK request or it is not formatted properly.

The call flow for this application looks like this:



PRACK Interworking Configuration

You enable PRACK interworking for ingress and egress SIP interfaces. Be sure you know on what side, ingress or egress, you need this feature applied.

To configure PRACK interworking for a SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter. If you are editing an existing configuration, select the one on which you want to enable this feature.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **100rel-interworking** with a plus sign in front of it, and then press Enter.

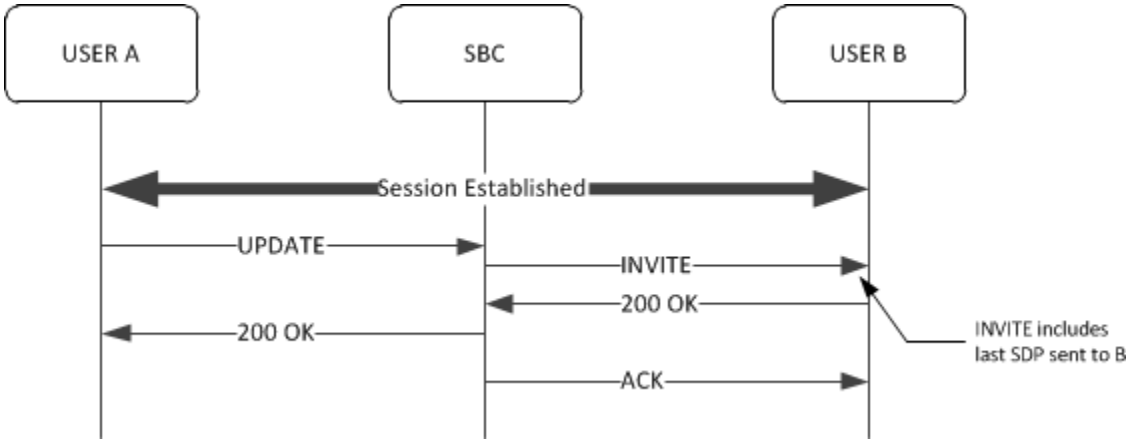
   ```
   ORACLE(sip-interface)# options +100rel-interworking
   ```

If you type options and then the option value for either of these entries **without the plus sign, you will overwrite any previously configured options. In order to append the new option to this** configuration's **options list, you must prepend the new option with a plus sign as shown in the previous example.**

5. Save and activate your configuration.

After Dialog Establishment (INVITE transaction terminated)

Inside a dialog that has already been established, we should offer a way to convert UPDATE methods (with or without SDP) to INVITE methods. During the duration of this UPDATE based transaction, the method has to be modified from UPDATE to INVITE in all the appropriate places.



In the case that the original UPDATE does not contain SDP, the INVITE will include the last SDP sent to Peer B.

During dialog establishment (INVITE transaction not yet terminated)

There are six different use cases here depending on the following factors:

- Caller/called requirements of reliable responses
- Delayed/early offer
- SDP insertion in delayed offer or not

Use Case	100rel Required by	Delayed offer	SDP injection
Use Case 1	Callee	No	N/A
Use Case 2	Callee	Yes	Yes
Use Case 3	Callee	Yes	No
Use Case 4	Caller	No	N/A
Use Case 5	Caller	Yes	Yes
Use Case 6	Caller	Yes	No

PRACK IWF on ingress side:

- When the 100rel-interworking (or equivalent CLI) option is activated on the ingress realm, if an INVITE comes with a 100rel tag in a Require header, the INVITE will be forwarded with the tag only in the Supported header.

- If the response is that the UAS do not support 100rel, the function will be triggered. If the response comes with a supported 100rel, the function will not be triggered.

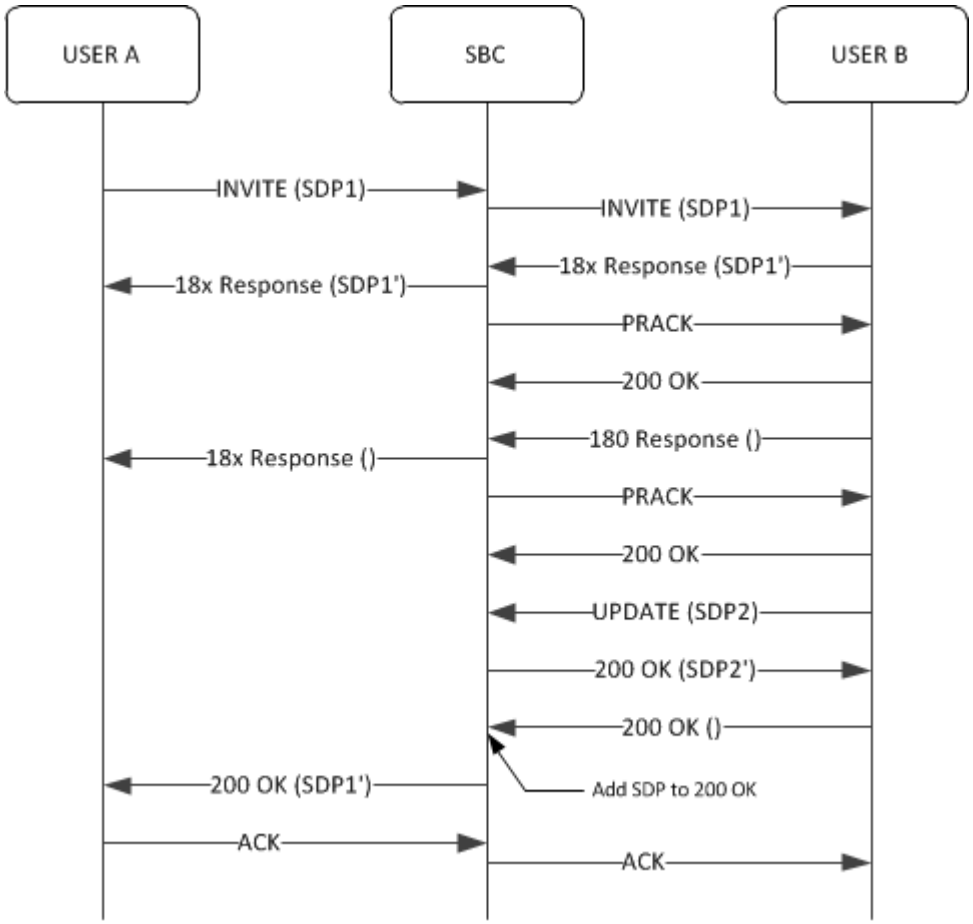
PRACK IWF on egress side:

When the 100rel-interworking option is activated on the egress realm:

- If an INVITE comes with a 100rel tag in a Require header, the function will not be triggered.
- If an INVITE comes with no 100rel tag, it will be included in the Supported header.
  - If the response includes 100rel requirements, the function will be triggered

Use Case 1

In this use case the caller leg does not support reliable responses and the called leg requires them. The initial INVITE comes with an SDP offer.



Actions:

- Upon reception of a response with SDP (it can only happen once)
  - Forward it to A side
  - Send PRACK and wait for 200OK
  - Keep the SDP of the first provisional response (SDP1').
    NOTE: The SDP answer must come in a reliable response. The 200OK of a PRACK is not reliable
- Upon reception of a response with no SDP
  - Forward it to A side

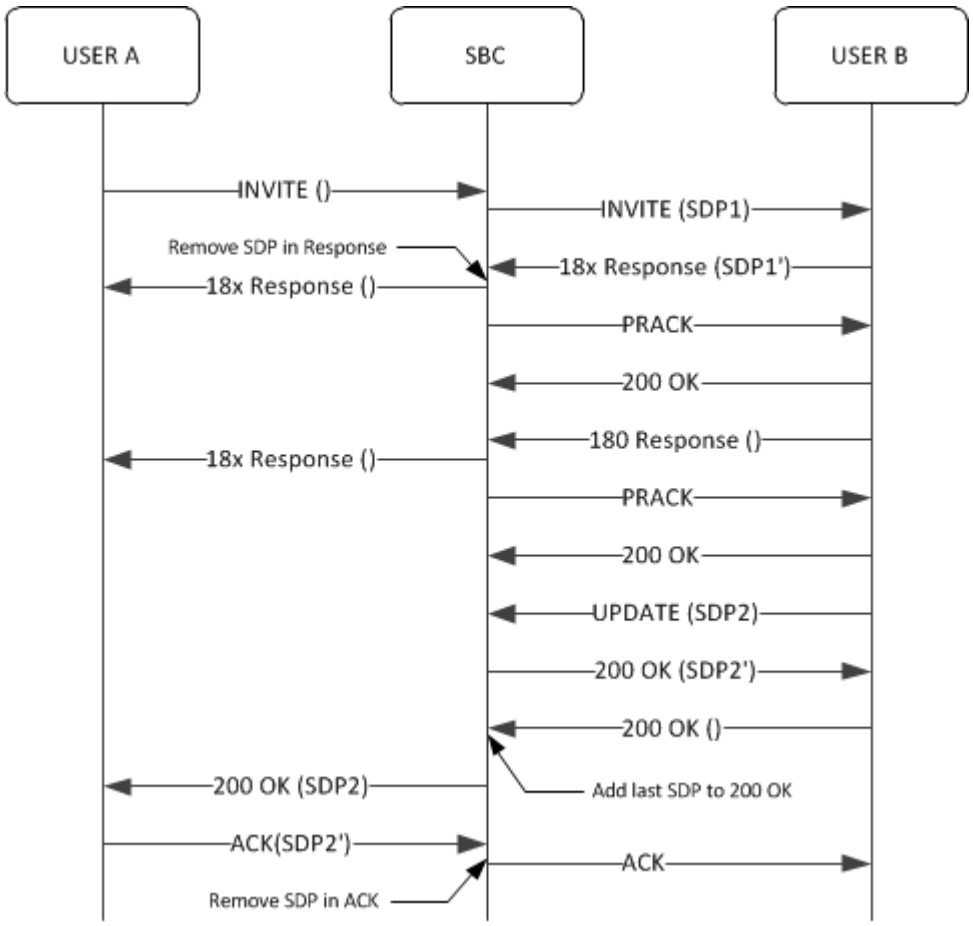
  - Send PRACK and wait for 200OK
- Upon reception of an UPDATE with SDP from B after the SDP answer,
  - Answer locally the UPDATE in the called side. The SDP of the 200OK will contain:
    * The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    * The tel-events and image codecs from the new offer.
- Upon reception of an UPDATE with SDP from B before the SDP answer, reject it with 488 (INVITE is still ongoing)
- Upon reception of any additional response with no SDP
  - Forward it to A side
  - Send PRACK and wait for 200OK
- 200OK for INVITE should come with no SDP. We'll include the same SDP as in the previous message in this side (SDP1').
- Depending of the codecs offered and answered in both sides transcoding may be triggered.

Use Case 2 (Not applicable to SR)

In this use case the caller leg does not support reliable responses and the called leg requires them.

The initial INVITE comes without SDP offer, and the SBC is adding SDP in the outbound INVITE

This use case is not applicable in a SR installation since we don't have a way to indicate the proper IP address in the generated SDP.



Actions:

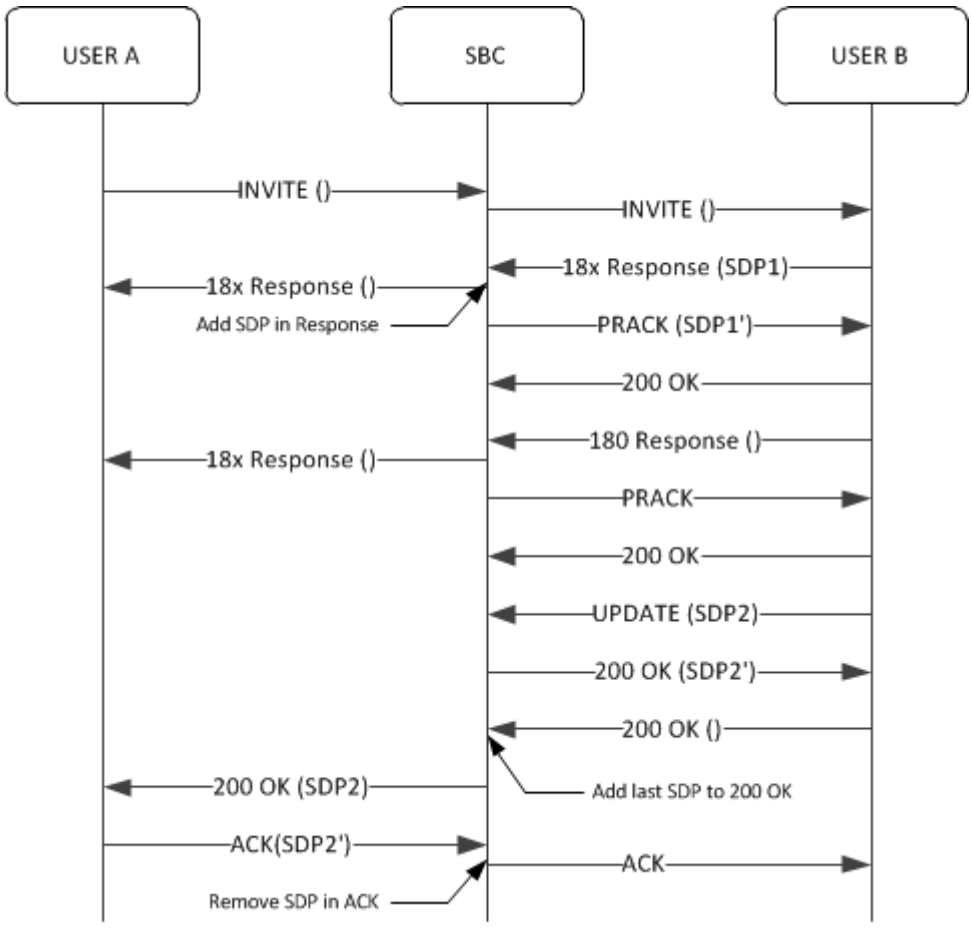
- Upon reception of offer-less INVITE, and add-SDP is used:
  - Add SDP in the egress INVITE (as today).
- Upon reception of a response with no SDP
  - Forward it to A side
  - Send PRACK and wait for 200OK
- Upon reception of a response with SDP (it can only happen once)
  - Remove SDP and forward it to A side
  - Send PRACK and wait for 200OK
  - Keep the SDP.
    NOTE: The SDP answer must come in a reliable response. The 200OK of a PRACK is not reliable.
- Upon reception of an UPDATE with SDP from B after the SDP answer,
  - Keep the SDP (don't need the previous kept SDP)
  - Answer locally the UPDATE in the called side. The SDP of the 200OK will contain:
    * The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    * The tel-events and image codecs from the new offer.

- Upon reception of an UPDATE with SDP from B before the SDP answer, reject it with 488 (INVITE is still ongoing)
- Upon reception of any additional response with no SDP
  - Forward it to A side
  - Send PRACK and wait for 200OK
- 200OK for INVITE should come with no SDP. We'll include the last SDP received from the B side..
- The ACK from the calling side will come with SDP. Remove it before relaying the ACK to the other side.
- Depending of the codecs offered and answered in both sides transcoding may be triggered.

Use Case 3 (Not applicable to SR)

In this use case the caller leg does not support reliable responses and the called leg requires them. The initial INVITE comes without SDP offer, and the SBC is not adding SDP in the outbound INVITE

This use case is not applicable in a SR installation since we don't have a way to indicate the proper IP address in the generated SDP.



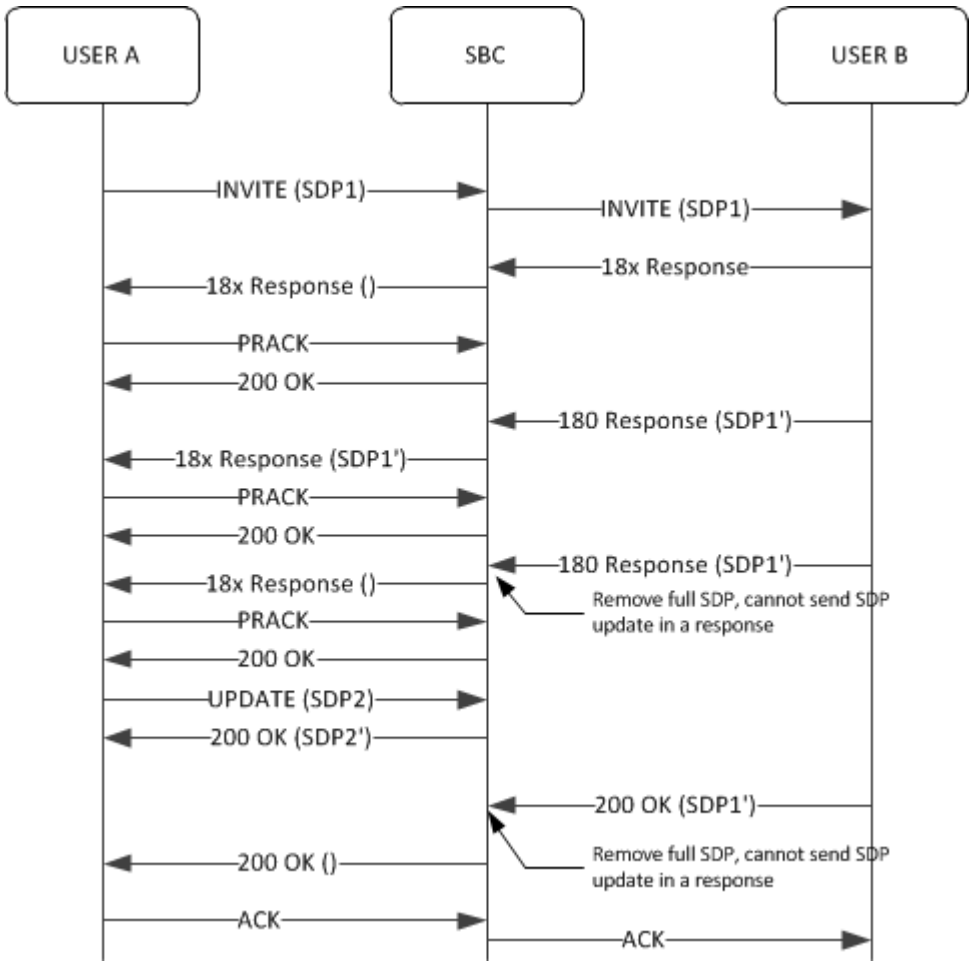
Actions:

- Upon reception of a response with no SDP (Illegal, but should we care?)
  - Forward it to A side

  - Send PRACK and wait for 200OK
- Upon reception of a response with SDP (it can only happen once)
  - Keep the SDP.
  - Remove SDP and forward it to A side
  - Send PRACK with SDP. Include a SDP answer to the PRACK that acknowledges the provisional response with SDP offer. This SDP will contain:
    * The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    * The tel-events and image codecs from the new offer.
  - Wait for 200OK for PRACK
- Upon reception of an UPDATE with SDP from B after the SDP answer,
  - Keep the SDP (don't need the previous kept SDP)
  - Answer locally the UPDATE in the called side. The SDP of the 200OK will contain:
    * The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    * The tel-events and image codecs from the new offer.
- Upon reception of an UPDATE with SDP from B before the SDP answer, reject it with 488 (INVITE is still ongoing). This is completely illegal, remove it if required.
- Upon reception of any additional response with no SDP:
  - Forward it to A side
  - Send PRACK and wait for 200OK
- 200OK for INVITE should come with no SDP. We'll include the last SDP received from the B side.
- The ACK from the calling side will come with SDP. Remove it before relaying the ACK to the other side.
- Depending of the codecs offered and answered in both sides transcoding may be triggered

Use Case 4

In this use case the caller leg does require reliable responses and the called side does not support them. The initial INVITE comes with SDP offer.



Actions:

- Upon reception of a response with no SDP:
  - Forward it to A side
  - Answer locally the PRACK with 200OK
- Upon reception of a response with SDP (it can only happen once):
  - Keep the SDP of the first provisional response (SDP1').
  - Forward it to A side
  - Wait for PRACK.
- If PRACK comes with SDP, handle it as an UPDATE (see below)
- If PRACK comes with no SDP, just answer it as today.
- Upon reception of a new response with SDP (new response with SDP again):
  - Remove the SDP
  - Forward it to A side
  - Wait for PRACK.
    - If PRACK comes with SDP, handle it as an UPDATE (see below)
    - If PRACK comes with no SDP, just answer it as today.
- Upon reception of an UPDATE with SDP from A after the SDP answer:

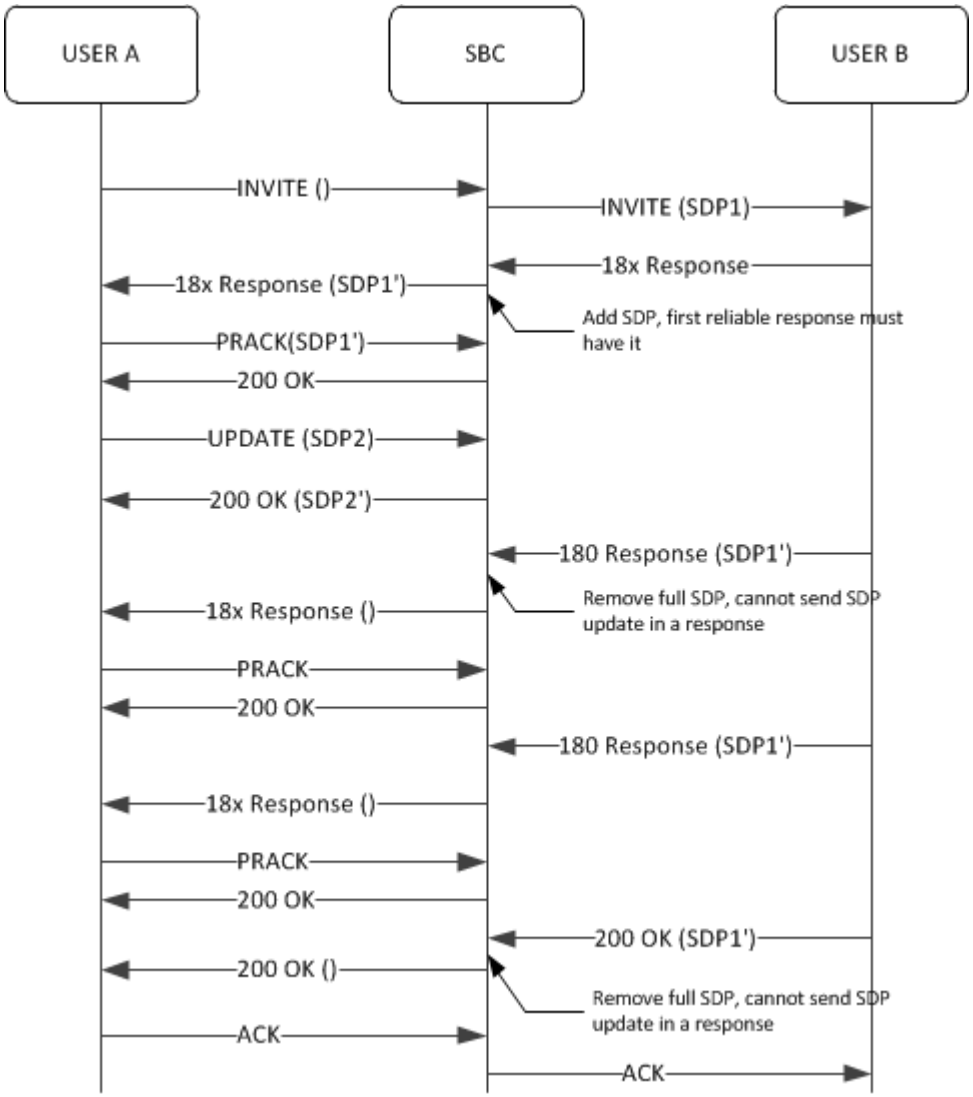
  - Answer locally the UPDATE. The SDP of the 200OK will contain:
    * The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    * The tel-events and image codecs from the new offer.
- Upon reception of an UPDATE with SDP from A before the SDP answer, reject it with 488 (INVITE is still ongoing)
- Upon reception of any additional response with no SDP:
  - Forward it to A side
  - Answer locally the PRACK with 200OK
- 200OK for INVITE should come with SDP:
  - Remove SDP
  - Forward 200OK to A side
- Depending of the codecs offered and answered in both sides transcoding may be triggered.

Use Case 5 (Not applicable to SR)

In this use case the caller leg does require reliable responses and the called leg does not support them. The initial INVITE comes without SDP offer, and we have the SBC configured to add the SDP to the initial INVITE.

Also, the first provisional response comes with no SDP, so the SBC will add SDP to the first response.

This use case is not applicable in a SR installation since we don’t have a way to indicate the proper IP address in the generated SDP.

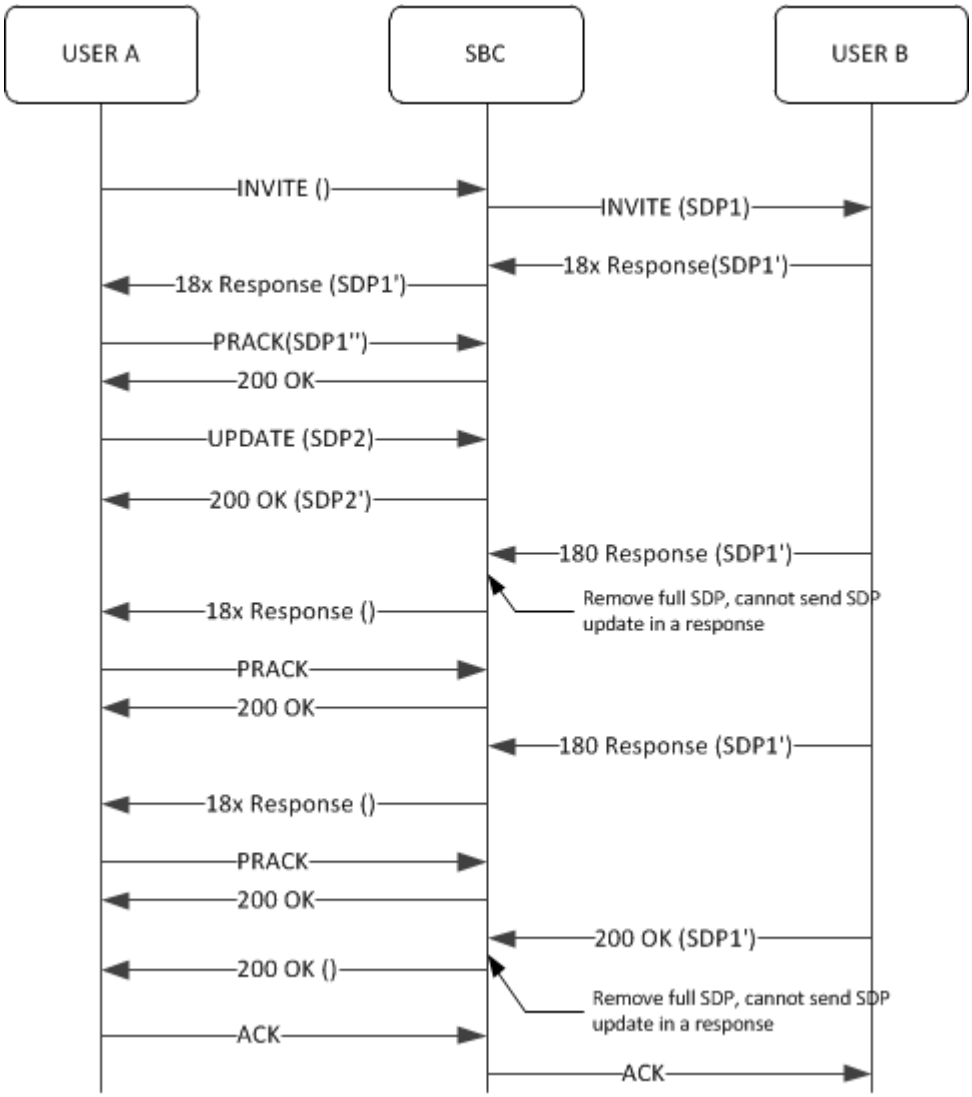


Actions:

- Add SDP in the egress INVITE.
- The first provisional response comes without SDP, so the SBC will add a predefined (media-profile) to the SDP to the response.
  - Forward it to A side
  - Wait for PRACK.
    - Will come with SDP1''
    - And answer it
- Upon reception of a new response with SDP:
  - Remove the SDP
  - Forward it to A side
  - Wait for PRACK.
    - If PRACK comes with SDP, handle it as an UPDATE (see below)
    - If PRACK comes with no SDP, just answer it as today.
- Upon reception of an UPDATE with SDP from A after the SDP answer:

  - Answer locally the UPDATE. The SDP of the 200OK will contain:
    * The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    * The tel-events and image codecs from the new offer.
- Upon reception of an UPDATE with SDP from A before the SDP answer, reject it with 488 (INVITE is still ongoing)
- Upon reception of any additional response with no SDP:
  - Forward it to A side
  - Wait for PRACK:
    * If PRACK comes with SDP, handle it as an UPDATE (see previous step)
    * If PRACK comes with no SDP, just answer it as today.
- 200OK for INVITE should come with SDP:
  - Remove SDP
  - Forward 200OK to A side
- Depending of the codecs offered and answered in both sides transcoding may be triggered

As an alternative to use-case 5 we have the case where the first provisional response already comes with SDP:



Actions:

- Add SDP in the egress INVITE.
- The first provisional response comes with SDP:
  - Forward it to A side
  - Wait for PRACK.
    - Will come with SDP1''
    - And answer it
- Upon reception of a new response with SDP (new response with SDP again):
  - Remove the SDP
  - Forward it to A side
  - Wait for PRACK.
    - If PRACK comes with SDP, handle it as an UPDATE (see below)
    - If PRACK comes with no SDP, just answer it as today.
    -

- Upon reception of an UPDATE with SDP from A after the SDP answer:
  - Answer locally the UPDATE. The SDP of the 200OK will contain:
    - The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    - The tel-events and image codecs from the new offer.
- Upon reception of an UPDATE with SDP from A before the SDP answer, reject it with 488 (INVITE is still ongoing)
- Upon reception of any additional response with no SDP:
  - Forward it to A side
  - Wait for PRACK.
    - If PRACK comes with SDP, handle it as an UPDATE (see previous step)
    - If PRACK comes with no SDP, just answer it as today.
- 200OK for INVITE should come with SDP:
  - Remove SDP
  - Forward 200OK to A side
- Depending of the codecs offered and answered in both sides transcoding may be triggered.

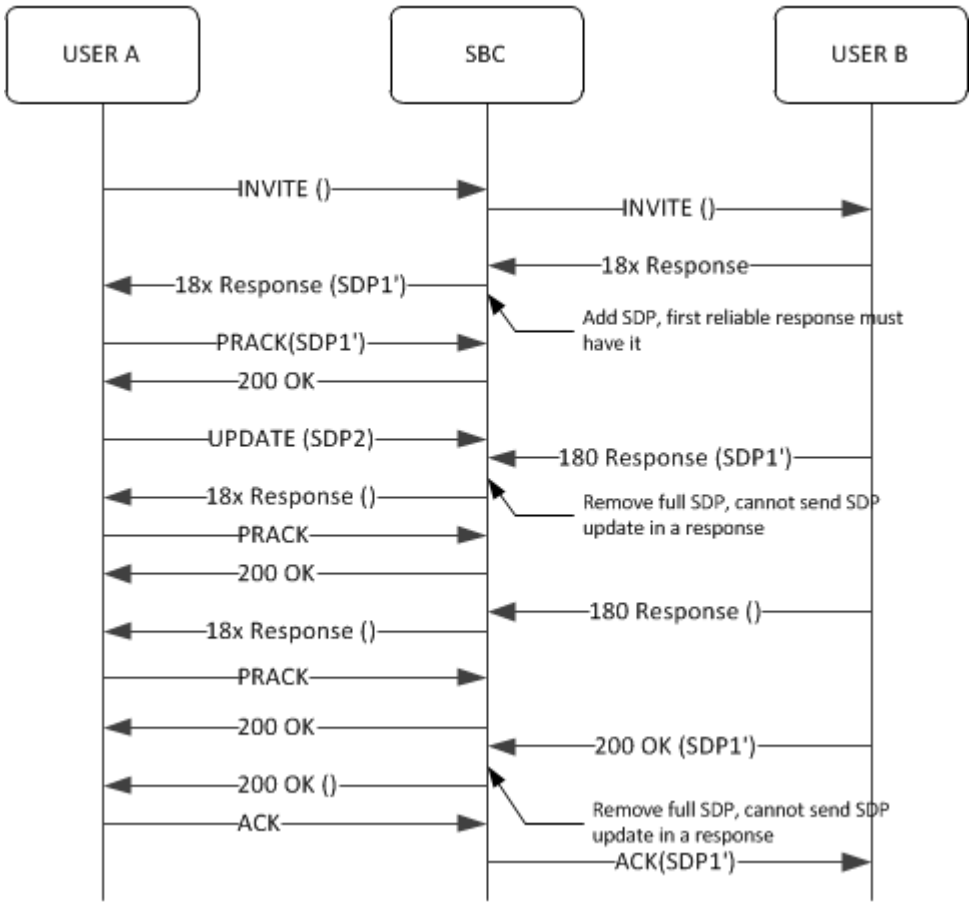
Use Case 6 (not applicable to SR)

In this use case the caller leg does require reliable responses and the called leg does not support them. The initial INVITE comes without SDP offer, and the SBC is not configured to add the SDP to the initial INVITE.

This use case is not applicable in a SR installation since we don’t have a way to indicate the proper IP address in the generated SDP.

From the IETF point of view, the first SDP offer should come in the first reliable response from the UAS, in this case the 200OK. Any other case would be illegal. However, in order to protect for possible use cases, and leveraging the previous use case, we’ll offer also this one:

** LRBT is currently planned for a later release of SBC and so any interactions with LRBT will not be implemented as part of this PRACK IWF feature in 7.3 M2



Actions:

- The first provisional response comes without SDP:
  - o Add a predefined (media-profile) to the SDP in the response.
  - o Forward it to A side
  - o Wait for PRACK.
    - Will come with SDP1''
    - And answer it
- Upon reception of a new response with SDP:
  - Remove the SDP
  - Forward it to A side
  - Wait for PRACK.
    - If PRACK comes with SDP, handle it as an UPDATE (see below)
    - If PRACK comes with no SDP, just answer it as today.
- Upon reception of an UPDATE with SDP from A after the SDP answer:
  - Answer locally the UPDATE. The SDP of the 200OK will contain:
    - The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    - The tel-events and image codecs from the new offer.

- Upon reception of an UPDATE with SDP from A before the SDP answer, reject it with 488 (INVITE is still ongoing)
- Upon reception of any additional response with no SDP:
  - Forward it to A side
  - Wait for PRACK.
    - If PRACK comes with SDP, handle it as an UPDATE (see previous step)
    - If PRACK comes with no SDP, just answer it as today.
- 200OK for INVITE should come with SDP:
  - Remove SDP
  - Forward 200OK to A side
- In the ACK insert SDP. The SDP will contain:
  - The first codec of the codec list present in the new offer (SDP1') that complies with the configured codec-policies.
  - The tel-events and image codecs from the new offer (SDP1').
- Depending of the codecs offered and answered in both sides transcoding may be triggered.

Alternative case where the first reliable response comes with SDP:

Actions:

- The first provisional response comes with SDP:
  - Forward it to A side
  - Wait for PRACK.
    - Will come with SDP1''
    - And answer it
- Upon reception of a new response with SDP (new response with SDP again):
  - Remove the SDP
  - Forward it to A side
  - Wait for PRACK.
    - If PRACK comes with SDP, handle it as an UPDATE (see below)
    - If PRACK comes with no SDP, just answer it as today.
- Upon reception of an UPDATE with SDP from A after the SDP answer:
  - Answer locally the UPDATE. The SDP of the 200OK will contain:
    - The first codec of the codec list present in the new offer that complies with the configured codec-policies.
    - The tel-events and image codecs from the new offer.
- Upon reception of an UPDATE with SDP from A before the SDP answer, reject it with 488 (INVITE is still ongoing)
- Upon reception of any additional response with no SDP:
  - Forward it to A side
  - Wait for PRACK.

    * If PRACK comes with SDP, handle it as an UPDATE (see previous step)
    * If PRACK comes with no SDP, just answer it as today.
- 200OK for INVITE should come with SDP:
  - Remove SDP
  - Forward 200OK to A side
- In the ACK insert SDP. The SDP will contain:
  - The first codec of the codec list present in the new offer (SDP1') that complies with the configured codec-policies.
  - The tel-events and image codecs from the new offer (SDP1').
- Depending of the codecs offered and answered in both sides transcoding may be triggered.

Global SIP Timers

This section explains how to configure SIP retransmission and expiration timers.

> **Note:**
>
> you can also set timers and counters per SIP interface.

Overview

SIP timers define the transaction expiration timers, retransmission intervals when UDP is used as a transport, and the lifetime of dynamic TCP connections. The retransmission and expiration timers correspond to the timers defined in RFC 3261.

- init timer: is the initial request retransmission interval. It corresponds to Timer T1 in RFC 3261.
  This timer is used when sending requests over UDP. If the response is not received within this interval, the request is retransmitted. The retransmission interval is doubled after each retransmission.
- max timer: is the maximum retransmission interval for non-INVITE requests. It corresponds to Timer T2 in RFC 3261.
  The retransmission interval is doubled after each retransmission. If the resulting retransmission interval exceeds the max timer, it is set to the max timer value.
- trans expire: is the transaction expiration timer. This value is used for timers B, D, F, H and J as defined in RFC 3261.
- invite expire: defines the transaction expiration time for an INVITE transaction after a provisional response has been received. This corresponds to timer C in RFC 3261.
  If a final response is not received within this time, the INVITE is cancelled. In accordance with RFC 3261, the timer is reset to the invite expire value when any additional provisional responses are received.
- Inactive dynamic conn timer defines the idle time of a dynamic TCP connection before the connection is torn down. Idle is defined as not transporting any traffic. There is no timer in RFC 3261 corresponding to this function.

Timers Configuration

To configure timers:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

4. **init-timer**—Enter the initial timeout value in milliseconds for a response to an INVITE request, and it applies to any SIP request in UDP. In RFC 3261, this value is also referred to as TIMER_T1. The default is **500**. The valid range is:
   - Minimum—0
   - Maximum—4294967295
5. **max-timer**—Enter the maximum transmission timeout (T2) for SIP in milliseconds.

   When sending SIP over UDP, a re-transmission timer is used. If the timer expires and the message is re-transmitted, the re-transmission timer is then set to twice the previous value (but will not exceed the maximum timer value). Using the default values of 500 milliseconds and 4000 milliseconds, the re-transmission timer is 0.5, then 1, 2, and finally 4. The incrementing continues until the transmission expire timer activates. The default is **4000**. The valid range is:
   - Minimum—0
   - Maximum—4294967295
6. **trans-expire**—Enter the transaction expire timeout value (Timer B) in seconds to set the time for SIP transactions to live. The same value is used for Timers D, F, H and J. The default is **32**. The valid range is:
   - Minimum—0
   - Maximum—2147473
7. **invite-expire**—Enter the invite expire timeout value (Timer C) in seconds to indicate the time for SIP client transaction will live after receiving a provisional response. The default is **180**. The valid range is:
   - Minimum—0
   - Maximum—2147473
8. **inactive-dynamic-conn**—Enter the inactive dynamic connection value in seconds to set the time limit for inactive dynamic connections.

   If the connection between the SIP proxy and a session agent is dynamic (for example, through dTCP), and the connection has been idle for the amount of time specified here, the

SIP proxy breaks the connection. Idle is defined as not transporting any traffic. The default value is **32**. The valid range is:

- Minimum—0
- Maximum—4294967295

> **Note:**
>
> Setting this parameter to 0 disables this parameter.

The following example shows SIP config timer values for a peering network. Some parameters are omitted for brevity.

```
sip-config
        state                           enabled
        operation-mode                  dialog
dialog-transparency        disabled
home-realm-id                   acme
        egress-realm-id
        nat-mode                        Public
        registrar-domain
        registrar-host
        registrar-port                  0
        init-timer                      500
        max-timer                       4000
        trans-expire                    32
        invite-expire                   180
        inactive-dynamic-conn           32
```

SIP Timers Discreet Configuration

Previous releases controlled various SIP timers with a single ACLI command, **trans-expire**, available in both sip-config and sip-interface modes. When executed in sip-config mode, the command essentially established a global default transaction expiration timer value. Executed at the sip-interface level, the command established a local, interface-specific value that overrode the global default.

Specific timers controlled by **trans-expire** are as follows:

Timer B, the INVITE transaction timeout timer, defined in Section 17.1.1.2 and Appendix A of RFC 3261, *SIP: Session Initiation Protocol*.

Timer D, the Wait-Time for response retransmitals timer, defined in Section 17.1.1.2 and Appendix A of RFC 3261, *SIP: Session Initiation Protocol*.

Timer F, the non-INVITE transaction timeout timer, defined in Section 17.1.2.2 and Appendix A of RFC 3261, *SIP: Session Initiation Protocol*.

Timer H, the Wait-Time for ACK receipt timer, defined in Section 17.2.1 and Appendix A of RFC 3261, *SIP: Session Initiation Protocol*.

Timer J, the Wait-Time for non-INVITE requests timer, defined in Section 17.2.2 and Appendix A of RFC 3261, *SIP: Session Initiation Protocol*.

A new ACLI command (**initial-inv-trans-expire**) that enables user control over SIP Timer B for initial INVITE transactions. Other timers, namely B for non-initial INVITEs, D, F, H, and J remain under the control of **trans-expire**.

Use **initial-inv-trans-expire** in the sip-config configuration mode, to establish a global, default transaction timeout value (expressed in seconds) used exclusively for initial INVITE transactions.

```
ORACLE(sip-config)# initial-inv-trans-expire 4
ORACLE(sip-config)#
```

Allowable values are integers within the range 0 (the default) through 999999999. The default value, 0, indicates that a dedicated INVITE Timer B is not enabled. Non-default integer values enable a dedicated Timer B and set the timer value.

The default value retains compatibility with previous operational behavior in that Timers B, D, F, H, and J all remain subject to the single timer value set by **trans-expire**. However, when **initial-inv-trans-expire** is et to a supported non-zero value, SIP Timer B as it applies to initial INVITEs, assumes that value rather than the value assigned by **trans-expire**. This functionality is available in both sip-config and in sip-interface objects.

If a dedicated Timer B is enabled at the sip-config level, you can use **initial-inv-trans-expire** in the sip-interface configuration mode, to establish a local interface-specific Timer B timeout value that overrides the global default value.

```
ORACLE(sip-interface)# initial-inv-trans-expire 8
ORACLE(sip-interface)#
```

Session Timer Support

The Oracle Communications Session Border Controller partially supports RFC4028 by establishing session timers without participating in the session timer negotiation.

When a 2xx response to a Session Refresh Request arrives, the Oracle Communications Session Border Controller will start a new timer or refresh the existing timer using the value of the Session-Expires header. When the session timer expires, the Oracle Communications Session Border Controller will send a BYE to both the upstream and downstream endpoints.

When accounting is configured, the Oracle Communications Session Border Controller will also send a RADIUS STOP record with Acct-Terminate-Cause=Session-Timeout.

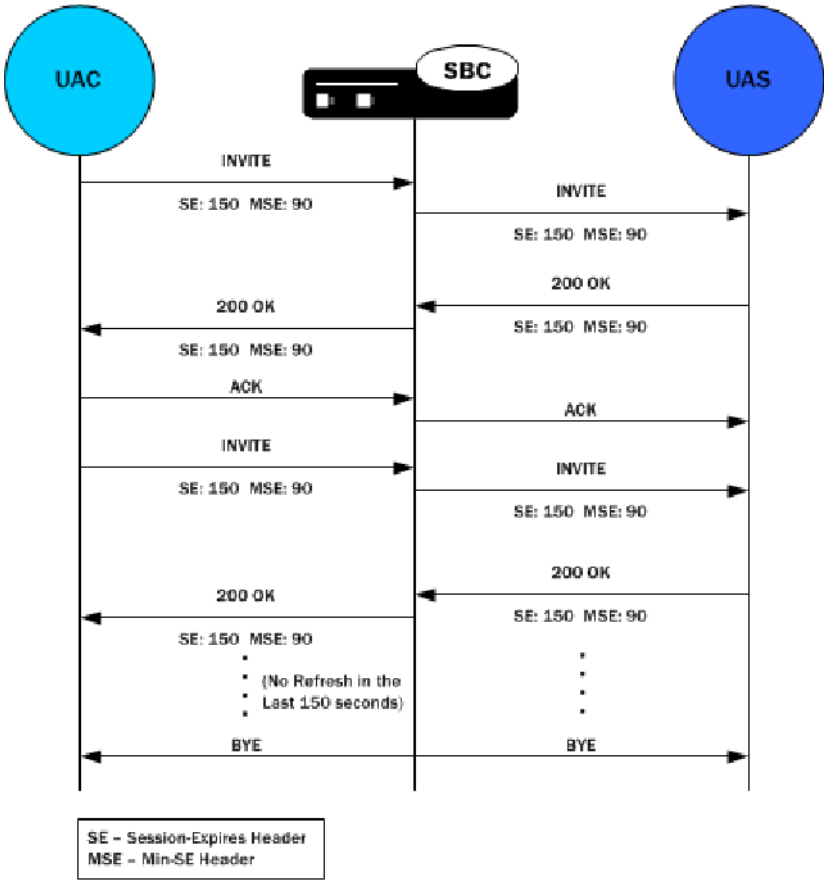
Call Flow Example

The UAS obtains the value from the Session-Expires header field in a 2xx response to a session refresh request that it sends.

Proxies and UACs obtain this value from the Session-Expires header field in a 2xx response to a session refresh request that they receive.

Once the session timer runs out, the Oracle Communications Session Border Controller sends a BYE to both the UAC and the UAS to clear the session.

Enable this feature by adding the **session-timer-support** option to the sip config.



SIP Per-User CAC

The Oracle Communications Session Border Controller's call admission control (CAC) supports an enhanced degree of granularity for SIP sessions.

Without this feature enabled, the Oracle Communications Session Border Controller performs call admission control (CAC) based on:

- Bandwidth limits configured in realms and nested realms
- Number of media flows available through the steering pool per realm
- Number of inbound sessions configured for a SIP session agent
- Number of total sessions (inbound and outbound) per SIP session agent
- Use of the Oracle Communications Session Border Controller's support for common open policy service (COPS), allowing the Oracle Communications Session Border Controller to perform CAC based on the policies hosted in an external policy server

These methods provide a basic level of call admission control in order to ensure that a SIP session agent's capacity is not exceeded. You can also ensure that signaling and media bandwidth capacities are not exceeded for physical trunks and peers.

With this feature enabled, the Oracle Communications Session Border Controller changes behavior so that it will only allow the configured number of calls or total bandwidth to and from each user in a particular realm. The overall realm bandwidth and steering pool limits still apply, and as before, the Oracle Communications Session Border Controller still rejects users who

might be within their CAC limitations if accepting them with exceed the bandwidth limitations for parent or child realms and steering pools.

For SIP sessions, the Oracle Communications Session Border Controller now keeps track of the amount of bandwidth a user consumes and the number of active sessions per address of record (AoR) or per IP address, depending on the CAC mode you select (either aor or ip). When an endpoint registers with the Oracle Communications Session Border Controller, theOracle Communications Session Border Controller allots it a total amount of bandwidth and total number of sessions.

This section describes the details of how SIP per user CAC works.

You should note that the functionality this section describes only works if you enable registration caching on your Oracle Communications Session Border Controller.

For SIP sessions, the Oracle Communications Session Border Controller now keeps track of the amount of bandwidth a user consumes and the number of active sessions per address of record (AoR) or per IP address, depending on the CAC mode you select (either aor or ip). When an endpoint registers with the Oracle Communications Session Border Controller, the Oracle Communications Session Border Controller allots it a total amount of bandwidth and total number of sessions.

Per User CAC Modes

There are three modes that you can set for this feature, and each has an impact on how the other two per-user-CAC parameters are implemented:

- none—No per user CAC is performed for users in the realm.
- aor—The Oracle Communications Session Border Controller performs per user CAC according to the AoR and the contact associated with that AoR for users in the realm.
- ip—The Oracle Communications Session Border Controller performs per user CAC according to the IP address and all endpoints that are sending REGISTER messages from the IP address for users in the realm.

Per User CAC Sessions

You can set the number of CAC for sessions per user in the realm configuration. Depending on the CAC mode you set, the sessions are shared between contacts for the same AoR or the endpoints behind the same IP address.

When it receives an INVITE, the Oracle Communications Session Border Controller determines the registration entry for the calling endpoint and the registration for the called endpoint. It then decides if session can be established between the two. If it can, the Oracle Communications Session Border Controller establishes the session and changes the active session count for the calling and called endpoints. The count is returned to its original value once the session is terminated.

Per User CAC Bandwidth

You can set the per user CAC bandwidth in realm configuration, too, and it is handled much the same way that the sessions are handled. That is, depending on the CAC mode you set, the bandwidth is shared between contacts for the AoR or the endpoints behind the same IP address. All endpoints must be registered with the Oracle Communications Session Border Controller.

When it receives a Request with SDP, the Oracle Communications Session Border Controller checks to see if there is enough bandwidth for the calling endpoint and for the called endpoint. The Oracle Communications Session Border Controller assumes that the bandwidth usage is symmetric, and it uses the maximum bandwidth configured for the codec that it finds in the Request. In the event that there are multiple streams, the Oracle Communications Session Border Controller determines the total bandwidth required for all of the streams. If the required bandwidth exceeds what is available for either endpoint, the Oracle Communications Session Border Controller rejects the call (with a 503 error response). If the amount of available bandwidth is sufficient, then the used bandwidth value is increased for both the registered endpoints: calling and called. Any mid-session requests for changes in bandwidth, such as those caused by modifications in codec use, are handled the same way.

The Oracle Communications Session Border Controller also keeps track of the bandwidth usage on a global level. When the call terminates, the bandwidth it was consuming is returned to the pool of available bandwidth.

Notes on HA Nodes

This feature has been implemented so that a newly active system is able to perform SIP per user CAC. The standby Oracle Communications Session Border Controller is updated with the appropriate parameters as part of the SIP session update.

SIP per User CAC Configuration

Note that you must enable registration caching for this feature to work.

To configure SIP per user CAC:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Select the realm where you want to want to add SIP per user CAC.

   ```
   ORACLE(realm-config)# select
   ```

5. **user-cac-mode**—Set this parameter to the per user CAC mode that you want yo use. The default value is **none**. The valid values are:
   - **none**—No user CAC for users in this realm
   - **aor**—User CAC per AOR
   - **ip**—User CAC per IP
6. **user-cac-sessions**—Enter the maximum number of sessions per user for dynamic flows to and from the user. The default is **0**. Leaving this parameter set to its means that there is

unlimited sessions, meaning that the per user CAC feature is disabled in terms of the constraint on sessions. The valid range is:

7. Minimum—0
8. Maximum—999999999
9. **user-cac-bandwidth**—Enter the maximum bandwidth per user for dynamic flows to and from the user. The default is **0** and leaving this parameter set to the default means that there is unlimited bandwidth, meaning that the per user CAC feature is disabled in terms of the constraint on bandwidth. The valid range is:
   - Minimum—0
   - Maximum—999999999

SIP Per-Realm CAC

Building on the Oracle Communications Session Border Controller's pre-existing call admission control methods, CAC can be performed based on how many minutes are being used by SIP or H.323 calls per-realm for a calendar month.

In the realm configuration, you can now set a value representing the maximum number of minutes to use for SIP and H.323 session using that realm. Although the value you configure is in minutes, the Oracle Communications Session Border Controller performs CAC based on this value to the second. When you use this feature for configurations with nested realms, the parent realm will have the total minutes for all its child realms (i.e., at least the sum of minutes configured for the child realms).

The Oracle Communications Session Border Controller calculates the number of minutes used when a call completes, and counts both call legs for a call that uses the same realm for ingress and egress. The total time attributed to a call is the amount of time between connection (SIP 200 OK) and disconnect (SIP BYE), regardless of whether media is released or not; there is no pause for calls being placed on hold.

If the number of minutes is exhausted, the Oracle Communications Session Border Controller rejects calls with a SIP 503 Service Unavailable message (including additional information "monthly minutes exceeded). In the event that the limit is reached mid-call, the Oracle Communications Session Border Controller continues with the call that pushed the realm over its threshold but does not accept new calls. When the limit is exceeded, the Oracle Communications Session Border Controller issues an alarm and sends out a trap including the name of the realm; a trap is also sent when the alarm condition clears.

> **Note:**
>
> The Oracle Communications Session Border Controller does not reject GETS/NSEP calls based on monthly minutes CAC.

You can change the value for minutes-based CAC in a realm configuration at any time, though revising the value downward might cause limits to be reached. This value resets to zero (0) at the beginning of every month, and is checkpointed across both system in an HA node. Because this data changes so rapidly, however, the value will not persist across and HA node if both systems undergo simultaneous failure or reboot.

You can use the ACLI **show monthly minutes <realm-id>** command (where **<realm-id> is** the realm identifier of the specific realm for which you want data) to see how many minutes are

configured for a realm, how many of those are still available, and how many calls have been rejected due to exceeding the limit.

SIP per Realm CAC Configuration

This section shows you how to configure minutes-based CAC for realms and how to display minutes-based CAC data for a specific realm.

Enabling Realm-Based CAC

Note that setting the new monthly-minutes parameters to zero (0), or leaving it set to its default of 0, disables this feature.

To configure minutes-based CAC:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **media-manager** and press Enter.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Select the realm where you want to want to add SIP per user CAC.

   ```
   ORACLE(realm-config)# select
   ```

5. **monthly-minutes**—Enter the number of minutes allowed during a calendar month in this realm for SIP and H.323 calls. By default, this parameter is set to zero (0), which disabled monthly minutes-based CAC. You can enter a value as high as 71582788.
6. Save and activate your configuration.

Viewing Realm-Based CAC Data

Use the ACLI show monthly-minutes command to see the following information:

- How many minutes are configured for a realm
- How many of those are still available
- How many calls have been rejected due to exceeding the limit
  To view information about SIP per user CAC using the IP address mode:

- In either User or Superuser mode, type **show monthly-minutes <realm-id>**, a Space, and the IP address for which you want to view data. Then press Enter. The **<realm-id>** is the realm identifier for. the realm identifier of the specific realm for which you want data

```
ORACLE# show monthly-minutes private_realm
```

SIP Options Tag Handling

This section explains how to configure SIP options on a global or per-realm level and how to specify whether the feature treatment applies to traffic inbound to or outbound from a realm, or both.

SIP extensions that require specific behavior by UAs or proxies are identified by option tags. Option tags are unique identifiers used to designate new options (for example, extensions) in SIP. These option tags appear in the Require, Proxy-Require, and Supported headers of SIP messages.

Option tags are compatibility mechanisms for extensions and are used in header fields such as Require, Supported, Proxy-Require, and Unsupported in support of SIP.

The option tag itself is a string that is associated with a particular SIP option (i.e., an extension). It identifies this option to SIP endpoints.

Overview

The SIP specification (RFC 3261) requires that the Oracle Communications Session Border Controller B2BUA reject any request that contains a Require header with an option tag the Oracle Communications Session Border Controller does not support. However, many of these extensions operate transparently through the Oracle Communications Session Border Controller's B2BUA. You can configure how SIP defines the Oracle Communications Session Border Controllers B2BUA treatment of specific option tags.

Also, there might be certain extensions that an endpoint indicates support for by including the option tag in a Supported header. If you do not want a given extension used in your network, the you can configure SIP option tag handling to remove the undesired option tag from the Supported header. You can also specify how option tags in Proxy-Require headers are to be treated.

Configuration Overview

You configure the SIP feature element to define option tag names and their treatment by the Oracle Communications Session Border Controller when the option tag appears in a Supported header, a Require header, and a Proxy-Require header. If an option tag is encountered that is not configured as a SIP feature, the default treatments apply. You only need to configure option tag handling in the SIP feature element when non-default treatment is required.

You can specify whether a SIP feature should be applied to a specific realm or globally across realms. You can also specify the treatment for an option based on whether it appears in an inbound or outbound packet. Inbound packets are those that are coming from a realm to the Oracle Communications Session Border Controller and outbound packets are those which are going from the Oracle Communications Session Border Controller to the realm.

The following tables lists the SIP option tag parameters you must configure.

Parameter	Description
name	SIP feature tag name
realm	Realm name with which the feature will be associated. To make the feature global, leave the field empty.
support mode inbound	Action for tag in Supported header in an inbound packet.
require mode inbound	Action for tag in Require header in an inbound packet
proxy require mode inbound	Action for tag in Proxy-Require header in an inbound packet
support mode outbound	Action for tag in Supported header in an outbound packet
require mode outbound	Action for tag in Require header in an outbound packet
proxy require mode outbound	Action for tag in Proxy-Require header in an outbound packet

SIP Option Tag Handling Configuration

To configure SIP option tag handling:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-feature** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-feature
   ORACLE(sip-feature)#
   ```

   From this point, you can configure SIP option tags parameters. To view all sip-feature parameters, enter a **?** at the system prompt.

4. **name**—Enter a name for the option tag that will appear in the Require, Supported, or Proxy-Require headers of inbound and outbound SIP messages.

   You must enter a unique value.

   > **Note:**
   >
   > Valid option tags are registered with the IANA Protocol Number Assignment Services under Session Initiation Protocol Parameters. Because option tags are not registered until the SIP extension is published as a RFC, there might be implementations based on Internet-Drafts or proprietary implementations that use unregistered option tags.

5. **realm**—Enter the name of the realm with which this option tag will be associated. If you want to apply it globally across realms, leave this parameter blank.
6. **support-mode-inbound**—Optional. Indicate the support mode to define how the option tag is treated when encountered in an inbound SIP message's Supported header. The default value is **pass**. Valid values are:

- **pass**—Indicates the B2BUA should include the tag in the corresponding outgoing message.
- **strip**—Indicates the tag should not be included in the outgoing message. Use strip if you do not want the extension used.

7. **require-mode-inbound**—Optional. Indicate the require mode to define how the option tag is treated when it is encountered in an inbound SIP message's Require header. The default value is **reject**. The valid values are:
   - **pass**—Indicates the B2BUA should include the tag in the corresponding outgoing message.
   - **reject**—Indicates the B2BUA should reject the request with a 420 (Bad Extension) response. The option tag is included in an Unsupported header in the reject response.
8. **support-mode-outbound**—Optional. Indicate the support mode to define how the option tag is treated when encountered in an outbound SIP message's Supported header. The default value is pass. Valid values are:
   - **pass**—Indicates the B2BUA should include the tag.
   - **strip**—Indicates the tag should not be included in the outgoing message. Use strip if you do not want the extension used.
9. **require-mode-outbound**—Optional. Indicate the require proxy mode to define how the option tag is treated when encountered in an outgoing SIP message's Proxy-Require header. The default value is **reject**. The valid values are:
   - **pass**—Indicates the B2BUA should include the tag.
   - **reject**—Indicates the B2BUA should reject the request with a 420 (Bad Extension) response. The option tag is included in an Unsupported header in the reject response.

   The following example shows SIP option tag handling configured for non-default treatment of option tags.

```
sip-feature
        name                            newfeature
        realm                           peer-1
        support-mode-inbound            Strip
        require-mode-inbound            Reject
        proxy-require-mode-inbound      Pass
        support-mode-outbound           Pass
        require-mode-outbound           Reject
        proxy-require-mode-outbound     Reject
        last-modified-date              2004-12-08 03:55:05
```

Replaces Header Support

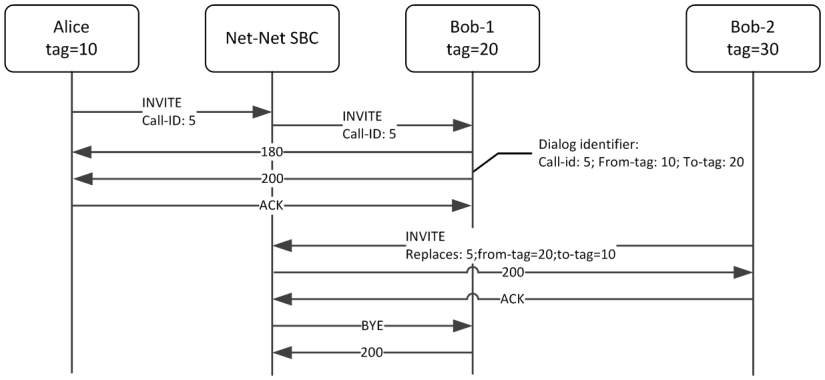
The Oracle Communications Session Border Controller (SBC) supports the Replaces: header in SIP messages according to RFC 3891. The header, included within SIP INVITE messages, provides a mechanism to replace an existing early or established dialog with a different dialog. The different dialog can be used for services such as call parking, attended call transfer and various conferencing features.

The Replaces: header specifies the dialog to replace by containing the corresponding dialog identifier. The identifier includes the from tag, to tag, and call id. The orientation of endpoint-created tags, as from-tag and to-tag, matches each of the two dialogs for a standard call. For

example, the Replaces: header from an endpoint that specifies assuming the dialog between the SBC and Bob-1 appears as follows:

```
Replaces:5555;from-tag=20;to-tag=10
```

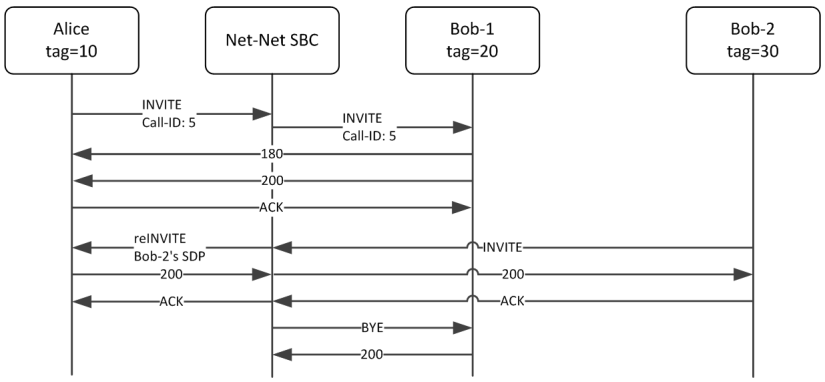
The SBC validates the dialog identifier by matching an existing dialog, tries to install the new endpoint, and tries to remove the old endpoint by gracefully ending that dialog with a BYE. The replaces INVITE must come from an endpoint in the same realm as the endpoint it is replacing. If the UA sending the Replaces header is in a different realm as the original call leg (or indicates such architecture from a malformed Replaces: header), the SBC replies to the Replaces: endpoint with a 481 Missing Dialog. Refer to the following diagram for the standard scenario.



Note that when the endpoints are in the same realm, you must enable the **mm-in-realm** parameter in realm-config or the SBC cannot generate the SDP for the 200 OK. Without the SDP, the call is unsuccessful.

New SDP Parameters in INVITE with Replaces

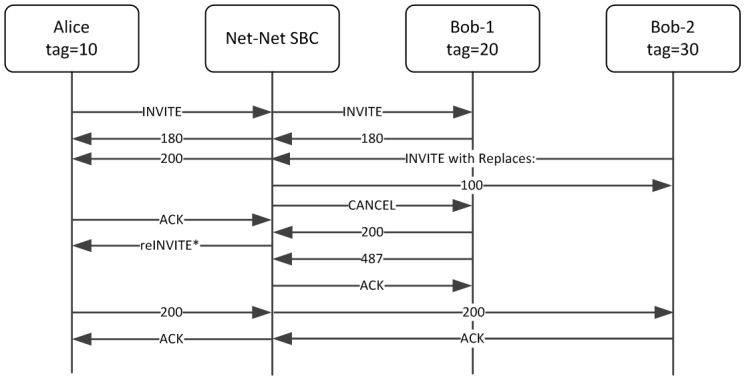
When an INVITE with Replaces: header is received, the media parameters in the new SDP are compared against the SDP of the dialog to be replaced. If any portion of the SDPs (excluding the session-origin line) is different, then the media must be renegotiated. The Oracle Communications Session Border Controller sends a re-INVITE with the new SDP to the dialog opposite of the one being replaced as shown below. If the re-INVITE fails for any reason, then the original dialogs will remain.



It is important to note that, if the SDP matches, the SBC suppresses this re-INVITE. As inferred above, when an INVITE with a REPLACES header arrives, the SBC notes the matching dialog and then makes SDP changes, including codec manipulation, codec-policy application and, in the case of SRTP to RTP sessions, crypto removal. It is only after these changes that the SBC compares everything in the dialog's most recent SDP with the new SDP, excepting the SDP version and whitespace. If the SDP does match, the SBC suppresses the re-INVITE to the original client and proceeds with the replaced dialog.

Early Dialog Replacement

An INVITE with Replaces: header can replace an early dialog. That is, a dialog where the final 2xx class response to INVITE request has not arrived yet. The Oracle Communications Session Border Controller completes the originating side of the call with a 200 OK. The original dialog with the terminator is cancelled. SDP from the new terminator can be renegotiated if it changes.



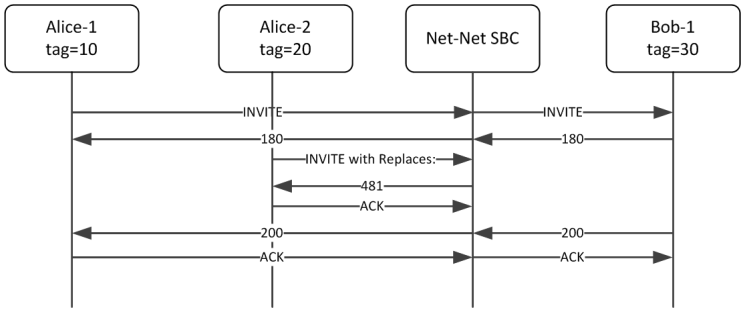
The SDP from the original 183 response is used for the 200 response back to the originator if present to complete the early transaction. If reliable provisional messages are used, then no SDP is included in the 200 response.

If no SDP is present in any of the provisional messages, then the Oracle Communications Session Border Controller constructs it from the original offer and modifying the IP port information for each c= and m= line with information from the INVITE with Replaces: header. If there are more m= lines in the original offer than ports from the INVITE with Replaces: header, then the extra ports are disabled with port value of 0. If no SDP was offered in the original INVITE, then the SDP from the INVITE with Replaces: header is used as the offer in the 200 OK.

If the SDP media parameters were compatible between the replaced and replacing SDPs, then media does not need to be renegotiated and no re-INVITE is created. If the re-INVITE fails, the original dialogs are torn down using a BYE for the original server dialog.

INVITE with Replaces in Early Dialog Server Side

The Oracle Communications Session Border Controller does not support replacing an early server dialog. It replies with a 481 (Dialog/Transaction does not exist) response to the endpoint requesting the replace.



Replace Header Configuration

Replaces: header support is configured in the session-agent, realm, or sip-interface via the sip-profile configuration element. sip-profiles are defined once and attached to a chosen interface, realm or session-agent.

The replace-dialogs parameter is set to either **enabled** or **disabled**. In addition, you may set this parameter to **inherit** which uses the next lower order of precedence object. If there are no sip-profiles referenced in the higher ordered object, or if all the replace-dialogs parameters are set to **inherit**, then the feature is disabled.

To configure Replaces: header support:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-profile** and press Enter. **If you are adding this feature to an existing configuration, then remember you must select the configuration you want to edit.**

   ```
   ORACLE (session-router)# sip-profile
   ORACLE(sip-profile)#
   ```

4. **replace-dialogs**—Set this parameter to **enabled** to enable Replaces: header support. A replaces parameter is also inservted in the Supported: header as sent into the realm where this sip profile is applied. You may also set this parameter to **inherit** for the element which this sip-profile is applied to, to inheret the value from the next-lower element.
5. Type **done** to save your work and continue.

Debugging

show sipd status

Includes Replaced Dialogs counts to show successfully replaced dialogs:

```
# show sipd status
17:41:38-142
```

```
SIP Status                -- Period -- -------- Lifetime --------
                  Active     High   Total      Total  PerMax    High
Replaced Dialogs      -        -       1          1       1
```

show sipd errors

Includes Replace Dialog Fails to show failed dialog replacements. This counter is incremented only when the dialog replacement attempt actually occurred but failed to successfully complete.

```
# show sipd errors
17:58:04-181
SIP Errors/Events             ---- Lifetime ----
                        Recent      Total  PerMax
Replace Dialog Fails         0          0       0
```

SIP Options

This section explains how you can configure a limited list of specialized SIP features and/or parameters called options. The options described here were developed to meet specific needs not addressed by the standard SIP configuration parameters. Not all users have a need for these options.

> **Note:**
>
> Oracle recommends checking with your Oracle representative before applying any of these options.

Overview

You can configure options for the SIP configuration and SIP interface. Both elements include a parameter (options) that you use to configure the options.

Global SIP Options

The following table lists the SIP options supported by the Oracle Communications Session Border Controller (SBC).

Option	Description
add-error-to-tag=no	If present (even when set to no), suppresses the addition of an Acme tag on 3xx-6xx responses.
add-prov-to-tag=no	Prevents the SBC from adding a tag parameter to the To header (to-tag) to non-100 provisional responses to INVITE requests. Used when a provisional (101-199) response is received from the UAS on a client transaction without a to-tag. By default, the SBC adds the tag cookie in the response (as though it had a tag) sent back to the UAC for the associated server transaction. When you include this option in the SIP configuration, and the response from the UAS does not have a to-tag, the response forwarded to the UAC will not have a to-tag.

Option	Description
add-reg-expires	Causes an Expires header to always be included in a REGISTER response with the registration caching and HNT traversal functions of the SBC. Use for endpoints that do not understand the Expires parameter in the Contact header.
add-ruri-user=<methods>	Causes a userinfo portion to be added to a Request-URI when one is not present. Used to support the OKI phone, which registers a Contact of just an IP-Address but rejects initial INVITEs if the Request_URI does not have a userinfo part. <methods> is a comma-separated list of methods to which the option should apply. If more than one method is listed, the list must be enclosed in quotes. This option only applies to out-of-dialog requests (no tag parameter in the To header). However, if ACK is listed, it will apply to all ACK requests because an ACK is always supposed to have a to-tag.
allow-notify-no-contact	Prevents the SBC from rejecting NOTIFYs with a 400 Bad Request response.NOTIFY requests without Contact header are allowed to pass through the SBC instead.
call-id-host=<host>	Causes the SBC to include a host part (ID@host) in the Call-ID it generated. <host> is the hostname (or IP address) that is to appear in the host part of the Call-ID. If not specified, the SIP port address is used.
contact-endpoint=<param-name>	Defines a URL parameter to report the real Contact address of an endpoint in a REGISTER message forwarded to a registrar, when the SBC is caching registration. (plain or HNT). If <param-name> is not specified, the default value endpoint is used. This parameter is added as a URL parameter in the Contact on the REGISTER message. In order for the registration cache to work properly, the softswitch/ registrar is expected to include the endpoint parameter in the Request-URI of a SIP request it forwards to the address-of-record.
contact-firewall=<param-name>	Defines a URL parameter to report the NAT between the SBC and the real Contact address of an endpoint in a REGISTRAR message forwarded to a registrar when the SBC is doing registration caching for NHT. If <param-name> is not specified, the default value firewall is used. This parameter will be added as a URL parameter in the Contact on the REGISTER message. In order for the registration cache to work properly, the softswitch/ registrar is expected to include the endpoint parameter in the Request-URI of any SIP request it forwards for the address-of-record.
disable-privacy	Prevents the change of the P-Preferred-Identity to P-Asserted-Identity and lets the P-Preferred-Identity go through unchanged.
drain-sendonly	Causes the SBC to examine the SDP attributes and change sendonly mode to sendrecv. This causes the endpoint receiving the SDP to send RTP, which is required for HNT traversal endpoints to work with media servers. The SBC sets up the flow so that RTP coming from the endpoint are dropped to prevent the UA that sent the sendonly SDP from receiving packets. See the option video-sbc-session also.

Option	Description
encode-contact=<prefix>	Causes the SBC to encode Contact addresses into the userinfo part of the URI. It applies only to Contact address that usually get the maddr parameter. Use when the SBC needs requests sent to the URI in the Contact sent instead to the SBC. The host part of the URI will have the SBC's address. The <prefix> serves as a place between the original userinfo and the encoded address. If a <prefix> is specified, a default of +SD is used. Without this option, the SBC adds a maddr parameter.
fix-to-header	For requests that have the SBC address in both the Request-URI and the To-URI, it sets the hostport of the To-URI to a local policy's next hop target on out-of-dialog requests (no to-tag). This is the default IWF behavior, even without this option configured.
forward-reg-callid-change	Addresses the case when an endpoint reboots and performs a third party registration before its old registration expires. During this re-registration, the contact header is the same as it was pre-reregistration. As a consequence of the reboot, the SIP Call-ID changes. In this situation, the SBC does not forward the REGISTER to the registrar, because it believes the endpoint is already registered, based on a previous registration from the same Contact: header URI. To remedy this problem, the SBC now keeps track of the Call-ID in its registration cache. A new option in the SIP interface configuration element forces the SBC to forward a REGISTER message to the registrar when the Call-ID header changes in a REGISTER message received from a reregistering UAC.
global-contact	Addresses interoperability in the Dialog and Presence event packages that are used in hosted PBX and IP Centrex offerings. This option enables persistent URIs in the Contact headers inserted into outgoing SIP messages. If this option is not used, URIs placed in the Contact header of outgoing messages are only valid within the context of the dialog to which the message is associated.
ignore-register-service-route-oos	Prohibits a Register message from using a service route if that service route is an out-of-service session agent.
load-limit=<cpu percentage>	Defines the CPU usage percentage at which the SBC should start rejecting calls. Default value is 90%.
lp-sa-match=<match strategy>	Changes the ways local policies and session agents match; accounts for realm in matching process. Strategy choices are: all, realm, sub-realm, interface, and network.
max-register-forward=<value>	Defines a limit (as assigned in the value field) of REGISTER refreshes to be forwarded to the registrar. During each second, the sipd counts how many REGISTER refreshes have been sent to the registrar. It checks the threshold when it receives a REGISTER refresh from the UA and determines that less than half the real registration lifetime is left. If the number of REGISTER refreshes forwarded (new and updates) in the current second exceeds the configured threshold, it will respond to the UA from the cache.

Option	Description
max-register-refresh=<value>	Defines the desired limit of REGISTER refreshes from all the UAs. Each second of time, sipd counts the number of REGISTER/200-OK responses sent back. When the threshold is exceeded, it increments the expire time (based on NAT interval) by one second and resets the count. By default no threshold is applied. The recommended value is somewhat dependent on the SBC hardware used, but 300 can be used as an initial value.
max-routes=<number of routes>	Restricts the number of routes through which the sipd will iterate from a local policy lookup. For example, setting this option to 1 causes the SBC to only try the first, best, route. Setting this option to 0, or omitting it, lets the SBC use all of the routes available to it (with the priority scheme for route matching). When you test a policy using the test-policy ACLI command, this option is not recognized and all options that match the criteria are displayed.
max-udp-length=<maximum length>	Setting this option to zero (0) forces sipd to send fragmented UDP packets. Using this option, you override the default value of the maximum UDP datagram size (1500 bytes; sipd requires the use of SIP/TCP at 1300 bytes). You can set the global SIP configuration's max-udp-length=x option for global use in your SIP configuration, or you can override it on a per-interface basis by configuring this option in a SIP interface configuration.
media-release=<header-name>[;<header-param>]	Enables the multi-system media release feature that encodes IP address and port information for the media streams described by SDP. It lets another SBC decode the data to restore the original SDP, which allows the media to flow directly between endpoints in the same network (that is serviced by multiple SBCs). The media release information can appear in the following places: • SIP header P-Media-Release: <encoded-media-interface-information> • Header parameter on a SIP header Contact: <sip:1234@abc.com> ; acme-media=<encoded-media-interface-information> • SDP attribute in the message body a=acme-media: <encoded-media-interface-information> Option includes the following: • <header-name> is SIP header in which to put the information or the special value sdp, which indicates the information should be put into the SDP. • <header-param> is the header parameter name in which to put the information or in the case of the special header name value sdp, it is the SDP attribute name in which to put the information. They identify to where the encoded information is passed. If you do not specify a header, P-Media-Release is used.

Option	Description
no-contact-endpoint-port	Enables the SBC to add a URL parameter (defined as an argument to the contact-endpoint option) to the Contact headers of REGISTER messages that it forwards to the registrar when it performs registration caching. The value of the contact-endpoint URL parameter is the real address of the endpoint; and if the endpoint is behind a NAT, this includes the IP address and a port number. However, not all network entities can parse that port number, which is included unconditionally. This feature allows you to configure the exclusion of the port number. Despite the fact that you set this parameter in the global SIP configuration, it is applied only to SIP interfaces. However, you can set a contact-endpoint option in the realm configuration, on which this new parameter has no effect.
refer-to-uri-prefix=<prefix>	Defines a prefix to be matched against the userinfo part of Contact headers (config=), of which the SBC should create a B2BUA map. This ensures that outgoing messages include the correct userinfo value. This option is used to enable add-on conferencing. 1. On the SBC, set **refer-to-uri-prefix=<string>**, for example, **refer-to-uri-prefix="conf="**. 2. When the SBC receives either an INVITE or 200 OK, it stores the Contact:sip:conf=<ID@IP:port> contained in the SIP message. 3. When the SBC receives a REFER in a separate call session, the config=<ID>@ IP2:port2 in this message is different. 4. The SBC searches for the original conf=<ID> map, replaces the IP2:port2 with the stored IP:port, and forwards the updated REFER message.
reg-cache-mode=<mode>	Affects how the userinfo part of Contact address is constructed with registration caching. <mode> values are: • none: userinfo from the received (post NAT) Contact is retained • from: userinfo from the From header is copied to the userinfo of the forwarded Contact header • append: append the UA's Contact address into a cookie appended to the userinfo from the original Contact userinfo. For HNT, the NAT/firewall address is used. • append-from: takes userinfo from the From header and appends the encrypted address to the userinfo from the original Contact userinfo. For HNT, the NAT/firewall address is used. The from mode is used with softswitches that do not use the cookies used by the SBC. It also helps limit the number of bytes in the userinfo; which might create duplicate contacts. For example, if the SBC address is 1.2.3.4, both 1234@5.6.7.8 and 1234@4.3.2.1 will result in a SBC contact of 1234@5.6.7.8.

Option	Description
reg-contact-user-random	Support the SIP random registered-contact feature. Gives the SBC the ability to support endpoints that randomly change their contact usernames every time they re-register. Only applicable to operators who need to support the Japan TTC standard JJ-90.22 in specific applications. Applies to cases when an endpoint re-registers with a different contact username, but with the same hostname/IP address and the same address of record (AoR). Without this feature enabled, the SBC forwards every re-registration to the registrar with the new contact information without it being considered a registration refresh. The SBC forwards it to the Registrar using the same sd-contact as the previous registration. When you set this option, the SBC does treat such a re-registration as a registration refresh when it is received prior to the half-life time for the specific contact. The SBC also uses the new contact username for the Request-URI in requests it sends to the UA, and verifies that the UA uses the correct one when that SBC is set to allow-anonymous registered mode. NOTE: The registration cache mode is set using the option reg-cache-mode, but regardless of how you configure it, the registration cache mode will be set to contact when SIP random registered-contact feature is enabled.
register-grace-timer	Makes the grace time for the SIP Registration configurable. You can configure the grace timer in seconds.
reinvite-trying=[yes | no]	When set to "yes", the SBC sends a 100 Trying in response to Re-Invites. Whet set to "no", it does not. If you enter the option but omit the value, the option takes the value "yes". The default SBC behavior (the option not set) works differently on standalone and HA systems. For standalone, the default is to send the 100 Trying for Re-Invites. For HA, it does not. The difference between default behaviors is because of the timing involved with switching over. An active SBC can receive the re-INVITE before receiving a 200 OK. In that case, a new active SBC handles the re-INVITE properly after a switchover. But, if the SBC sends a 100 Trying before the switchover, the new active is not aware of the 200 OK transaction, and therefore discards the re-INVITE as a stray message.
reject-interval=<value>	Acts as a multiplier to increase the value presented to the UAC in the Retry-After field. For example, if reject-interval=5 (reject interval is set to 10); at a 90% rejection rate the SBC sends Retry-After: 45. When rejecting calls because of CPU load limiting, the SBC adds a Retry-After parameter to the error response (typically 503 Service Unavailable). By default the SBC sets the Retry-After value to be 1/10th of the current rejection rate.
reject-register=[no | refresh]	Allows REGISTER messages through even during load limiting. By default, REGISTER messages are subject to load limiting.
response-for-not-found=<response code>	Change the 404 Not Found generated by the SBC to a different response code.

Option	Description
route-register-no-service-route	Controls how a UA is registered. Option can have three values: • route-register-no-service-route—This option prevents the use of the Service-Route procedure to route the Re-Register requests after the UA has initially registered. • route-register-no-service-route=all—Prevents the use of the Service-Route procedure to route the Re-Register requests for all messages, after the UA has initially registered. • route-register-no-service-route=refresh—Prevents the use of the Service-Route procedure to route the Re-Register requests for all refresh-register messages, but not de-register messages, after the UA has initially registered. Addition idle argument ensures that, when enabled, the SBC follows the previously defined rules for idle calls, where idle means not engaged in any INVITE-based sessions. Sample syntax: route-register-no-service-route=refresh;idle
sdp-insert-sendrecv	When a call is initiated, the SDP communicates between call offerer and call answerer to determine a route for the media. Devices can be configured to only send media (“a=sendonly”), to only receive media (“a=recvonly”), or to do both (“a=sendrecv”). Some devices, do not disclose this information. With this option configured, when either the offerer or answerer does not disclose its directional attribute, the SBC automatically inserts a sendrecv direction attribute to the media session.
set-inv-exp-at-100-resp	Set Timer C when a 100 Trying response is received (instead of waiting until 1xx (> 100) is received). If the SBC does not receive a 100 Trying response within Timer B, the call should be dropped because there is a problem communicating with the next hop.
strip-domain-suffix-route	Causes sipd to strip any Router headers from the inbound messages coming to the external address of a SIP NAT; if the message contains a FQDN that matches the configured domain suffix for that SIP NAT.
video-sbc-session	Use with drain-sendonly for conference floor support. When configured with drain-sendonly and when the SBC receives an SDP, the SBC proxies the m=control and its related a= and c= unchanged. Although media streams are allocated for this m line, an actual flow is not set up. SDP received with the following: m=video a=sendonly is sent out as the following: m=video a=sendonly a=X-SBC-Session
session-timer-support	This option enables the SBC to start the session timer for session refreshes coming from the UAC. The SBC determines whether or not a session is active based on session refreshes or responses. It terminates the session when no session refreshes occur within the session timer interval.
session-timer-support	Enables RFC4028 session timer support.
inmanip-before-validate	Enables SIP Header Pre-processing for HMR.
proccess-implicit-tel-URI	Correctly appends coodie in REGISTER message when user=phone does not exist.
offerless-bw-media	Reserves appropriate bandwidth for an INVITE with no SDP.

SIP Interface Options

The following table lists the SIP interface options supported by the Oracle Communications Session Border Controller (SBC).

Option	Description
100rel-interworking	Enables RFC 3262, *Reliability of Provisional Responses in the Session Initiation Protocol* support.
change-contact-user	The SBC alters the **user-uri** portion of the contact header. This option works only when the **user-uri** contact header is different than the FROM header. 1. In **sip-config**, **options** apply `reg-cache-mode=from`. 2. In the ingress **sip-interface**, **options** apply `change-contact-user`. When these settings are applied, the contact header's user-uri is changed to the user-uri of the FROM header. This feature works for out of dialog INVITE and in-dialog messages (ACK, BYE, UPDATE,REFER,INFO,SUBSCRIBE,NOTIFY,PUBLISH,MESSAGE,PRACK), however, does not work for REGISTER messages.
contact-endpoint=<endpoint name>	The SBC inserts the endpoint IP address and port into the Contact headers as messages egress using that SIP interface. The inserted data is the same as the information received in the Request or Response being forwarded. If the endpoint name is not specified, the default value endpoint is used.
contact-firewall=<firewall name>	The SBC inserts the firewall IP address and port into the Contact headers as messages egress using that SIP interface. The inserted data is the same as the information received in the Request or Response being forwarded. If the endpoint name is not specified, the default value firewall is used.
contact-vlan=<VLAN/realm name>	The SBC inserts the realm and VLAN ID into the Contact headers as messages egress using that SIP interface. The inserted data is the same as the information received in the Request or Response being forwarded. If the endpoint name is not specified, the default value vlan is used.

Option	Description
dropResponse	The SBC drops responses by specified status codes. The option value can contain one or more status codes separated by colons. Response code ranges can also be entered. If any of the response codes matches, then a response is not sent. If the dropResponse option is set in both the sip-interface and the session-agent elements, the session-agent setting takes precedence. **Note:** This feature screens all messages passing through SBC against the dropResponse list. If there is a hit, the response message is dropped. However, for error messages generated by the SBC, only the response messages generated after the initial routing is complete are screened against the dropResponse list.
max-udp-length=<maximum length>	Sets the largest UDP packers that the SBC will pass. Packets exceeding this length trigger the establishment of an outgoing TCP session to deliver the packet; this margin is defined in RFC 3261. The system default for the maximum UDP packet length is 1500. You can set the global SIP configuration's max-udp-length=x option for global use in your SIP configuration, or you can override it on a per-interface basis by configuring this option in a SIP interface configuration.
response-for-not-found=<response code>	Change the 404 Not Found generated by the SBC to a different response code.
strip-route-headers	Causes the SBC to disregard and strip all route headers for requests received on a SIP interface.
upd-fallback	When a request needs to be sent out on the SIP interface for which you have configured this option, the SBC first tries to send it over TCP. If the SIP endpoint does not support TCP, however, then the SBC falls back to UDP and tries the request again.
via-header-transparency	Enables the SBC to insert its Via header on top of the top-most Via header received from user equipment (UE). It then forwards it on to the IP Multimedia Subsystem (IMS) core with the original Via header now located as the bottom-most Via header. The SBC still replaces the Contact and other header addresses with its own, and does not pass on the core's Via headers in outbound requests.
use-redirect-route	Use Route parameter in Contact header as next-hop as received in a 3xx response.
reg-via-proxy	Enables your SBC to support endpoints that register using an intervening proxy.
lmsd-interworking	Enables 3GPP2 LMSD Interworking.
suppress-reinvite	Enables reINVITE supression.

SIP Session Agent Options

The following table lists the SIP session agent options supported by the Oracle Communications Session Border Controller.

Option	Description
dropResponse	The Oracle Communications Session Border Controllerdrops responses by specified status codes. The option value can contain one or more status codes separated by semicolons. Error ranges can also be entered. If any of the response codes matches then a response is not sent. If the dropResponse option is set in both the sip-interface and the session-agent elements, the session-agent setting takes precedence.
trans-timeouts=<value>	Defines the number of consecutive non-ping transaction timeouts that will cause a session agent to be out of service. When the session agent is configured, i.e. when the PING options are defined, the value is 10. If not defined, the default value is 5. A Value of 0 prevents the session agent from going out of service because of a non-ping transaction timeout.
via-origin=<parameter-name>	Causes a parameter to be included in the top Via header of requests sent to the session agent. The parameter indicates the source IP address of the corresponding request received by the Oracle Communications Session Border Controller. <parameter-name> defines the name of the parameter. If not specified, the default value origin is used.
refer-reinvite	Enables SIP REFER with Replaces.

SIP Realm Options

The following table lists the SIP session agent options supported by the Oracle Communications Session Border Controller.

Option	Description
number-normalization	Applies to the SIP To URI. (Currently the Oracle Communications Session Border Controller supports number normalization on From and To addresses for both inbound and outbound call legs.) Number normalization includes add, delete, and replace string functions that result in consistent number formats. Number normalization occurs on ingress traffic, prior to the generation of accounting records or local policy lookups. (also applies for H.323 to SIP calls.)
refer-reinvite	Enables SIP REFER with Replaces.

SIP Realm Options Configuration

To configure options:

Labels enclosed in <> indicate that a value for the option is to be substituted for the label. For example, <value>. In order to change a portion of an options field entry, you must re-type the entire field entry.

1. Navigate to the options parameter in the SIP configuration or SIP interface elements.

2. Enter the following:

   ```
   options Space <option name>=”<value>”
   ```

   For example, if you want to configure the refer-to-uri-prefix option (the add-on conferencing feature):

   Type options, followed by a Space.

   Type refer-to-uri-prefix, followed by an equal sign (=).

   Type the opening quotation mark (“) followed by conf, another equal sign and the closing quotation mark.

   Press Enter.

   For example:

   ```
   options refer-to-uri-prefix=conf=
   ```

   If the feature value itself is a comma-separated list, it must be enclosed in quotation marks.

Configuring Multiple Options

You can enter a list of options for this field:

1. Type **options** followed by a space.
2. Within quotation marks, enter the feature names and values of the parameters you need. Separate each one with a comma.
3. Close the quotation marks.
4. Press Enter.

   For example:

   ```
   ACMEPACKET(sip-config)# options “refer-to-uri-prefix=“conf=”,encode-
   contact=“+SD”,add-ruri-user=INVITE,ACK”
   ```

Adding an Entry

Enter the new entry with a preceding plus (+) sign. For example:

```
options +response-for-not-found
```

This format allows previously configured options field values to remain intact without requiring re-entry of the entire field value.

SIP Security

This section provides an overview of Oracle Communications Session Border Controller’s security capability. Oracle Communications Session Border Controller security is designed to provide security for VoIP and other multi-media services. It includes access control, DoS attack, and overload protection, which help secure service and protect the network infrastructure (including the Oracle Communications Session Border Controller). In addition,

Oracle Communications Session Border Controller security lets legitimate users to still place calls during attack conditions, protecting the service itself.

Oracle Communications Session Border Controller security includes the Net-SAFE framework's numerous features and architecture designs. Net-SAFE is a requirements framework for the components required to provide protection for the Session Border Controller (SBC), the service provider's infrastructure equipment (proxies, gateways, call agents, application servers, and so on), and the service itself.

Denial of Service Protection

The Oracle Communications Session Border Controller Denial of Service (DoS) protection functionality protects softswitches and gateways with overload protection, dynamic and static access control, and trusted device classification and separation at Layers 3-5. The Oracle Communications Session Border Controller itself is protected from signaling and media overload, but more importantly the feature allows legitimate, trusted devices to continue receiving service even during an attack. DoS protection prevents the Oracle Communications Session Border Controller host processor from being overwhelmed by a targeted DoS attack from the following:

- IP packets from an untrusted source as defined by provisioned or dynamic ACLs
- IP packets for unsupported or disabled protocols
- Nonconforming/malformed (garbage) packets to signaling ports
- Volume-based attack (flood) of valid or invalid call requests, signaling messages, and so on.
- Overload of valid or invalid call requests from legitimate, trusted sources

Levels of DoS Protection

The multi-level Oracle Communications Session Border Controller Denial of Service protection consists of the following strategies:

- Fast path filtering/access control: involves access control for signaling packets destined for the Oracle Communications Session Border Controller host processor as well as media (RTP) packets. The SBC accomplishes media filtering using the existing dynamic pinhole firewall capabilities. Fast path filtering packets destined for the host processor require the configuration and management of a trusted list and a deny list for each Oracle Communications Session Border Controller realm (although the actual devices can be dynamically trusted or denied by the Oracle Communications Session Border Controller based on configuration). You do not have to provision every endpoint/device on the Oracle Communications Session Border Controller, but instead retain the default values.
- Host path protection: includes flow classification, host path policing and unique signaling flow policing. Fast path filtering alone cannot protect the Oracle Communications Session Border Controller host processor from being overwhelmed by a malicious attack from a trusted source. The host path and individual signaling flows must be policed to ensure that a volume-based attack will not overwhelm the Oracle Communications Session Border Controller's normal call processing; and subsequently not overwhelm systems beyond it. The Oracle Communications Session Border Controller must classify each source based on its ability to pass certain criteria that is signaling- and application-dependent. At first each source is considered untrusted with the possibility of being promoted to fully trusted. The Oracle Communications Session Border Controller maintains two host paths, one for each class of traffic (trusted and untrusted), with different policing characteristics to ensure that fully trusted traffic always gets precedence.

- Host-based malicious source detection and isolation – dynamic deny list. Malicious sources can be automatically detected in real-time and denied in the fast path to block them from reaching the host processor.

Configuration Overview

NAT table entries are used to filter out undesired IP addresses (deny list). After the packet from an endpoint is accepted through NAT filtering, policing is implemented in the Traffic Manager based on the sender's IP address. NAT table entries are used to distinguish signaling packets coming in from different sources for policing purposes.

You can configure deny rules based on the following:

- ingress realm
- source IP address
- transport protocol (TCP/UDP)
- application protocol (SIP)

You can configure guaranteed minimum bandwidth for trusted and untrusted signaling paths.

You can configure signaling path policing parameters for individual source addresses. Policing parameters include:

- peak data rate in bits per second
- average data rate in bits per second
- maximum burst size

SIP Unauthorized Endpoint Call Routing

The Oracle Communications Session Border Controller (SBC) can route new dialog-creating SIP INVITEs from unauthorized endpoints to a session agent or session agent group; then rejection can occur based on the allow-anonymous setting for the SIP port. This type of provisional acceptance and subsequent rejection applies only to INVITEs; the SBC continues to reject all other requests, such as SUBSCRIBE.

You might enable this feature if you have a network in which unauthorized SIP endpoints continually try to register even if the Oracle Communications Session Border Controller has previously rejected them and never will accept them. For instance, the user account associated with the endpoint might have been removed or core registrars might be overloaded.

SIP Unauthorized Endpoint Call Routing Configuration

You enable the routing of unauthorized endpoints to session agents and session agent groups that will reject them in the SIP interface configuration.

To enable SIP unauthorized endpoint call routing:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

   If you are adding this feature to an existing configuration, then you will need to select the configuration you want to edit.

4. **route-unauthorized-calls**—Enter the name (or IP address) of the session agent or session agent group to which you want calls from unauthorized endpoints routed. This parameter is blank by default, meaning the SIP unauthorized call routing feature is disabled.

   Remember your settings in the **allow-anonymous** parameter in the SIP port configuration provide the basis for rejection.

5. Save and activate your configuration.

SIP NAT Function

This section explains how to configure the optional SIP NAT function. You can configure the SIP NAT function if you need to translate IP address and UDP/TCP port information. The SIP NAT function also prevents private IP addresses in SIP message URIs from traveling through an untrusted network.

Overview

TheOracle Communications Session Border Controller is an intermediary device that provides NAT functions between two or more realms. It translates IP addresses between untrusted and trusted networks using NAT. A trusted network is inside the NAT, and a untrusted network is outside the NAT. A NAT also lets a single IP address represent a group of computers.

For SIP, the SIP NAT function on the Oracle Communications Session Border Controller does the following:

- routes SIP packets between the Oracle Communications Session Border Controller's SIP proxy (B2BUA) and external networks (or realms), including the translation of IP address and UDP/TCP port information.
- prevents private IP addresses in SIP message URIs from traveling through the untrusted network. SIP NAT either translates the private address to one appropriate for an untrusted address or encrypts the private address into the URI.

Packets arriving on the external address (at port 5060) are forwarded to the Oracle Communications Session Border Controller's SIP proxy with the source address changed to the home address (at port 5060). When the Oracle Communications Session Border Controller's SIP proxy sends packets to the home address (at port 5060), they are forwarded to the external proxy address (and external proxy port), with the source address changed to the external address (at port 5060).

> **Note:**
>
> The SIP config's NAT mode parameter works in conjunction with the SIP NAT function configuration. It identifies the type of realm in which the SIP proxy is located (public or private) and affects whether IPvr addresses in SIP messages are encoded.

The translation of URIs in the actual SIP message occurs as messages are received and sent from the Oracle Communications Session Border Controller's SIP proxy. For the messages being sent to the external network, the contents of the SIP message are examined after the translation to determine if the destination needs to be changed from the external proxy address to an address and port indicated by the SIP message. This process takes place so the request is sent to where the Request-URI or the Route header indicates, or so the response is sent to where the Via indicates.

NAT Modes

The specific addresses used in translating URIs in the SIP message depend on whether the Oracle Communications Session Border Controller is performing NAT functions for a trusted or untrusted network. This condition is determined by the NAT mode value you enter when you configure the SIP config element. The NAT modes are:

- **untrusted**—The SIP proxy is associated with an address for an untrusted network (the address value you entered when you configured the SIP interface's SIP port parameter), and the home address in the SIP NAT is the address of the external realm/network. When the URI contains the external address, it is translated to the SIP NAT's home proxy address (or to the SIP port address if the home proxy address field is empty). When a URI contains the external proxy address, it is translated to the home address.
  If the URI contains any other private address (matching the realm's address prefix, identified in the SIP NAT's realm ID), it is encrypted and the address is replaced with the home address value. If the URI contains a user part, a suffix consisting of the user NAT tag and the encrypted address is appended to the user part. For example, with a user NAT tag value of -private-, the private URI of sip@123192.169.200.17:5060 will become the public URI of sip:123-private-eolmhet2chbl3@172.16.0.15.

  If there is no user part, the host consists of the host NAT tag followed by the encrypted address and the domain suffix. A maddr parameter equal to the home address (or received in the case of a Via header) is added to the URI. For example, with a host NAT tag value of PRIVATE- and a domain suffix value of private.com, the private URI of sip:192.168.200.17:5060 will become the public URI of sip:PRIVATE-eolmhet2chbl3.private.com:5060;maddr=172.16.0.15.
- **trusted**—The SIP proxy is on a trusted network (the address value you entered when you configured the SIP interface's SIP port parameter), and the SIP NAT's external address is the public address of the external realm/network. When the URI contains the home address value, it is translated to the value set for the external proxy address. When the URI contains the SIP proxy's address, it is translated to the external address. If the URI contains any other private address (matching the realm's address prefix, identified in the SIP NAT's realm ID), the private address is encrypted and the address is replaced with the external address.

> **Note:**
>
> Do not use the home proxy address value with private NAT functioning.

Adding a maddr Parameter to a URI

When you configure a SIP interface, you can configure the contact mode. The contact mode sets the contact header routing mode, which determines how the contact address from a trusted network is formatted. You set the contact mode to add a maddr parameter equal to the SIP proxy to the URI in the Contact header. For example, the URI from the prior example (sip:192.168.200.17:5060) becomes sip:123-trusted-eolmhet2chbl3@172.16.0.15;maddr=172.16.0.12.

> **Note:**
>
> For SIP elements that do not support the maddr parameter, configure a Contact mode as none.

You might require this encryption to cause other SIP elements in the untrusted network to send requests directly to the SIP proxy. Otherwise, the requests are sent to the home address. However, responses sent by the SIP proxy will have the SIP proxy's source address, rather than the home address. Some SIP elements might drop responses that come from a IP address different from the one to which the request is sent.

About Headers

You can specify which SIP headers you want effected by the SIP NAT function. The URIs in these headers are translated and encrypted, the encryption occurs according to the rules of this SIP NAT function.

You can enter header values by using either the full header name or its corresponding abbreviation, if applicable. The following table lists the available headers and their corresponding abbreviations.

Header	Abbreviation
Call-ID	i
Contact	m
From	f
Record-Route	none
Route	none
Ready-To	none
Replaces	none
Refer-To	r
To	t
Via	v

SIP sessions are terminated and re-originated as new sessions as they are routed through the Oracle Communications Session Border Controller. Among the actions performed, SIP headers are modified to prevent the transmission of IP address and route information.

Replacing Headers

In the SIP signaling message, any Via headers are stripped out and a new one is constructed with the Oracle Communications Session Border Controller's IP address in the sent-by portion.

If a Contact header is present, it is replaced with one that has the Oracle Communications Session Border Controller's IP address. All other headers are subject to NATing based on the following rules:

- The Request-URI is replaced with the next hop's IP or FQDN address.
- All other headers are replaced based on the two SIP NAT function SIP NAT function rules

Mapping FQDNs

The Oracle Communications Session Border Controller maps FQDNs that appear in the certain headers of incoming SIP messages to the IP address that the SBC inserts in outgoing SIP contact headers. The mapped FQDNs are restored in the SIP headers in messages that are sent back to the originator.

This feature is useful to carriers that use IP addresses in the SIP From address to create trunk groups in a softswitch for routing purposes. When the carrier's peer uses FQDNs, the carrier is forced to create trunk groups for each possible FQDN that it might receive from a given peer. Similarly, this can apply to SIP Contact and P-Asserted-Identity headers.

SIP NAT Function Cookies

Cookies are inserted to hide that information is coming from a realm external to the home realm. They are used when information needs to be placed into a given element of a SIP message that must also be seen in subsequent SIP messages within a flow. When forwarding a SIP message, the Oracle Communications Session Border Controller (SBC) encodes various information in the outgoing message, which is passed from one side to another in SIP transactions.

SIP NAT function cookies let the SBC hide headers, IPv4 addresses, and SIP URIs. These cookies are included when certain conditions are present in SBC SIP transactions.

Oracle's SIP NAT function cookies can be used in the userinfo, host, URL parameter, and tel URL parameter portions of the SIP message.

userinfo

The Oracle Communications Session Border Controller places a cookie in the userinfo portion of a SIP URI when a SIP header contains a SIP URI, and includes that header type in the list of headers to be hidden (encrypted) in the associated SIP NAT function. The cookie for the userinfo portion is the following:

```
[user nat tag][encrypted 13-byte host IP][encrypted 13 byte maddr IP (if
present)]
```

where:

- [user nat tag] refers to the SIP NAT function's original user NAT tag field.
- [encrypted 13-byte host IP] refers to the host IP encryption.
- [encrypted 13 byte maddr IP (if present)] refers to the maddr IP encryption, if it exists.

With a user NAT tag of -acme, the following SIP-URI:

```
sip:6175551212@192.168.1.100
```

might be translated into:

```
sip:6175551212-acme-pfi1s7n2pstna@172.16.1.10
```

> **Note:**
>
> Multiple additional cookies might be appended with each hop (for example, from the external proxy to the home proxy and back).

host

When hiding IP addresses in a SIP message, the SIP NAT function generates the following cookie for a SIP-URI with no userinfo portion:

```
[host nat tag][encrypted 13-byte host IP][encrypted 13 byte maddr IP (if
present)][domain suffix]
```

where:

- [host nat tag] refers to the SIP NAT function's host NAT tag.
- [encrypted 13-byte host IP] refers to the host IP encryption.
- [encrypted 13 byte maddr IP (if present)] refers to the maddr IP encryption, if it exists.
- [domain suffix] refers to the SIP NAT function's domain suffix field.

With a SIP NAT function's host tag of ACME- and a domain suffix of .acme.com, the following SIP header:

Via: SIP/2.0/UDP 192.168.1.100:5060

might be translated into the following:

```
Via: SIP/2.0/UDP ACME-pfi1s7n2pstna.acme.com
```

URL Parameter

If the SIP NAT function's use url parameter field has a value of from-to or all, the SIP NAT function places all cookies generated to hide SIP URIs in a custom tag appended to the header. Setting the use url parameter field to:

- from-to only affects the behavior of the SIP NAT function's cookies in the From and To headers.
- all affects all SIP headers processed by the SIP NAT function

The cookie is the following:

[;url-parameter]=[host nat tag][encrypted 13-byte host IP][encrypted 13-byte maddr IP]

where:

- [;url-parameter] refers to the SIP NAT function's parameter name field.
  This cookie type is associated with the all and from-to field value options of the SIP NAT function's use url parameter field.

- [host nat tag] refers to the SIP NAT function's host NAT tag field.
- [encrypted 13-byte host IP] refers to the host IP encryption.
- [encrypted 13 byte maddr IP (if present)] refers to the maddr IP encryption, if it exists.

With a host NAT tag of ACME- and a parameter name of acme_param, the following SIP-URI:

```
sip:6175551212@192.168.1.100
```

might be translated into the following:

```
sip:6175551212@172.16.1.10;acme_param=ACME-pfi1s7n2pstna.
```

tel URL

The SIP NAT function cookie is used when devices in your network are strict about the context portion of SIP messages regarding the conversion of tel URLs. This cookie for the tel URL parameter portion of a SIP message is the following:

```
tel URL parameter-[13-byte host IP][13 byte optional maddr IP]domain suffix
```

where:

- tel URL parameter refers to the SIP NAT function's use url parameter.
  This cookie type is associated with the use url parameter's phone field value for the SIP NAT.
- [13-byte host IP] refers to the host IP encryption.
- [13 byte optional maddr IP] refers to the maddr IP encryption, if it exists.
- domain suffix refers to the SIP NAT function's domain suffix field.

Configuration Overview

Configuring the SIP NAT function falls into two areas, the SIP NAT interface parameters and the SIP NAT policies.

SIP NAT Interface

The following tables lists the SIP NAT function interface parameters you need to configure on the Oracle Communications Session Border Controller (SBC).

Parameter	Description
realm ID	Name of the external realm. The realm ID must be unique; no two SIP NATs can have the same realm ID. This realm ID must also correspond to a valid realm identifier entered when you configured the realm.
external proxy address	IPv4 address of the SIP element (for example, a SIP proxy) in the external network with which the SBC communicates. Entries must follow the IP address format.
external proxy port	UDP/TCP port of the SIP element (for example, a SIP proxy) in the external network with which the SBC communicates. Minimum value is 1025, and maximum value is 65535. Default is 5060.

Parameter	Description
external address	IPv4 address on the media interface in the external realm. Enter a value that ensures any packet with an external address value as its destination address is routed to the SBC through the media interface connected to or routable from the external realm. Entries must follow the IP address format. To specify whether the external realm referenced in this field is private or public, configure the SIP config's NAT mode.
home address	IPv4 address on the media interface in the home realm. Enter a value that ensures any packet with a home address value as its destination address must be routed to the SBC through the media interface connected to or routable from the home realm. Entries must follow the IP address format. The value entered in this field must be different from the IP address value of the home realm's network interface element. The home realm network interface is associated with this SIP NAT by its realm ID and the realm's identifier and network interface value you entered when you configured the realm. The realm's network interface identifier value corresponds to this SIP NAT's realm ID, the SIP config's home realm ID, and the media manager's home realm ID.
home proxy address	Sets the IP address for the home proxy (from the perspective of the external realm). By default, this field is empty. An empty home proxy address field value signifies that there is no home proxy, and the external address will translate to the address of the SBC 's SIP proxy. Entries must follow the IP address format.
home proxy port	Sets the port number for the home realm proxy. Value can be set to zero (0). Minimum is 1025 and maximum is 65535. Default is 5060.
route home proxy	Whether to route all inbound requests for the SIP NAT to the home proxy. enabled adds route if Request-URI is not the SBC disabled does not route inbound requests to the home proxy forced always adds route

SIP NAT Function Policies

The following tables lists the SIP NAT function policy parameters you need to configure on the Oracle Communications Session Border Controller (SBC).

Parameter	Description
domain suffix	Domain name suffix of the external realm. The domain name suffix refers to and must conform to the hostname part of a URI. In combination with the user NAT tag and host NAT tag values, this value is used to help the SBC identify an encoded URI that it needs to translate when moving between public and private realms. This suffix is appended to encoded hostnames that the SIP NAT function creates. For example, if the encoded hostname is ACME-abc123 and the domain-suffix value is .netnetsystem.com, the resulting FQDN will be ACME-abc123.netnetsystem.com.
address prefix	Defines which IPv4 address prefixes from incoming messages require SIP-NAT encoding (regardless of the realm from which these messages came).

Parameter	Description
tunnel redirect	Controls whether Contact headers in a 3xx Response message received by the SBC are NATed when sent to the initiator of the SIP INVITE message.
use url parameter	Establishes whether SIP headers will use the URL parameter entered in the parameter name for encoded addresses that the SIP NAT function creates. Also, if SIP headers will be used, which type of headers will use the URL parameter. For example, all headers or just the From and To headers. Enumeration field.
parameter name	Indicates the name of the URL parameter when use url applies. This field value will be used in SIP NAT encoding addresses that have a use url parameter value of either from-to or all.
user NAT tag	Identifies the prefix used when an address is encoded into the username portion of user@host;name=xxxx; where name = parameter name. The user NAT tag values can consist of any characters that are valid for the userinfo part of a URI. In combination with the domain suffix and host NAT tag field values, this value is used to help the SBC identify an encoded URI that it needs to translate when moving between public and private realms.
host NAT tag	Identifies the prefix used when encoding an address into the hostname part of the URI or into a URL parameter. The host NAT tag values refer to domain labels and can consist of any characters that are valid for the hostname part of a URI. In combination with the domain suffix and user NAT tag values, this value is used to help the SBC identify an encoded URI that it needs to translate when moving between public and private realms.
headers	Lists the SIP headers to be affected by the SBC SIP NAT function. The URIs in these headers will be translated and encrypted, and encryption will occur according to the rules of this SIP NAT.

SIP NAT Function Configuration

To configure the SIP NAT function on an Oracle Communications Session Border Controller (SBC):

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-nat** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-nat
   ORACLE(sip-nat)#
   ```

4. **realm-ID**—Enter the name of the realm you want to identify as the external realm.

   The name you use as the realm ID must be unique. No two SIP NAT functions can have the same realm ID. Also, this value must correspond to a valid identifier entry already configured for the realm.

5. **domain-suffix**—Enter the domain suffix to identify the domain name suffix of the external realm. The domain suffix must begin with a (.) dot.

   The domain name suffix refers to and must conform to the hostname part of a URI. For example:

   ```
   .netnetsystem.com
   ```

   The domain suffix is appended to encoded hostnames that the SIP NAT function creates. For example, if the encoded hostname is ACME-abc123, the resulting FQDN is ACME-abc123.netnetsystem.com.

6. **external-proxy-address**—Enter the external proxy address to identify the IPv4 address of the SIP element (for example, a SIP proxy) in the external network with which the SBC communicates.

   Enter the value in the IP address format. For example:

   ```
   192.168.11.200
   ```

7. **external-proxy-port**—Enter the external proxy port value to identify the UDP/TCP port of the SIP element (for example, a SIP proxy) in the external network with which the SBC communicates. The default is **5060**. The valid range is:

   - Minimum—1025
   - Maximum—65535

8. **external-address**—Enter the external address, which is an IPv4 address on the media interface in the external realm.

   Enter the value in the IP address format. For example:

   ```
   192.168.11.101
   ```

   This value must be such that any packet with an external address value as its destination address is routed to the SBC through the media interface connected to or routable from the external realm.

9. **home-address**—Enter the home address, which is an IPv4 address on the network interface in the home realm. This value must be such that any packet with a home address value as its destination address must be routed to the SBC through the media interface connected to or routable from the home realm.

   Enter the value in the IP address format. For example:

   ```
   127.0.0.10
   ```

   The value entered in this field **must be different** from the IP address value of the home realm's network interface element.

   The home realm network interface is associated with this SIP NAT by its realm ID and the realm's identifier and network interface value you entered when you configured the realm. The realm's network interface identifier value corresponds to this SIP NAT's realm ID, the SIP config's home realm ID, and the media manager's home realm ID.

10. **home-proxy-address**—Enter the home proxy address to set the IP address for the home proxy (from the perspective of the external realm).

By default, this field is empty. No home proxy address entry signifies there is no home proxy, and the external address will translate to the address of the SBC's SIP proxy.

Enter the value in the IP address format. For example:

```
127.1.0.10
```

11. **home-proxy-port**—Enter the home proxy port to set the port number for the home realm proxy. The default value is **0**. The valid range is:
    - Minimum—0, 1025
    - Maximum—65535
12. **route-home-proxy**—Optional. Enable or disable requests being routed from a given SIP-NAT to the home proxy. The default value is **disabled**. The valid values are:
    - **enabled**—All inbound requests for a specific SIP NAT are routed to the home proxy
    - **disabled**—All inbound requests are not routed through the home proxy.
    - **forced**—The Request is forwarded to the home proxy without using a local policy.
13. **address-prefix**—Optional. Indicate the IPv4 address prefix from incoming messages that requires SIP NAT function encoding (regardless of the realm from which these messages came).

    > **Note:**
    >
    > This value overrides the value set in the realm's address prefix field.

    This field's format incorporates an IPv4 address and number of bits in the network portion of the address. For example, a Class C address has a 24-bit network part. The address prefix for 101.102.103.x would be represented as 10.102.103.0/24.

    The default value is an asterisk (*****). When you enter this value or do not enter a value, the realm's address prefix value is used.
14. **tunnel-redirect**—Set to one of the following values to indicate whether certain headers in a 3xx Response message received by the SBC are NATed when sent to the initiator of the SIP INVITE message. The default is **disabled**. The valid values are:
    - **enabled**—Certain headers in a 3xx Response message are NATed.
    - **disabled**—Certain headers in a 3xx Response message are not NATed.
15. **use-url-parameter**—Establish whether SIP headers will use the URL parameter (configured in the next step) for encoded addresses created by the SIP NAT function. If SIP headers will be used, this value identifies which types of headers will use the URL parameter. The default value is **none**. The available values include:
    - **none**—No headers will use the URL parameter for address encoding.

      The following example illustrates the functionality of an SBC using a use url parameter value of none:

      ```
      sip: 1234@1.2.3.4 is translated into sip: 1234-acme-xxxx@5.6.7.8
      ```

      where -acme-xxxx is a cookie and xxxx is the encoded version of 1.2.3.4.
    - **from-to**—From and To headers will use the URL parameter for address encoding

The following example illustrates the functionality of a SBC using a use url parameter value of none:

```
sip: 1234@1.2.3.4 is translated into sip: 1234@5.6.7.8; pn=acme-xxxx
```

where -acme-xxxx is a cookie and xxxx is the encoded version of 1.2.3.4.

- **all**—All headers will use the URL parameter for address encoding. Oracle recommends not using this values because other SIP elements or implementations (other than the Oracle Communications Session Border Controller) might not retain the URL parameter in subsequent SIP messages that they send to the Oracle Communications Session Border Controller.
- **phone**—

  If this field is set to either from-to or all, the SBC puts the encoded address of the SIP NAT into a URL parameter instead of using the encoding name inside the userinfo part of the address.

16. **parameter-name**—If you have configured the **use-url-parameter** with the from-to or all value, you need to indicate the hostname prefix.

    The parameter name value is used in SIP NAT encoding addresses that have the use url parameter values of from-to or all.

17. **user-NAT-tag**—Enter a value to identify the username prefix used for SIP URIs. The values you can use can include any characters valid for the userinfo part of a URI. This should be made unique for each realm and SIP NAT function.

    The default value is **-acme-**.

    In combination with the domain suffix and host NAT tag values, this value is used to help the SBC identify an encoded URI that it needs to translate when moving between public and private realms.

18. **host-NAT-tag**—Enter a value for the host NAT tag field to identify the hostname prefix used for SIP URIs. The value refers to domain labels and can include any characters valid for the hostname part of the URI. This should be made unique for each realm and SIP NAT function.

    The default value is **ACME-**.

    In combination with the domain suffix and user NAT tag values, this value is used to help the SBC identify an encoded URI that it needs to translate when moving between public and private realms.

19. **headers**—List the SIP headers you want affected by the SIP NAT function. The URIs in these headers are translated and encrypted, and encryption occurs according to the SIP NAT function rules.

    To enter the full default list, type headers, followed by a Space and -d, then press Enter.

    You can also insert the following tags in SIP NAT headers if you want to replace FQDNs with next hop or SIP interface IP addresses:

    - fqdn-ip-tgt: replaces the FQDN with the target address
    - fqdn-ip-ext: replaces the FQDN with the SIP NAT external address

      Enter the tag using the following format:

      <header-name>=<tag>

      For example:

To=fqdn-ip-tgt

The FQDN in a To header is replaced with the target IP address.

You can insert the following tags to apply NAT treatment to a From header in an INVITE when the gateway sends it into the home realm.

- ip-ip-tgt: replaces any IP address in the From header with the next hop target
- ip-ip-ext: replaces any IP address in the From header with the SBC's external address

To view all SIP NAT function parameters, enter a **?** at the system prompt. The following example shows SIP NAT configuration for peering network.

```
sip-nat
        realm-id                        peer-1
        domain-suffix                   .p1.acme.com
        ext-proxy-address               192.168.11.200
        ext-proxy-port                  5060
        ext-address                     192.168.11.101
        home-address                    127.0.0.10
        home-proxy-address              127.1.0.10
        home-proxy-port                 5060
        route-home-proxy                enabled
        address-prefix                  *
        tunnel-redirect                 disabled
        use-url-parameter               none
        parameter-name
        user-nat-tag                    -p1-
        host-nat-tag                    P1-
        headers                         Call-ID Contact From Join Record-

SIP Realm Bridging

This section explains how to configure the internal routing among realms known as realm bridging. Realm bridging lets you cross-connect SIP interfaces. You can use one of the following two methods for bridging realms:

- local policy bridging: use this method to enable dynamic internal routing between realms if your SIP interfaces do not have the SIP NAT function applied.
- SIP NAT bridging: use this method if your SIP interfaces have the SIP NAT function applied.

About SIP NAT Bridging

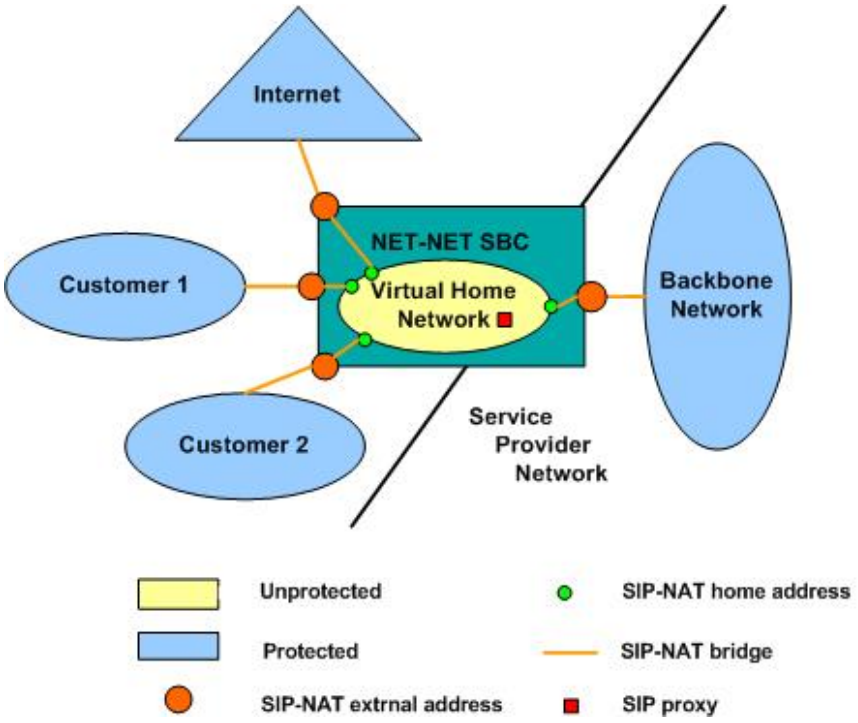
Each SIP NAT has a presence in two realms, trusted and untrusted. The SIP NAT bridge is the conduit for packages in and out of the home realm. It creates a bridge between realms by providing address translations; removing all references to the original IP addressing from the packets sent to the destination network.

With the SIP NAT bridge, an untrusted (or public) home network can reside within the Oracle Communications Session Border Controller, while the other entities (the backbone network, the Internet, or customer networks) are all trusted (or private). One of the primary functions of the

SIP NAT bridge is to protect networks from one another so that address bases can remain hidden. Using a SIP NAT bridge, no one network has direct access to the data of other networks.

Establishing a SIP NAT bridge lets you route every SIP Request message through the backbone. Without using this functionality, it would appear as though all messages/sessions were coming from the Oracle Communications Session Border Controller's SIP proxy (the SIP server that receives SIP requests and forwards them on behalf of the requestor).

The following diagram illustrates this unprotected (or public) and protected (or private) division.



SIP NAT Bridge Configuration Scenarios

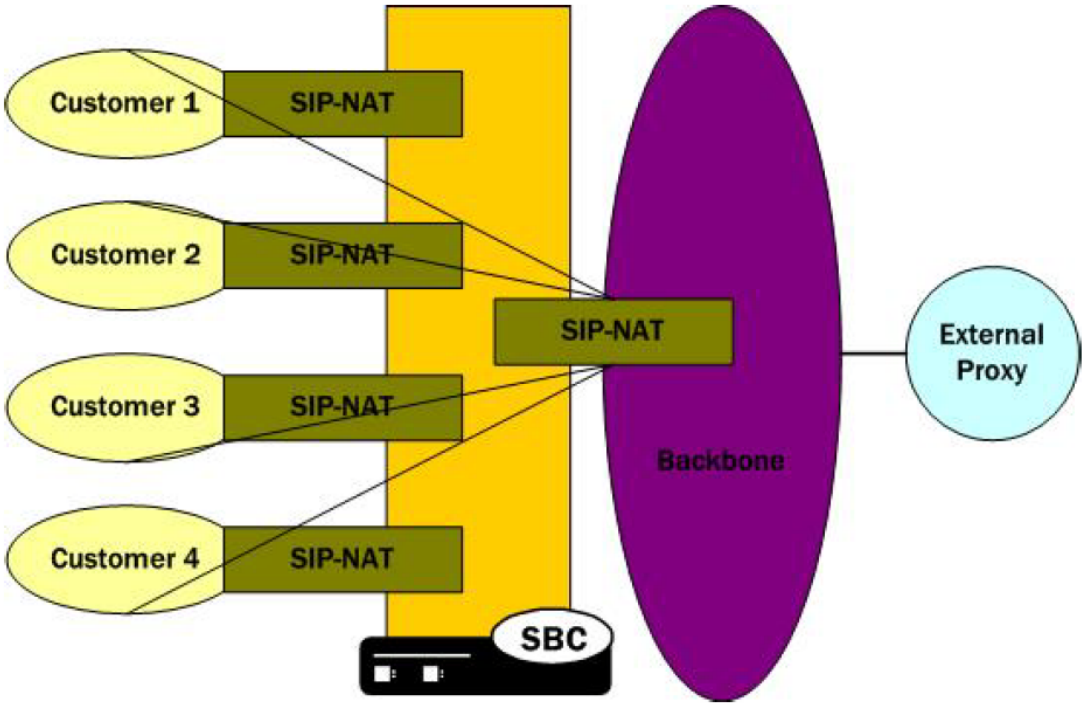
You can configure the SIP NAT bridge functionality in a many-to-one or a one-to-one relationship. For example, multiple customer SIP NATs can be tied to a single backbone SIP NAT, or a single customer SIP NAT can be tied to a single backbone SIP NAT.

You might need to use several SIP NATs on the customer side while using only one on the backbone side in a many-to-one relationship. Or you might configure one SIP NAT on the backbone side for every one that you configure on the customer side in a one-to-one relationship.

You can route all customer side SIP NAT requests to the corresponding backbone SIP NAT regardless of the Request URI. If a request arrives from the customer network with a Request URI that does not match the customer SIP NAT external address or the local policy that would route it to the backbone SIP NAT; the route home proxy value is used.

Many to One Configuration

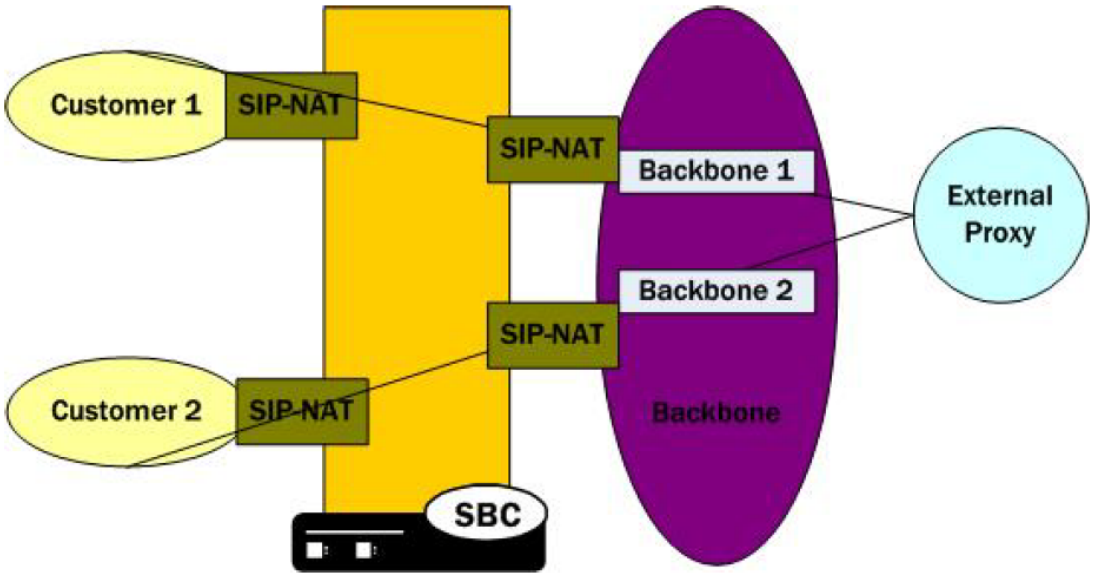
In the many-to-one scenario, multiple customer SIP NATs are tied to a single backbone SIP NAT. The following diagram illustrates the many-to-one SIP NAT bridge configuration.



One-to-One Configuration

In the one-to-one scenario, a single customer SIP NAT is tied to a single backbone SIP NAT. On the backbone SIP NAT side, you configure the home proxy address to match the home address of the customer SIP NAT. On the customer side, you configure the home proxy address to match the home address of the backbone SIP NAT.

The following diagram illustrates the one-to-one SIP-NAT bridge configuration.



SIP NAT Bridge Configuration

You create a bridge between SIP NATs by pointing them at one another. You point the SIP NATs at each other by configuring the home address and home proxy address to create the bridge. In addition, you can configure the route home proxy on the customer's side of a SIP NAT to force all requests to be routed to the corresponding backbone SIP NAT, regardless of the Request URI. You need to force requests when elements in the customer's network send requests with a Request URI that does not match the customer's SIP NAT external address. Or when the Request URI does not match a local policy element that would route the requests to the backbone SIP NAT.

You also need a home network to create a SIP NAT bridge. If you do not have a real home network, you need to create a virtual one. You also need to configure instances of the SIP NAT to create the SIP NAT bridge within your network.

Creating a Virtual Home Network

A virtual home network is a home network that resides entirely within the Oracle Communications Session Border Controller, as does a real home network. The difference between the two is the real home network also has a physical connection to the Oracle Communications Session Border Controller.

The internal home realm/network is usually configured with addresses within the special loopback range (127.0.0.0/8) as described in RFC 3330. This applies to the SIP port addresses for the home realm's SIP interface, and all home addresses for SIP NATs. The address 127.0.0.1 should not be used because it conflicts with the default loopback interface setup by the system for inter-process communication.

To create a virtual home network:

1. Set the name and subport ID of the network interface associated with the home realm element to lo0:0.
2. To enable the SIP proxy to listen for messages on the virtual home realm, configure the home realm ID. It must correspond to the realm's identifier, in which you set the network interface subelement to point to the appropriate network interface element.

   The following table lists the field values you need to set when you are using SIP NAT bridge functionality and you do not have a real home network.

Configuration Element	Configuration Parameter	Sample Values
realm configuration	identifier	home
N/A	network interfaces	lo0:0
N/A	address prefix	127.0.0.0/8
SIP configuration	home realm ID	home
N/A	SIP ports address	127.0.0.100

Many-to-One Configuration

To configure many-to-one:

1. For the backbone SIP NAT, ensure the home proxy address field is blank.
2. For the customer side SIP NAT:

Set the home address to match the home address of the customer.

Set the home proxy address to match the backbone SIP NAT home address.

Set route home proxy to forced.

The following table lists the field values you need to set to create a many-to-one SIP NAT bridge.

SIP NAT Entity	Field	Sample Values
Backbone SIP NAT	home address	IPv4 address of the home realm. For example: 127.0.0.120
N/A	home proxy address	IPv4 address of the home proxy from the perspective of the external realm. For a backbone SIP NAT, leave blank.
Customer SIP NAT	home address	127.0.0.120
N/A	home proxy address	127.0.0.110
N/A	route home proxy	forced

One-to-One Configuration

In the one-to-one scenario, a single customer SIP NAT is tied to a single backbone SIP NAT. The home proxy address field value of the backbone SIP NAT must match the home address of the customer SIP NAT. On the customer side, the home address of the customer SIP NAT should be defined as the home address of the customer, the home proxy address field value should match the home address of the backbone SIP NAT, and route home proxy should be set to forced.

The following table lists the field values you need to set to create a one-to-one SIP NAT bridge.

SIP NAT Entity	Field	Sample Values
Backbone SIP NAT	home address	IPv4 address of the home realm. For example: 127.0.0.110
N/A	home proxy address	IPv4 address of the home proxy from the perspective of the external realm. 127.0.0.120
Customer SIP NAT	home address	127.0.0.120
N/A	home proxy address	127.0.0.110
N/A	route home proxy	forced

Shared Session Agent

Usually, the same set of servers (the external proxy) is used for all SIP NATs to the backbone network. In order to support redundant servers in the backbone of a SIP NAT bridge, the original egress realm as determined by the incoming Request URI needs to be retained after a local policy lookup.

When a request arrives at the Oracle Communications Session Border Controller, it determines the matching (target) session agent and, after the local policy is examined, sets the new outbound session agent to the one from the selected target.

If the target session agent's realm is set to *, the Oracle Communications Session Border Controller retains the original session agent's realm ID. Because the target session agent does not have a realm ID defined, the original egress realm is retained.

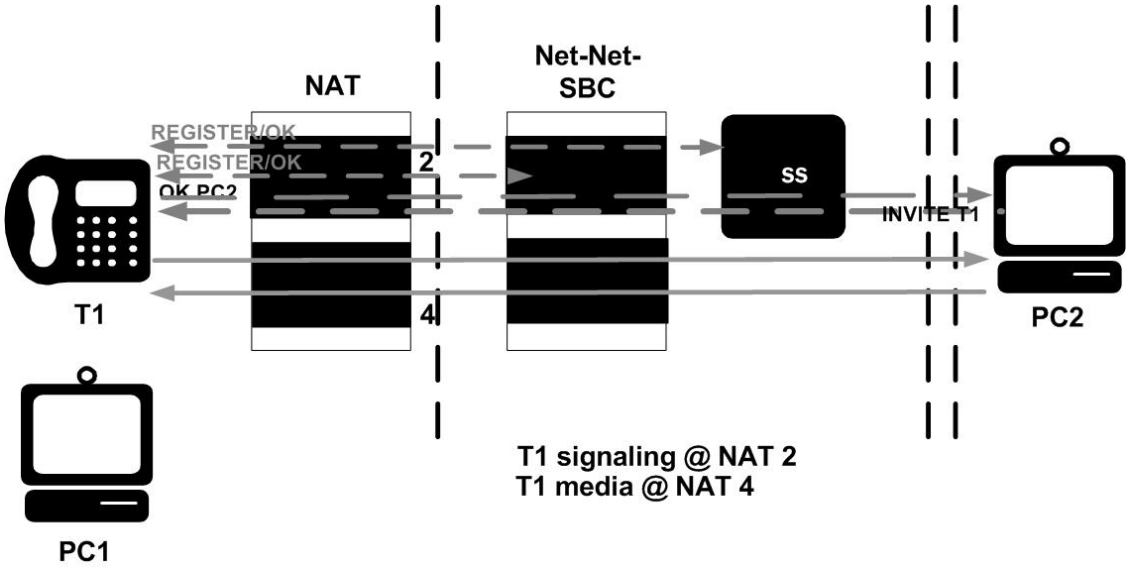
SIP Hosted NAT Traversal (HNT)

This section explains how to configure SIP Hosted Network Address Translation (HNT) traversal. SIP HNT lets endpoints behind a NAT/firewall device send and receive signaling and media using the Oracle Communications Session Border Controller as a relay.

About SIP HNT

SIP HNT is a technique the Oracle Communications Session Border Controller uses to provide persistent reachability for SIP UAs located in private Local Area Networks (LANs) behind Nat/firewall devices. It relies on frequent, persistent messaging to ensure that the binding on the intermediary NAT device is not torn down because of inactivity. HNT does not require support for the NAT in the SIP endpoint.

The following diagram illustrates SIP HNT traversal.



The Oracle Communications Session Border Controller's HNT function allows endpoints located behind NATs to communicate; providing means to traverse NATs. The Oracle Communications Session Border Controller interacts with endpoints (using SIP) to allow persistent inbound and outbound signaling and media communications through these NATs.

The Oracle Communications Session Border Controller automatically detects when an intermediate NAT exists between the UA and the Oracle Communications Session Border Controller by comparing the Layer 3 IP address of a REGISTER message with the IP address indicated within the UA. The Oracle Communications Session Border Controller sends signaling responses to the address and port that the request came from, rather than the address and port indicated in the request. The Via header in the request message indicates where the response should be sent.

Using HNT with Existing NAT Device

For network architectures in which premise devices and endpoints reside behind an existing NAT device, the Oracle Communications Session Border Controller's HNT function allows these premise NATs to be traversed without requiring an upgrade to the premise equipment, the deployment and management of additional premise-based hardware or software, or any NAT device configuration changes.

Registering Endpoints

The Oracle Communications Session Border Controller uses periodic endpoint registration messages to dynamically establish and maintain bindings in the NAT. These bindings keep a signaling port (port that is opened on a firewall to allow traffic to pass through it is a pinhole) open in the NAT that allows the inbound signaled communications to pass through. Using the endpoint registrations, the Oracle Communications Session Border Controller then maps the Layer 3 (OSI network layer that deals with switching and routing technologies for data transmission between network devices) IPv4 address/port information from the NAT device to the Layer 5 (OSI session layer that deals with session and connection coordination between applications) entity (for example, user name or phone number) behind the NAT so that when an incoming signaling message is received, the Oracle Communications Session Border Controller sends it to the appropriate address and port on the NAT for the called party.

Establishing Media Flows

During call setup, the ports for bidirectional media flows are established dynamically. Since the media flows also pass through the Oracle Communications Session Border Controller, it can identify the IPv4 address/port information on the NAT device used for the outgoing media coming from the user name/phone number. The Oracle Communications Session Border Controller then uses that same NAT's IPv4 address/port information to send incoming media to the correct user name/phone number behind the NAT device.

Prerequisites

In order to achieve HNT, the endpoints involved must be capable of:

- symmetric signaling: sending and receiving SIP messages from the same transport address (IP address or User Datagram Protocol/Transmission Control Protocol (UDP/TCP) port
- symmetric media: sending and receiving Real-Time Transport Protocol (RTP) messages from the same UDP port

These conditions are required to allow signaling and media packets back through the NAT (through the bound external address and port). These packets must come from the address and port to which the outbound packet that created the NAT binding was sent. The NAT sends these inbound packets to the source address and port of the original outbound packet.

When SIP HNT is used, the Oracle Communications Session Border Controller sends signaling responses to the address and port that the request came from rather than the address and port indicated in the request. The Via header in the request message indicates where the response should be sent.

Keeping the NAT Binding Open

Additional measures are also required to keep the NAT binding open because most NAT bindings are discarded after approximately a minute of inactivity. The Oracle Communications

Session Border Controller keeps the SIP NAT binding open by returning a short expiration time in REGISTER responses that forces the endpoint to send frequent REGISTER requests.

In order to keep the NAT binding open for SIP, the Oracle Communications Session Border Controller maintains the registration state. When an endpoint first registers, the Oracle Communications Session Border Controller forwards that REGISTER message on to the real registrar. You can define the real registrar using either of the following methods:

- Configure the SIP config registrar host and registrar port to indicate the real registrar.
- Map the SIP config registrar host and registrar port values to the SIP NAT home proxy address and home proxy port values. Then configure the SIP NAT's external proxy address and external proxy port values to correspond to the real registrar.

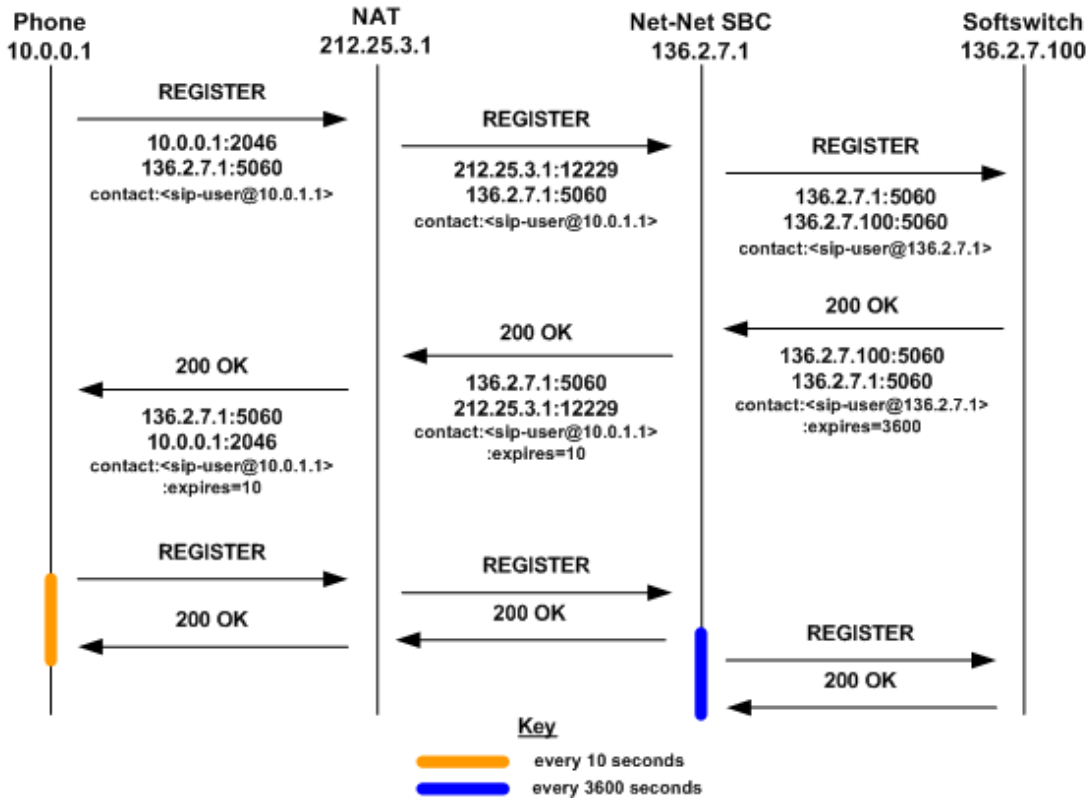
> **Note:**
>
> A registrar can be located in a SIP NAT realm.

When a successful response is received, the Oracle Communications Session Border Controller caches the registration to memory. This cached registration lives for the length of time indicated by the expiration period defined in the REGISTER response message from the registrar. The response sent back to the endpoint has a shorter expiration time (defined by the SIP config's NAT interval) that causes the endpoint to send another REGISTER message within that interval. If the endpoint sends another REGISTER message before the cached registration expires, the Oracle Communications Session Border Controller responds directly to the endpoint. It does not forward the message to the real registrar.

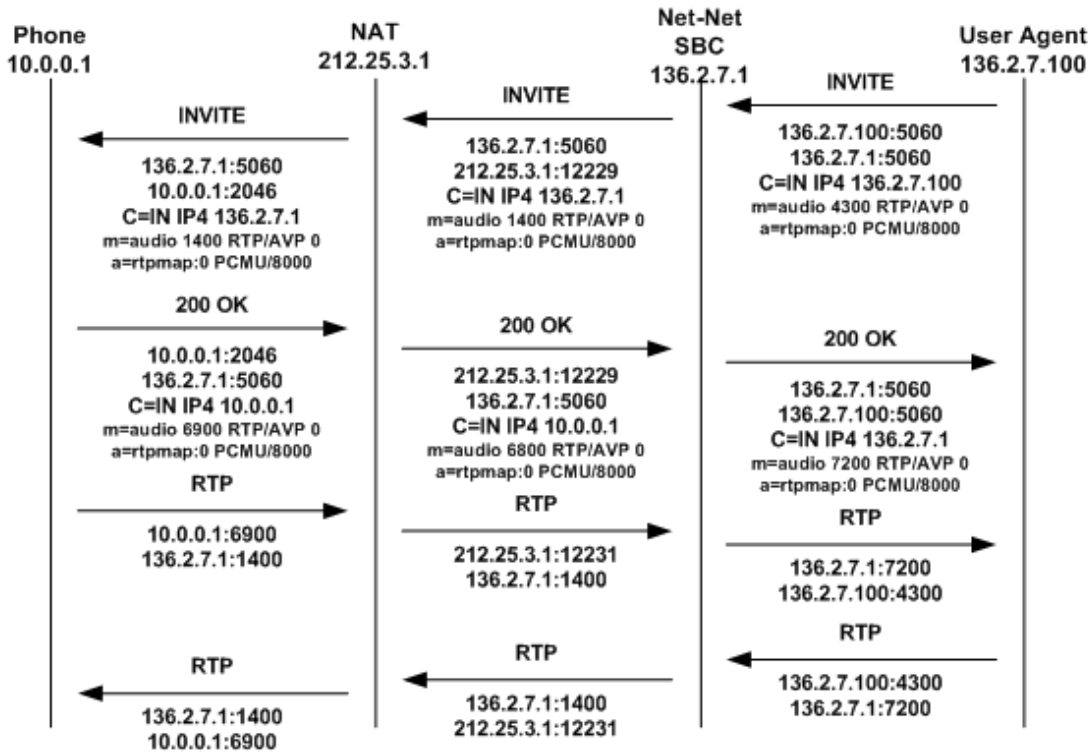
If the cached registration expires within the length of time indicated by the NAT interval, the REGISTER message is forwarded to the real registrar. If the Oracle Communications Session Border Controller does not receive another REGISTER message from the endpoint within the length of time indicated by the NAT interval, it discards the cached registration.

The Contact Uniform Resource Identifier (URI) in the REGISTER message sent to the registrar by the Oracle Communications Session Border Controller points at the Oracle Communications Session Border Controller so that the proxy associated with the real registrar sends inbound requests to the Oracle Communications Session Border Controller. This way, the inbound requests can be forwarded to the endpoint through the NAT binding.

The following example illustrates the SIP HNT registration call flow for the SIP HNT feature.



The following example illustrates the SIP HNT invitation call flow for the SIP HNT feature.



Working with Multiple Domains

You can use a wildcard (*) with the HNT feature to accommodate multiple domains and to allow the Oracle Communications Session Border Controller to cache all HNT endpoints. The wildcard functionality is enabled in the SIP config by entering an asterisk (*) in the registrar domain and registrar host fields.

The wildcard allows the use of either a local policy or Domain Name Service (DNS) to resolve the domain name to the correct registrar. Either method can be used to route the Fully Qualified Domain Name (FQDN) when the you enter an asterisk (*) for the register host. An FQDN consists of an unlimited number of domain labels (domain names), each separated by a dot (.). The FQDN can include the top level domain name (for example, acmepacket.com).

In the hostname acme-packet.domainlbl.example100.com, the syntax is as follows:

- acme-packet is a domain label
- domainlbl is a domain label
- example100 is a domain label
- com is the top label

The information configured in a local policy is used before DNS is used. If the next hop destination address (defined in the local policy's next hop field) is an IPv4 address, a DNS server is not needed. A DNS server is needed when the IPv4 address of the next hop destination address is a FQDN or cannot be determined from the Oracle Communications Session Border Controller's configuration. Even with a configured local policy, the next hop destination address might be an FQDN that requires a DNS lookup.

If the registrar host does not use the wildcard, the Oracle Communications Session Border Controller always uses the configured address. You can limit the number of endpoints that receive the HNT function. For example, you can use a non-wildcarded registrar domain field value (like acme.com) with a wildcarded registrar host field value.

HNT Configuration Overview

To configure SIP HNT NAT traversal, you need to configure both the SIP interface and the SIP config.

SIP HNT Single Domain Example

The following example shows values entered for the SIP config and SIP interface elements to configure SIP HNT for a single domain and registrar.

- SIP config

Parameter	Sample Value
registrar domain	netnetsystem.com
registrar host	192.168.12.1
registrar port	5060

- SIP interface

Parameter	Sample Value
NAT traversal	always

Parameter	Sample Value
NAT interval	60
minimum registration expire	200
registration caching	disabled
route to registrar	enabled

SIP HNT Multiple Domain Example

The following example shows values entered for the SIP config and SIP interface elements to configure SIP HNT for a multiple domains and multiple registrars.

- SIP config

Parameter	Sample Value
registrar domain	*
registrar host	*
registrar port	0

- SIP interface

Parameter	Sample Value
NAT traversal	always
NAT interval	60
minimum registration expire	200
registration caching	disabled
route to registrar	enabled

HNT Configuration

To configure a SIP interface on the Oracle Communications Session Border Controller (SBC):

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

   From this point, you can configure sip-interface parameters. To view all sip-interface parameters, enter a **?** at the system prompt.

4. **nat-traversal**—Define the type of HNT enabled for SIP. The default value is **none**. Available values include:

   - **none**—Disables the HNT feature for SIP (default value)

- **rport**—SIP HNT function only applies to endpoints that include the rport parameter in the Via header and the sent-by of the topmost VIA matches the Contact-URI host address, both of which must be different from the received Layer 3 address.
- **always**—SIP HNT applies to requests when the sent-by of the topmost VIA matches the Contact-URI host address, both of which must be different from the received Layer 3 address. (Even when the rport parameter is not present.)

5. **nat-interval**—Set the expiration time in seconds for the SBC's cached registration entry for an HNT endpoint. The default value is **30**. The valid range is:
   - Minimum—0
   - Maximum—4294967295

   Oracle recommends setting the NAT interval to one-third of the NAT binding lifetime. A NAT binding lifetime is the network connection inactivity timeout. The value is configured (or hardwired) in the NAT device (firewall). This timer is used to prevent the NAT device from keeping an unused port open.
6. **registration-caching**—Enable for use with all UAs, not just those that are behind NATs. By default, this field is set to **disabled**. If enabled, the SBC caches the Contact header in the UA's REGISTER request when it is addressed to one of the following:
   - SBC
   - registrar domain value
   - registrar host value

   The SBC then generates a Contact header with the SBC's address as the host part of the URI and sends the REGISTER to the destination defined by the registrar host value.

   Whether or not SIP HNT functionality is enabled affects the value of the user part of the URI sent in the Contact header:
   - **enabled**—The SBC takes the user part of the URI in the From header of the request and appends a cookie to make the user unique. A cookie is information that the server stores on the client side of a client-server communication so that the information can be used in the future.
   - **disabled**—The user part of the Contact header is taken from the URI in the From header and no cookie is appended. This is the default behavior of the Oracle Communications Session Border Controller.

   When the registrar receives a request that matches the address-of-record (the To header in the REGISTER message), it sends the matching request to the SBC, which is the Contact address. Then, the v forwards the request to the Contact-URI it cached from the original REGISTER message.
7. **min-reg-expire**—Set the time in seconds for the SIP interface. The value you enter here sets the minimum registration expiration time in seconds for HNT registration caching. The default value is **300**. The valid range is:
   - Minimum—1
   - Maximum—999999999

   If, for example, an endpoint sends a REGISTER message with the "Expires:" field set to 60 seconds, then the SBC (when re-originating the REGISTER message to the registrar) changes that value to the min-reg-expire value if the latter is greater. This is because the SBC requires the value of the Expires field to be at least the value of the min-reg-expire parameter. If the value of the Expires field in the original message is

equal to or greater than the value of the min-reg-expire parameter, the SBC will not change it.

This value defines the minimum expiration value the SBC places in each REGISTER message it sends to the real registrar. In HNT, the SBC caches the registration after receiving a response from the real registrar and sets the expiration time to the NAT interval value.

Some UAs might change the registration expiration value they use in subsequent requests to the value specified in this field. This change causes the SBC to send frequent registrations on to the real registrar.

8. **registration-interval**—Set the SBC's cached registration entry interval for a non-HNT endpoint. Enter the expiration time in seconds that you want the SBC to use in the REGISTER response message sent back to the UA. The UA then refreshes its registration by sending another REGISTER message before that time expires. The default value is **3600**. The valid range is:

   - Minimum—1

     A registration interval of zero causes the SBC to pass back the expiration time set by and returned in the registration response from the registrar.

   - Maximum—999999999

     If the expiration time you set is less than the expiration time set by and returned from the real registrar, the SBC responds to the refresh request directly rather than forwarding it to the registrar.

     > **Note:**
     >
     > With registration caching, there is no NAT; therefore, a short registration interval causes the UA to send excess REGISTER messages.

   Although the registration interval applies to non-HNT registration cache entries, and the loosely related NAT interval applies to HNT registration cache entries, you can use the two in combination. Using a combination of the two means you can implement HNT and non-HNT architectures on the same SBC. You can then define a longer interval time in the registration interval field to reduce the network traffic and load caused by excess REGISTER messages because there is no NAT binding to maintain.

9. **route-to-registrar**—Enable routing to the registrar to send all requests that match a cached registration to the destination defined for the registrar host; used when the Request-URI matches the registrar host value or the registrar domain value, not the SBC's address. Because the registrar host is the real registrar, it should send the requests back to the SBC with the SBC's address in the Request-URI. The default value is **disabled**. The valid values are:

   - enabled | disabled

     For example, you should enable routing to the registrar if your network uses a SBC and needs requests to go through its service proxy, which is defined in the registrar host field.

Global SIP Configuration

To configure the SIP configuration:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   From this point, you can configure SIP config parameters. To view all SIP config parameters, enter a **?** at the system prompt.

4. **registrar-domain**—Optional. Define the domain to match against the host part of a URI to determine if a request is addressed to the registrar. If there is a match, the registration caching, NAT traversal, and route to registrar parameter values for the SIP interface are applied to the request. By default, this field remains empty. Available values are:

   - an asterisk (*) to specify the values apply to all requests.
   - any alphanumeric character or any combination of alphanumeric characters. For example, acme1.com.

     A hostname consists of any number of domain labels, separated by dots (.), and one top label. A top label is the last segment of the hostname. It must start with an alphabetical character. After the first character, a top label can consist of any number or combination of alphanumeric characters, including those separated by dashes. The dash must be preceded and followed by alphanumeric characters. A single alphabetical character is the minimum requirement for a hostname field (for example, c to indicate .com).

     When the REGISTER message's Request-URI has an FQDN, it is matched against the registrar domain's value to determine if the message needs to be forwarded to the registrar port on the registrar host. The registrar domain's value is also used when route to registrar is set to enabled, to determine if a request needs to be forwarded to the registrar.

     Only the right-hand part of the domain name in the Request-URI needs to match the registrar domain value. For example, acme3.acmepacket.com matches acmepacket.com. However, the entire domain label within the domain name must match. For example, the domain label "acme3.acmepacket.com" would not match packet.com.

5. **registrar-host**—Define the address of the registrar for which requests for registration caching, NAT traversal, and router to registrar options apply. You can use a specific hostname, a IP address, or a wildcard (*):

   - an asterisk (*) indicates normal routing (local policy, DNS resolution, and so on) is used to determine the registrar's address.
   - hostname: can consist of any alphanumeric character or any combination of alphanumeric characters (for example, acme1.com). The hostname can consist of any number of domain labels, separated by dots (.), and one top label. You can use the minimum field value of a single alphabetical character to indicate the top label value (for example, c to indicate .com).

- IPv4 address: must follow the dotted notation format. Each of the four segments can contain a numerical value between zero (0) and 255. For example, 192.168.201.2. An example of a invalid segment value is 256.

  By default, the registrar host field remains empty.

6. **registrar-port**—Set the SIP registrar port number. The SIP registrar server configured in this and the registrar host field is the real registrar. Or the values entered in those fields map to the home proxy address and home proxy port of the SIP NAT with external proxy address and external proxy port values that correspond to the real registrar. The default value is 0. The valid range is:

   - Minimum—0, 1025
   - Maximum—65535

   The following example shows the values for a single domain and registrar configuration.

```
sip-config
        state                         enabled
        operation-mode                dialog
dialog-transparency        disabled
        home-realm-id                 acme
        egress-realm-id
        nat-mode                      Public
        registrar-domain
        registrar-host
        registrar-port                0
        init-timer                    500
        max-timer                     4000
        trans-expire                  32
        invite-expire                 180
        inactive-dynamic-conn         32
        red-sip-port                  1988
        red-max-trans                 10000
        red-sync-start-time           5000
        red-sync-comp-time            1000
        last-modified-date            2005-03-19 12:41:28
```

Endpoint-Initiated Keep-Alives

The Oracle Communications Session Border Controller provides three Keep-Alive algorithms designed to generate sufficient traffic flow to maintain NAT (Network Address Translation) bindings. Prior releases provided a single Keep-Alive algorithm that is described in the SIP Hosted NAT Traversal (HNT) section of the SIP Signaling Services chapter of the *ACLI Configuration Guide*. This method is SD-based and requires no explicit participation by the SIP endpoint. Instead the SD manipulates SIP registration requests and responses to spoof the endpoint — generating frequent and extraneous registration requests that generate a periodic traffic flow to maintain existing NAT bindings.

Unlike the current SD-centric method, the new methods require the active participation of the SIP endpoint. With these methods the SIP endpoint initiates a Keep-Alive negotiation with the SD that produces a periodic request/response message sequence which also generates sufficient traffic flow to maintain NAT bindings.

The new methods are based upon the following RFCs.

RFC 5626, *Managing Client-Initiated Connections in the Session Initiation Protocol (SIP)*, which, in Section 3.5.2, provides a framework for the implementation of an endpoint-initiated Keep-Alive on both TCP and UDP connections and provides two approaches to generating endpoint-initiated Keep-Alive traffic flows. One approach described in Section 4.4.1 of the RFC is restricted to connection-oriented transport protocols such as TCP. It defines an end-point initiated ping which requires an SD pong in response. A second approach described in Section 4.4.2 of the RFC is restricted to connectionless transport protocols such as UDP. It defines an endpoint-initiated STUN binding request which requires as SD-originated STUN binding response.

RFC 6223, *Indication of support for Keep-Alive*, was initially published as an internet draft (most recently as draft-ietf-sipcore-keep-12.txt). RFC 6223 defines a procedure that enables a SIP endpoint to signal its capability and willingness to send and receive periodic Keep-Alive messages to a device referred to by the RFC as an edge proxy, a role performed by the SD. After receiving such a signal, the SD returns a response indicating its willingness to exchange Keep-Alives, and specifying the interval between Keep-Alive exchanges.

RFC 5389, *Session Traversal Utilities for NAT (STUN)*, defines STUN binding requests and responses in Section 6 of the RFC. Endpoints that support endpoint-initiated Keep-Alives over a UDP connection must be capable of constructing and transmitting a STUN binding request, and receiving and parsing a STUN binding response.

Endpoint-Initiated Keep-Alive Negotiation

Endpoint-initiated Keep-Alive negotiation requires the presence of the keep parameter in the Via header of Registration requests and responses issued and received by a SIP endpoint. As defined in RFC 6223, keep is

A SIP Via header field parameter that a SIP entity can insert in the topmost Via header field that it adds to the request, to explicitly indicate willingness to send keep-alives towards its adjacent downstream SIP entity. A SIP entity can add a parameter value to the keep parameter in a response to explicitly indicate willingness to receive keep-alives from its adjacent upstream SIP entity.

While RFC 6223 allows the presence of the keep parameter in either REGISTER or INVITE requests and responses, the current implementation, is registration-based. keep parameters contained in methods other than REGISTER are ignored.

As shown in the following sample registration exchange, the SIP endpoint signals its willingness to exchange Keep-Alive messages by placing an unvalued keep parameter in the SIP Via header of a REGISTER request.

```
REGISTER sip:512@172.16.101.23:5060 SIP/2.0
Via: SIP/2.0/UDP 172.16.101.38:5070;branch=dd1;keep
From: "512" <sip:512@172.16.101.38:5070;transport=UDP>;tag=443322
To: "512" <sip:512@172.16.101.38:5070>
Call-ID:1-14400@172.16.101.38

Connection Oriented Keep-Alives

After the endpoint-initiated Keep-Alive exchange has been negotiated for a TCP connection, the SIP endpoint transmits a periodic ping at intervals specified by the value of the keep

parameter. As shown below, the ping consists of carriage return (CR) and line feed (LF) characters.

```
CRLFCRLF
CR = %x0D
LF = %x0A
```

The SD responds with a pong as shown below.

```
CRLF
CR = %x0D
LF = %x0A
```

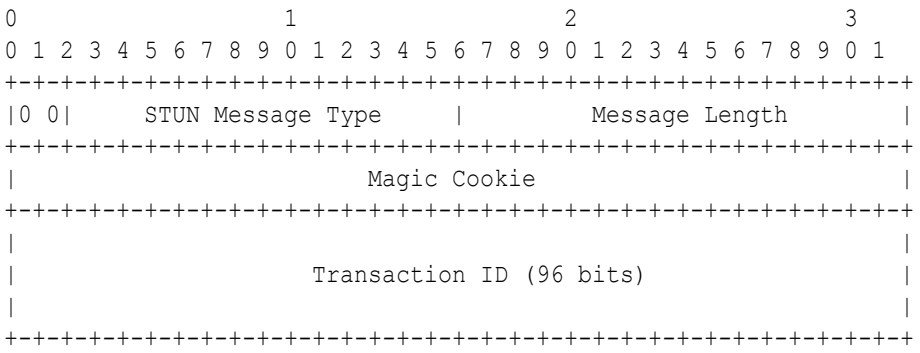
The request ping and the response pong are transmitted between SIP messages, and cannot be sent in the middle of SIP message. If the TCP connection is secured by TLS, the Keep-Alive requests and responses are transmitted within the TLS encrypted stream.

As specified in Section 4.4.1 of RFC 5626 the SD must respond to a ping within a 10-second interval. If the endpoint fails to receive a valid pong within that interval, it must treat the flow as failed.

Connectionless Keep-Alives

After the endpoint-initiated Keep-Alive exchange has been negotiated for an unreliable UDP connection, the SIP endpoint, acting as a STUN client, transmits a periodic STUN binding request so that the interval between each request is randomly distributed between 80 and 100 percent of the value of the keep parameter. Assuming a parameter value of 20 seconds, for example, the SIP endpoint transmits a STUN binding request at random intervals between 16 and 20 seconds in length.

The STUN binding request has the following format.



The initial two bits of any STUN message are always 00

STUN Message Type

This 14-bit field contains the message class and method — for a STUN binding request, class is request and method is binding.

Message Length

This 16-bit field contains the length, in octets, of the Attribute section of the STUN binding request. Since the Attribute section is not present in a binding request, this field contains a value of 0.

Magic Cookie

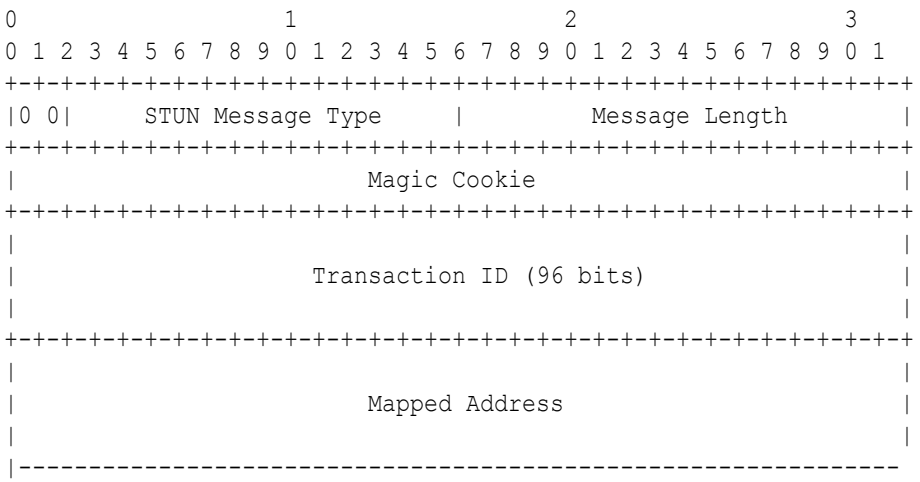
This 16-bit field always contains a value of 0x2112A442.

Transaction ID

This 96-bit field contains a random value that provides a transaction identifier. The value is generated by the STUN client and echoed in the STUN server response.

Upon receipt of a binding request, the SD, acting as a STUN server, transmits a STUN binding response. Receipt of the binding response by the endpoint confirms the UDP connection between the endpoint and the SD, and the viability of NAT bindings in the transmission path.

The STUN binding response has the following format.



The initial two bits of any STUN message are always 00.

STUN Message Type

This 14-bit field contains the message class and method — for a STUN binding response, class is response and method is binding.

Message Length

This 16-bit field contains the length, in octets, of the Attribute section of the STUN binding response. Since the binding response contains a single attribute, MAPPED-ADDRESS, the message length can be either 8 or 16 octets, depending on the IP address type.

Magic Cookie

This 16-bit field always contains a value of 0x2112A442.

Transaction ID

This 96-bit field contains a random value that provides a transaction identifier. The value is generated by the STUN client and echoed by the STUN server.

MAPPED-ADDRESS

This attribute contains the IP address and port number of the proximate NAT device, that is the address translator closest to the SD, that forwarded the STUN request toward the SD. Specific fields within the attribute identify the IP family (Version 4 or 6), the IP address, and port number. The attribute length is 8 octets if it contains an IPv4 address, or 16 octets if it contains an IPv6 address.

Once initiated, endpoint transmission of STUN binding requests and SD responses continue for the duration of the SIP Registration, 1 hour in the sample negotiation, or until the endpoint transmits a new REGISTER request. In the event of such a new request, the endpoint once again indicates its willingness to exchange STUN Keep-Alives with an unvalued keep parameter in the Via header. If endpoint-initiated Keep-Alive renegotiation is not successful, the endpoint must cease the transmission of Keep-Alive messages.

An endpoint failure to issue a timely STUN binding request is not fatal. In the absence of an expected request, the SD takes no action with regard to the UDP connection, or to current calls, nor does it remove entries from its registration cache. After reception of a tardy STUN request, the SD simply returns a STUN response.

In contrast, however, Section 4.4.2 of RFC 5626 states that an endpoint “considers the flow failed” if (1) it receives a malformed STUN bonding response from the SD, or (2) it fails to receive a timely binding response from the SD. If the endpoint receives a STUN binding response that contains a different MAP Address field from the previous response, It MUST treat this event as a failure on the flow.

Enpoint-Initiated Keep-Alives Configuration

You use the **registrar-keep-alive** attribute, available in SIP Interface configuration mode, to enable endpoint-initiated Keep-Alives on a SIP interface.

1. In Superuser mode, use the following ACLI command sequence to access SIP Interface configuration mode.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# session-router
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

2. The **registrar-keep-alive** attribute enables endpoint-initiated Keep-Alive on the current SIP interface.

   none — (the default) disables endpoint-initiated Keep-Alive processing

   always — assuming that the endpoint has included the keep parameter in the Via REGISTER request header, forces the SD to place a keep parameter and an assigned in the Via REGISTER response — thus enabling endpoint-initiated Keep-Alive exchange with that endpoint

   bnat — assuming that the endpoint has included the keep parameter in the Via REGISTER request header, forces the SD to place a keep parameter and an assigned value in Via REGISTER response only if the requesting endpoint is identified as being behind an intervening NAT device (based on comparing source IP packet addresses with IP addresses extracted from the SIP request).

   ```
   ORACLE(sip-interface)# registrar-keep-alive bnat
   ORACLE(sip-interface)#
   ```

3. If Keep-Alive is enabled on the current SIP interface (**registrar-keep-alive** is always or bnat), use the **nat-interval** attribute to specify the value of the keep parameter provided by the SD to SIP endpoints served by a UDP connection.

   Allowable values are integers within the range 1 through 4294967295 (seconds).

   In the absence of an explicit assignment, this attribute defaults to a value of 30 seconds.

The SIP endpoint transmits periodic STUN binding requests so that the interval between each request is randomly distributed between 80 and 100 percent of the value of the nat-interval attribute.

Assuming the default value (30 seconds) the interval between STUN binding requests would vary from 24 to 30 seconds. This default value closely aligns to Section 4.4.2 of RFC 5626, which recommends that the time between each keep-alive request SHOULD be a random number between 24 and 29 seconds.

```
ORACLE(sip-interface)# nat-interval 20
ORACLE(sip-interface)#
```

4. If Keep-Alive is enabled on the current SIP interface (**registrar-keep-alive** is always or bnat), use the **tcp-nat-interval** attribute to specify the value of the keep parameter provided by the SD to SIP endpoints served by a TCP or TCP/TLS connection.

   Allowable values are integers within the range 1 through 999999999 (seconds).

   In the absence of an explicit assignment, this attribute defaults to a value of 90 seconds.

   The SIP endpoint transmits periodic pings at intervals specified by this attribute.

   ```
   ORACLE(sip-interface)# tcp-nat-interval 120
   ORACLE(sip-interface)#
   ```

5. Use **done**, **exit**, and **verify-config** to complete this configuration.
6. If necessary, repeat Steps 1 through 5 to configure Keep-Alives on additional SIP interfaces.

SD-originated Keep-Alive Negotiation

SD-originated Keep-Alives are useful on TCP connections with iOS (iPhone Operating System) clients, such as iPhones or iPads. iOS places inactive clients in a dormant state after a period of time. Once in the dormant state, clients cannot transmit date unless awakened by network traffic. SD-originated Keep-Alives are generated at a sufficient frequency to prevent iOS clients from entering the dormant state.

SD-originated Keep-Alive negotiation is similar to the earlier described negotiation, except for the parameter used. SD-originated Keep-Alive negotiation requires the presence of a well known proprietary parameter in the Via header of Registration requests and responses issued and received by a SIP endpoint. The proprietary parameter can be defined as follows:

A SIP Via header field parameter that a SIP endpoint can insert in the topmost Via header field that it adds to the request, to explicitly indicate willingness to receive Keep-Alives from its adjacent downstream SIP entity. This same SIP endpoint can assign a value to this proprietary parameter in the response to specify the keep-alive interval.

As shown in the following sample registration exchange, the SIP endpoint signals its willingness to receive Keep-Alive messages by placing an rkeep parameter in the SIP Via header of a REGISTER request; the assigned value of 20 specifies the interval between Keep-Alives.

```
REGISTER sip:512@172.16.101.23:5060 SIP/2.0

SD-Originated Keep-Alive Format

After the Keep-Alive exchange has been negotiated for a TCP connection, the SD, transmits a periodic ping at a frequency specified by the proprietary parameter (rkeep in the example negotiation). As shown below, the ping consists of carriage return (CR) and line feed (LF) characters.

CRLFCRLF

CR = %x0D

LF = %x0A

pings are transmitted between SIP messages, and cannot be sent in the middle of SIP message. If the TCP connection is secured by TLS, pings are transmitted within the TLS encrypted stream.

SD-Initiated Keep-Alives Configuration

Use the following procedure to configure SD-initiated Keep-Alives.

1. In Superuser mode, use the following ACLI command sequence to access SIP Interface configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

2. The **options sbc-initiated-keep-alive-name** attribute enables SD-initiated Keep-Alive on the current SIP interface and specifies the name of the proprietary Via header parameter used during the SD-initiated Keep-Alive negotiation.

   Prefix the command with a plus (+) sign to avoid over-writing existing options configuration.

   The following example enables SD-initiated Keep-Alives and identifies the proprietary rkeep header as the header that contains negotiation information.

   > **Note:**
   >
   > Endpoints require prior knowledge of this proprietary header name because the SD lacks the capability to relay configuration data to relevant endpoints.

```
ORACLE(sip-interface)# options +sbc-initiated-keep-alive-name=rkeep
ORACLE(sip-interface)#
```

3. The **option sbc-initiated-keep-alive-interval** attribute specifies the frequency of SD-initiated Keep-Alives.
4. If SD-initiated Keep-Alive is enabled on the current SIP interface (**options sbc-initiated-keep-alive-name** identifies a proprietary Via header parameter used for Keep-Alive negotiations), use the **options sbc-initiated-keep-alive-interval** attribute to specify the default interval between SD-initiated pings.

   Prefix the command with a plus (+) sign to avoid over-writing existing options configuration.

Allowable values are integers within the range 1 through 999999999 (seconds).

In the absence of an explicit assignment, this attribute defaults to a value of 30 seconds.

This default interval will be used only the proprietary parameter proposed by the endpoint lacks a value.

```
ORACLE(sip-interface)# options +sbc-initiated-keep-alive-interval=45

ORACLE(sip-interface)#
```

5. Use **done**, **exit**, and **verify-config** to complete this configuration.
6. If necessary, repeat Steps 1 through 5 to configure SD-initiated Keep-Alives on additional SIP interfaces.

Statistics

The SD does not gather or maintain endpoint-initiated Keep-Alive statistical counts. However, malformed STUN binding requests and responses are included in the count of mal-formed SIP messages. Additionally, if DoS is enabled, STUN binding exchanges are included in endpoint message counts.

SIP Registration Local Expiration

When you deploy multiple Oracle Communications Session Border Controllers (SBC) in series and they have registration caching and HNT configured, registration cache entries might expire prematurely in instances with several devices provisioned with the same address of record (AoR). Now you can configure a SIP interface option to prevent the premature expiration.

When you use registration caching and HNT, the SBC adjusts the expiration time it sends to user agents (UAs) in REGISTER responses based on the registration interval you configure. It can be the case that a SIP user has multiple registered contact endpoints at the UA to which a response is sent. If the URI in the Contact contains the UA‘s address and that UA included the Contact in the REGISTER request, then the Contact is seen as exclusively belonging to that UA. In the REGISTER response, this Contact (exclusive to the UA) includes the local expiration time, a time based on the SIP interface configuration’s registration or NAT interval value. Additional Contacts (not exclusive to the UA) in the REGISTER response have the expiration time from the REGISTER response the registrar sent to the SBC.

It is this default behavior can cause registration cache entries to expire prematurely in the SBC nearest a registrar when multiple SBCs are deployed in series. Multiple registering UAs for a single SIP user, for example, might trigger the early expiration. The SIP you can configure an option per SIP interface that causes the SBC to send the local registration expiration time in all in the Expires parameter of all Contact headers included in REGISTER responses sent from the SIP interface.

SIP Registration Local Expiration Configuration

You can configure this feature either for the global SIP configuration, or for an individual SIP interface.

To configure SIP registration local expiration for the global SIP configuration:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter. If you are editing an existing configuration, select the configuration so you can enable this feature.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **reg-local-expires** with a plus sign in front of it, and then press Enter.

```
ORACLE(sip-config)# options +reg-local-expires
```

If you type options and then the option value for either of these entries **without the plus sign, you will overwrite any previously configured options. In order to append the new option to this** configuration's **options list, you must prepend the new option with a plus sign as shown in the previous example.**

5. Save and activate your configuration.

To configure SIP registration local expiration for an individual SIP interface:

6. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

7. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

8. Type **sip-interface** and press Enter. If you are editing an existing configuration, select the one on which you want to enable this feature.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

9. **options**—Set the options parameter by typing **options**, a Space, the option name **reg-local-expires** with a plus sign in front of it, and then press Enter.

```
ORACLE(sip-interface)# options +reg-local-expires
```

If you type options and then the option value for either of these entries **without the plus sign, you will overwrite any previously configured options. In order to append the new option to this** configuration's **options list, you must prepend the new option with a plus sign as shown in the previous example.**

10. Save and activate your configuration.

Simultaneous TCP Connection and Registration Cache Deletion

You can configure the Oracle Communications Session Border Controller to automatically start a timer when a user deregisters or changes location by registering with a new contact address.

Not all devices tear down TCP connections associated with these old addresses when a user registers with a new contact address.

Registration Cache Deletion Configuration

You can apply **suppress-reinvite** to the sip-interface facing the User Agents whose re-INVITEs are to be responded to locally.

To enable Registration Cache Deletion:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-interface** and press Enter. If you are adding this feature to a pre-existing configuration, you will need to select and edit it.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

4. **tcp-conn-dereg**—The delay (in seconds) that is used to determine when to terminate the TCP connection for a user that has been removed from the registration cache or changed location. This feature can be disable by setting the value to zero.

```
ORACLE(session-agent)# tcp-conn-dereg 5300
```

5. Save your work.

SBC Incorrectly Appends Cookie in SIP REGISTER Message

The Oracle Communications Session Border Controller does not recognize a SIP URI containing tel-URI information if it doesn't also contain a "user=phone" parameter. This behavior adversely affects creation of the acme_nat tag and placement of the cookie

You can enable the option **proces-implicit-tel-URI** to recognize an implicit tel-URI and places the cookie in the correct location.

process-implicit-tel-URI Configuration

To enable proccess-implicit-tel-URI

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. **options**—Set the options parameter by typing **options**, a Space, the option-name **proccess-implicit-tel-URI** with a plus sign in front of it, and then press Enter.

```
ORACLE(sip-config)# options +proccess-implicit-tel-URI
```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the SIP interface configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

SIP HNT Forced Unregistration

If you use HNT and experience the issue explained in this section, consider using the Oracle Communications Session Border Controller (SBC) forced unregistration feature. When this feature is enabled and a registration entry for an endpoint expires, the SBC notifies the soft switch to remove this binding using REGISTER message. In that REGISTER message, the expires header will be set to 0 and the expires parameter in the Contact header will also be set to 0.

The benefits of using forced unregistration include:

- Leveraging existing HNT configuration to provide near real-time information about the UA's status to the registrar/softswitch
- Preserving resource utilization for the SBC and the softswitch by deleting a contact binding that is no longer valid or needed
- Preventing extra bindings from being generated at the softswitch (e.g., in instances when the UA or NAT restart)

This feature applies to:

- HNT endpoints with registration caching enabled by default, and when the **nat-traversal** parameter in the SIP interface configuration is set to always
- non-HNT endpoints with registration caching enabled, when the registration-interval parameter in the SIP interface configuration is used in the expires header sent to the UA in the 200 OK

When to Use Forced Unregistration

For typical HNT use, it is common that the registration interval between the client UA and the Oracle Communications Session Border Controller (SBC) is between 60 and 120 seconds. This differs significantly from the re-registration interval between the SBC and the and the registrar, which varies from approximately 30 to 60 minutes.

If the UA fails to refresh its registration, the contact binding at the SBC is deleted after the registration expires. This expiration is determined by the expires= header in the 200 OK. The binding at the real registrar will remain intact. This creates a discrepancy between the real state of the UA and state of the softswitch. In the best case scenario, the contact binding expires at the softswitch after a few minutes.

For network management, this discrepancy can be problematic because the service provider would be unaware of the UA's status until the binding expires at the softswitch. This can take a considerable amount of time to happen.

In addition, the SBC encodes a cookie in the userinfo of the Contact header in the REGISTER message. This is a function of the source IPv4 address and port from which the request came, i.e., the ephemeral port in the NAT for DSL scenarios. Therefore, additional bindings that remain for long periods of time are created at the registrar if, for example, the:

- UA reboots
- Ethernet link between the UA and the DSL router is lost for over two minutes
- DSL crashes
- DSL/ATM layer between the DSL router

Caution for Using Forced Unregistration

You should use caution when applying SIP HNT forced unregistration for the following reasons:

- It can have an impact on the performance of your Oracle Communications Session Border Controller and the registrar, especially when you have a large number of HNT endpoints in your configuration that become unavailable simultaneously.
- It is possible that the registrar might become vulnerable to overload in the case where the registrar must authenticate a large number of register messages generated when HNT endpoints are de-registered. It is possible that the cached registration credentials might become "stale" over time (e.g., the nonce value usually has a limited lifetime). Without proper credentials, the registrar will reject the de-registrations.

Given these concerns, we recommend that you consult with your Oracle systems engineer before adopting the use of forced unregistration.

SIP HNT Forced Unregistration Configuration

To enable SIP HNT forced unregistration:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the **session-router** path.

```
ORACLE(configure)# session-router
```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-config
```

4. Use the ACLI **select** command so that you can work with the SIP configuration.

```
ORACLE(sip-config)# select
```

5. **options**—Set the options parameter by typing **options**, a Space, the option name **force-unregistration**, and then press Enter.

```
ORACLE(sip-config)# options +force-unregistration
```

If you type options force-unregistration, you will overwrite any previously configured options. In order to append the new option to the sip-config's options list, you must prepend the new option with a plus sign as shown in the previous example.

> **Note:**
>
> In the event of a failover, the Service Route information is required by the SBC to trigger a DE-REGISTER. When the **force-unregistration** option is set, the SBC expects the Registrar to send a Service-Route Header in the 200 OK response of the REGISTER Request.

Adaptive HNT

This section explains how to configure adaptive HNT. The adaptive HNT expires feature allows the Oracle Communications Session Border Controller to automatically determine the maximum SIP REGISTER message expires time interval in order to keep each individual NAT pinhole open when performing SIP HNT. This feature applies only to SIP over UDP.

Overview

Without adaptive HNT, the Oracle Communications Session Border Controller keeps NAT pinholes open and port mapping cached by forcing the UAC to send frequent SIP REGISTER messages. It does so by setting the expires time to a short interval. Some NATs only need a message to be sent by the private client once every twenty minutes, while other NATs delete their cache/pinhole in thirty seconds if no messages appear. Given this large variation in time intervals, the Oracle Communications Session Border Controller's **nat-interval** (expire time), set on the applicable **sip-interface**, has been set to a low value in order to support as many NAT types as possible. However, CPU performance and scalability issues result from such a small refresh time, especially when there is a very large number of potential registered users.

When you use adaptive HNT, the Oracle Communications Session Border Controller waits for a time interval and then sends a SIP OPTIONS message to the UAC to see if it can still be reached. If the UAC can still be reached, the Oracle Communications Session Border

Controller increases the timer and tries again. In case the pinhole closes because it has exceeded the NAT's cache time, the Oracle Communications Session Border Controller sets the expires time to be slightly longer than the time it tests using the OPTIONS method. This way, the UAC will send another REGISTER message shortly thereafter and impact on service will be minimal.

Adaptive HNT Example

An example call flow using adaptive HNT involves a basic HNT user and a Oracle Communications Session Border Controller. It begins when the Oracle Communications Session Border Controller receives and forwards the 200 OK for the REGISTER message. Then the Oracle Communications Session Border Controller sends an expires timer for slightly longer than the time for which to test; in this example, it begins the test for the amount of time set for the minimum NAT interval, specified by the **nat-interval** set on the applicable **sip-interface**. It adds ten seconds to this time when it sends the expires timer. This way, there is time for the OPTIONS message to be sent before the REGISTER message is received (which would refresh the NAT's cache). The Oracle Communications Session Border Controller also tries to keep the REGISTER time short enough so that even if the NAT pinhole closes, there is minimal time before the UAC creates a new NAT binding by sending another REGISTER. Because a ten second interval may be too long, you might want to set this value to a better-suited time.

The test succeeds with a minimum test-timer because the UAC responded to the OPTIONS message. So the test-timer value is increased by thirty seconds and tried again. The expires time in the REGISTER message will be increased to the test-timer value plus ten seconds. This time, the UAC does not respond to the OPTIONS message even though it was sent multiple times. Because the OPTIONS fails, when the Oracle Communications Session Border Controller receives another REGISTER, it responds with the previously successful timer value (in this case, the minimum NAT interval).

However, if the OPTIONS request succeeds, then the Oracle Communications Session Border Controller persists with the test until it fails or until the maximum NAT timer value is reached. In this case, when the OPTIONS message fails, the Oracle Communications Session Border Controller uses the last successful test-timer value as the time for the expires header in the 200 OK for the REGISTER message.

Adaptive HNT over TCP

The SBC supports Adaptive Host NAT Traversal (AHNT) over TCP in addition to UDP. TCP AHNT configuration and behavior is largely the same as for UDP. You use **sip-interface** parameters that are equivalent to, but separate from the UDP parameters to configure Adaptive HNT for TCP.

The SBC detects that an endpoint is behind a NAT using the same process for both UDP and TCP, comparing the layer 3 IP address of a REGISTER with the VIA header before proceeding with a registration. If the first VIA is different from the layer three address, the SBC assumes there is a NAT and sets up flows accordingly. For subsequent HNT timing processes, the SBC refers to TCP-related HNT configuration parameters, which are separate from those used for UDP transport.

When configuring adaptive HNT for TCP, you use the **tcp-nat-interval** parameter on a **sip-interface** to specify the NAT interval for TCP transport. The SBC starts AHNT testing using this value as the initial interval after which the SBC sends an OPTIONS request and waits for an OPTIONS response from the endpoint it is testing until the test expires, calculated as **tcp-nat-interval** plus the **tcp-nat-int-increment**.

Parameters on the **sip-interface** that apply to AHNT testing over TCP connections include:

- **tcp-sip-dynamic-hnt**
- **tcp-nat-interval**
- **tcp-max-nat-interval**
- **tcp-nat-int-increment**
- **tcp-nat-test-increment**

The system ends the AHNT test when:

- The OPTIONS request was not sent because the NAT gateway or UA closed the connection.
- The new expires header value calculated by the SBC for the next RE-REGISTERs 200 OK exceeds your configured value for **max-nat-interval** (or **tcp-max-nat-interval**).
- The early RE-REGISTER occurrence count, monitored by the SBC exceeds 3.
- The UE sends a keep-alive SIP request for a contact to keep the NAT port open for 5 or more consecutive times.
- When you configure the **nat-int-increment** (or **tcp-nat-int-increment**) value higher more than 32s, and the OPTIONS sent by the SBC has not received a response within the Client Transaction expires time (32s).

When the test is complete, the SBC uses the last successful test time for the expires value in the current and subsequent refresh REGISTER's 200 OK for that contact.

Feature Limitations

This Adaptive HNT over TCP feature generates several limitations on SBC operation:

- When you deploy this feature, the configuration change does not apply to existing contacts already using AHNT functionality.
- When you enable both **sip-dynamic-hnt** and **tcp-sip-dynamic-hnt**, the SBC applies this feature based on transport type of each REGISTER request. Either AHNT over TCP or UDP is applicable for a users contact.
- A UA with the same contact does not change its transport type when it sends refresh REGISTER. A UA can only change its transport type by a new registration with the new contact for that transport type.
- The SBC synchronizes the learned expires time to HA only after the AHNT test is complete for both UDP and TCP contacts.
- A SIP contact URI (IP:Port:transport) must remain the same in a user's REGISTER and RE-REGISTER. The transport type between the UA or NAT Gateway and the SBC cannot change until that contact expires.

Adaptive HNT Call Flows

This section presents call flow diagrams to help explain AHNT functionality on the SBC.

The call flows below depict the SBC performing AHNT testing to establish an expires value that keeps a NAT pinhole open while additional signaling and media traverses the NAT device for a specific call. The NAT device uses this pinhole for either UDP or TCP transport.

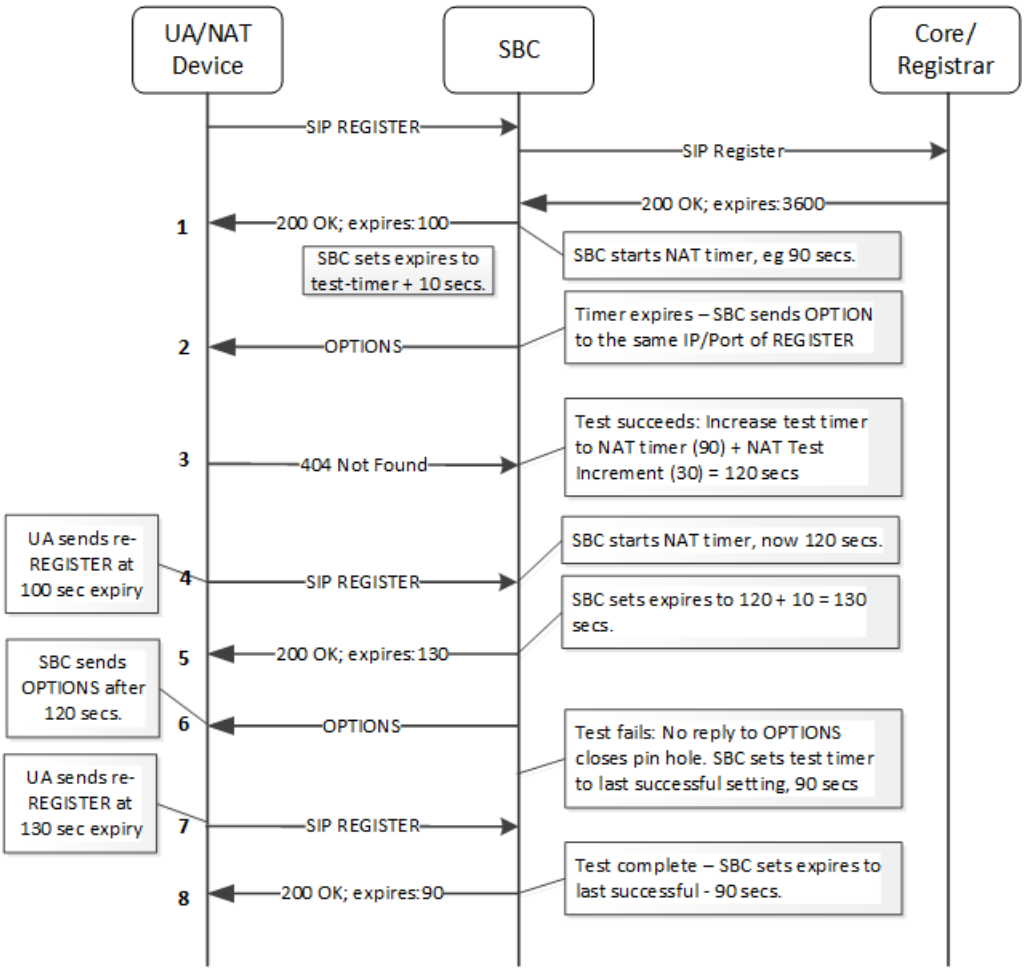
Call flows are the same for both TCP and UDP, using the applicable parameters on the **sip-interface**:

- **sip-dynamic-hnt** (or **tcp-sip-dynamic-hnt**)—Enables or disables AHNT for UDP or TCP connections respectively.

- **nat-interval** (or **tcp-nat-interval**)—The number of secs used to calculate the test-timer for sending OPTIONS request or to perform the AHNT test.
- **nat-int-increment** (or **tcp-nat-int-increment**)—The number of seconds added to the expires header value in REGISTERs 200 OK. The actual AHNT test would be done only during this incremented interval time we added to expires header in REGISTERs 200OK.
- **nat-test-increment** (or **tcp-nat-test-increment**)—The number of seconds used to increment the next test timer value when a RE-REGISTER arrives.
- **max-nat-interval** (or **tcp-max-nat-interval**)—The maximumn number of seconds used for the expires value. When reached, the SBC stops AHNT testing.

Normal ANHT Process

This call flow depicts an example of the SBC performing AHNT testing. The steps provided below expand upon the behavior.



As shown in the call flow above, the SBC implements this feature within the context of registration. The first three lines in the flow present a successful registration using the registrar, and ending with a 200 OK from the registrar to the SBC. Assume TCP transport, but note the behavior is the same for UDP when the equivalent configuration is in place.

When it receives the 200 OK reply to the REGISTER request from the registrar, the SBC refers to the expires value, normally 3600 seconds, and checks whether you have enabled the **tcp-sip-dynamic-hnt** parameter for this connection's transport protocol on the **sip-interface** where the REGISTER request arrived. If so, the SBC:

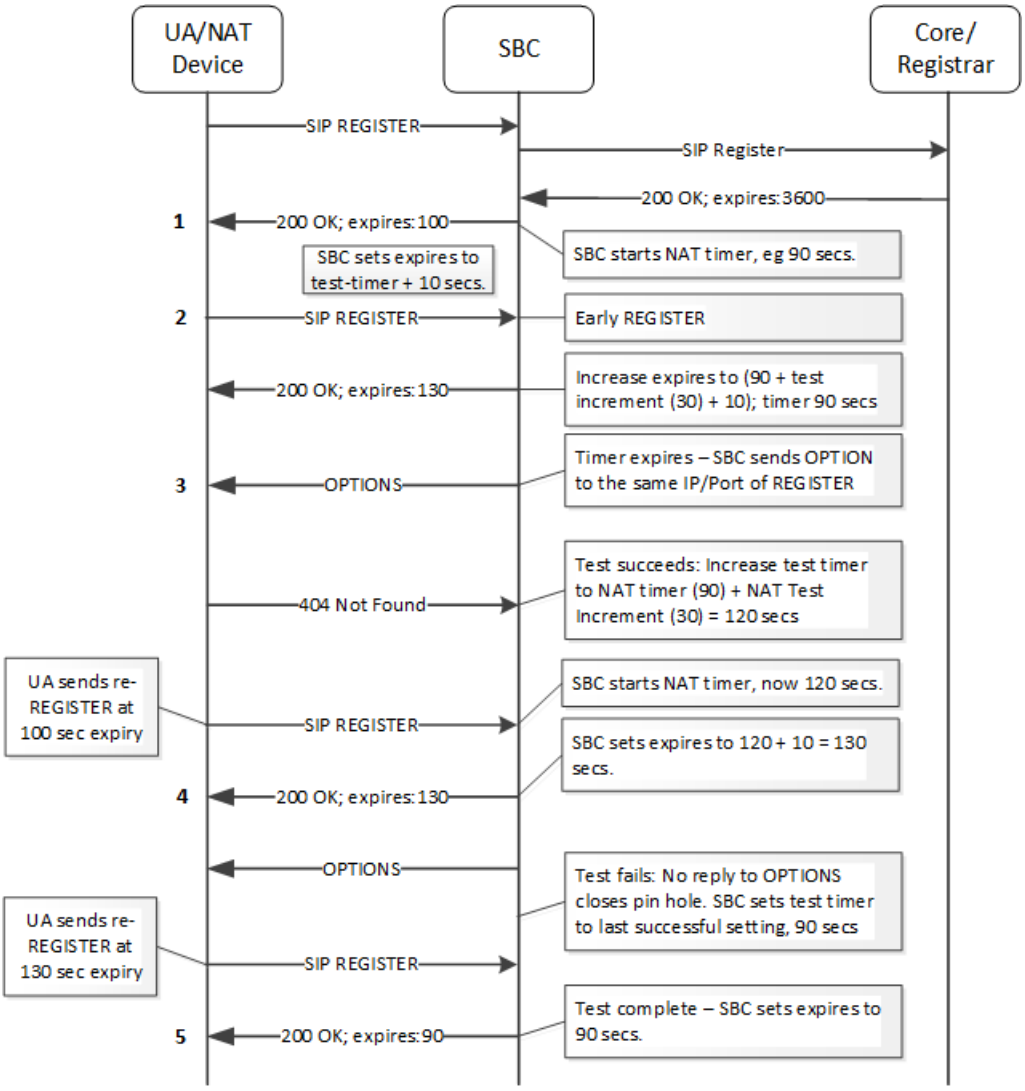
1. Replaces the expires header parameter value in its 200 OK to the endpoint with the sum of the values configured in the **tcp-nat-interval** and **tcp-nat-int-increment** parameters. In the flow, the system has used the defaults of both parameters respectively and arrived at an expires time of 90 + 10 = 100 seconds.
   In addition, the SBC starts a timer using the value configured in **tcp-nat-interval**. Notice that the expires time is slightly longer than the timer time. This allows the SBC to decide whether this test iteration succeeded or failed and change the value of the next expires time accordingly.
2. The SBC sends an OPTIONs message at the 90th second and waits for a reply. Note that the test timer is active.
3. The end station replies, in this case, with a 404 - Not found message within the test window. This concludes the first iteration of the AHNT test successfully, indicating that the NAT device does not close the pinhole sooner than the expires time of 90 seconds.
   Because this test was successful, the SBC recalculates the test time using the sum of the values configured in the **tcp-nat-interval** and **tcp-nat-testincrement** parameters. Again, the flow shows the system using the defaults of both parameters respectively and arriving at an expires time of 90 + 30 = 120 seconds.
4. The UA responds with a re-REGISTER at the original expires time.
5. The SBC sends the 200 OK to the re-REGISTER, including a new expires time and starts the test timer.
   The SBC sets the expires using the sum of the test times and the **tcp-nat-int-increment** parameters (120 +10 = 130 seconds).
6. The SBC sends an OPTIONS request at or after 120th second and waits for the response. The actual testing happens between 120th second to 130th second.
   For this test iteration, the UA does not respond before the test window expires (130 seconds). The SBC reverts is test timer to that last successful value of 90 seconds.
7. The UA sends a re-REGISTER at the expires time of 130 seconds.
8. The SBC sends a 200 OK for the re-REGISTER and sets the expires time to the same value as the last successful test timer value, which in this case is 90 seconds.

> **Note:**
>
> The system does not perform any calculation using the **tcp-nat-int-increment** value for the final setting.

Early Refresh REGISTER Scenario

In some cases, a UA may send a re-REGISTER before the expires time. The SBC does not end its AHNT testing when this happens, instead adjusting its test timing to try and avoid any further early REGISTER refreshes. Specifically, the SBC increases the expires time it sends to the UA in the 200 OK by the NAT test's increment value, and restarts the OPTIONS test timer without increasing its value.

The SBC, however, also tracks the number of early REGISTER refreshes that it receives during a session, and ends AHNT testing if that count reaches three in a row. Each early refresh REGISTER resets the NAT device pinhole. If the NAT device is keeping the pinhole open, there is no need for the SBC to expend processing cycles for the same purpose.



As shown in the call flow above, the SBC implements this feature within the context of registration. The first three lines in the flow present a successful registration using the registrar, ending with a 200 OK from the registrar to the SBC.

1. Like the first example, this flow includes the system using the defaults of the interval and increment parameters respectively to set an expires time of 90 + 10 = 100 seconds. In addition, the system starts the OPTIONS timer using 90 seconds.
2. In this flow, however, the UA sends a re-REGISTER before the OPTIONS timer expires. As described above, the SBC increases the expires time using the **tcp-nat-test-increment** value (30 seconds) and sends the 200 OK with an expires time of 130 seconds. The SBC also restarts the OPTIONS test timer using its original value of 90 seconds.
3. After 90 seconds, the SBC sends the OPTIONS request and gets a 200 OK (or other) response.
4. For this iteration, there is no early REGISTER refresh. The SBC starts the test timer using its normal calculation, in this case 90 + 30 = 120, and sends the 200 OK with an expires calculated as the first successful test, 130 seconds.
5. This call flow completes by receiving no reply to the OPTIONS request in time, so the SBC reverts to the last successful expires time of 90 seconds.

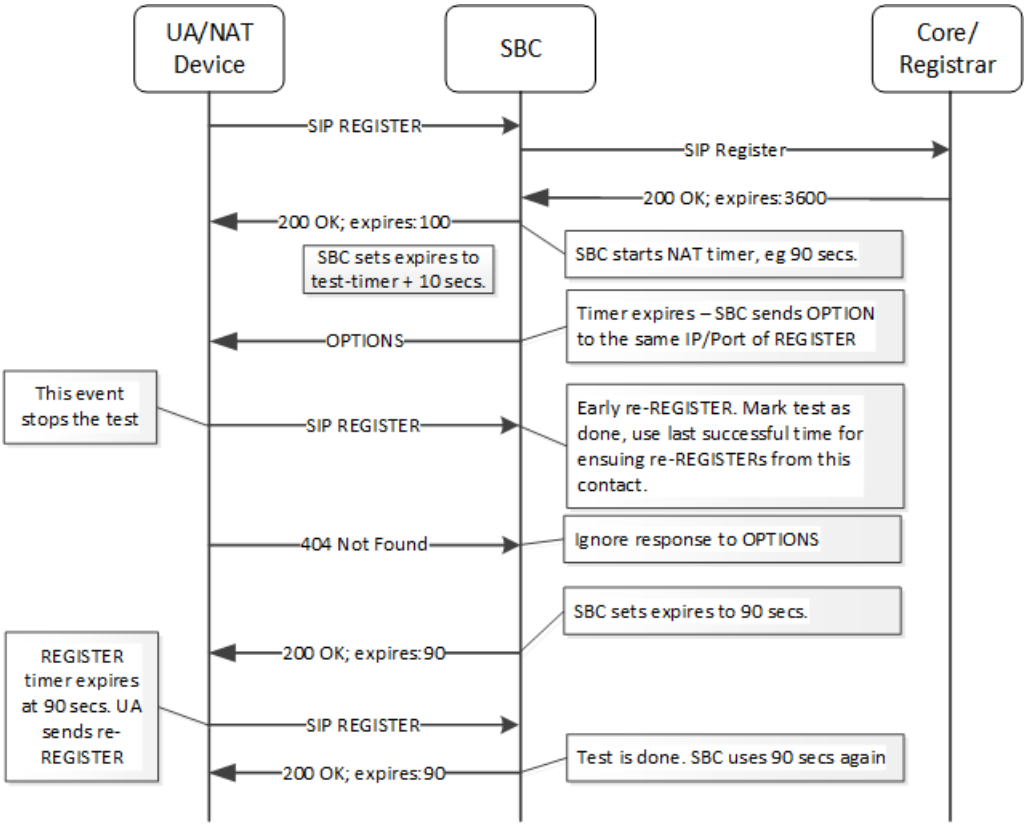
> **Note:**
>
> The system does not perform any calculation using the **tcp-nat-int-increment** value for the final setting.

If the UA/NAT sends another early refresh REGISTER at any time during the session, the SBC increases the expires time in the 200 OK by the **tcp-nat-test-increment** and restarts the test timer to its original value.

Early Refresh REGISTER while OPTIONS In-Progress

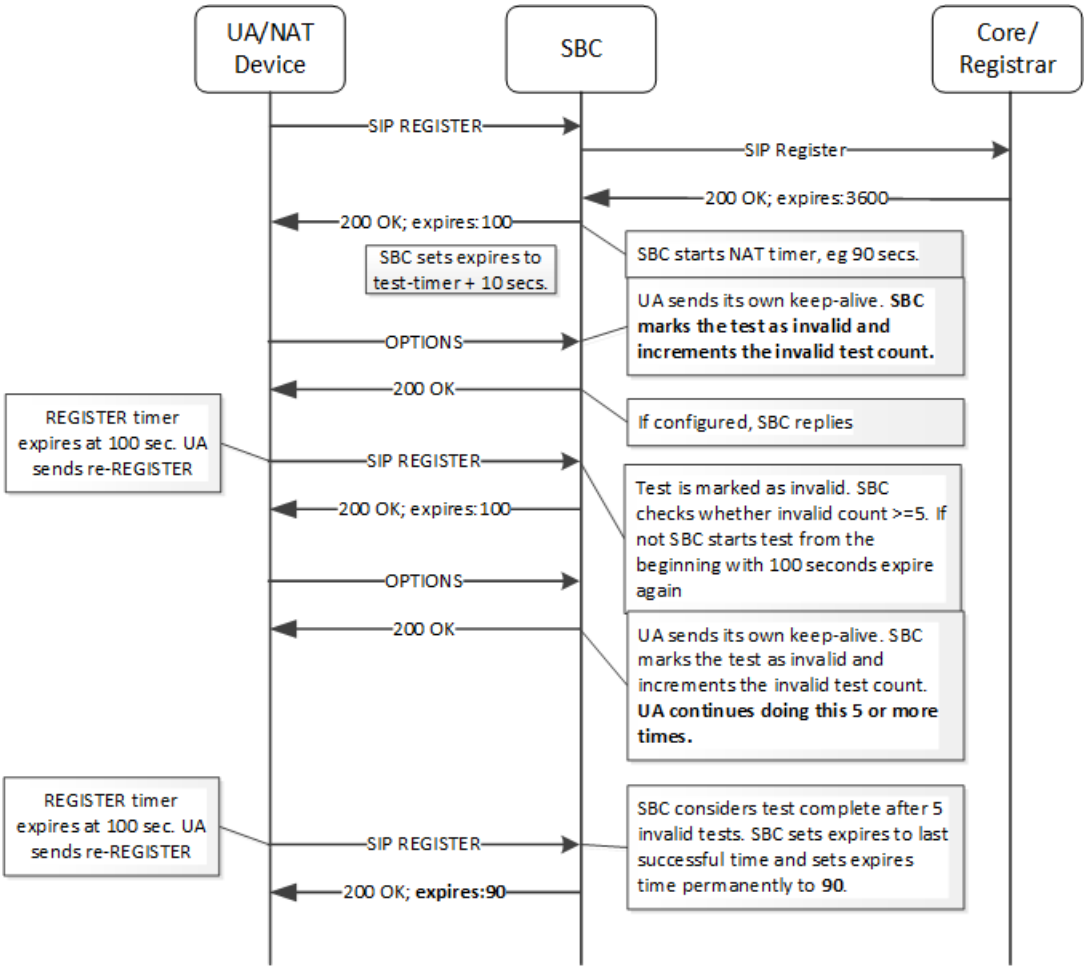
Within this example, the SBC receives a refresh REGISTER before getting a 200 OK for the OPTIONS request it sent to the UA. When it gets this refresh REGISTER, the SBC marks the test as done and sets the expires time to the **tcp-nat-interval** if no test completed successfully, or to the last successful test's expires time.

In this same scenario, if the OPTIONS client transaction expires due to no response from UA, the SBC marks the test as done and inserts the same expires header values as above. By default, OPTIONS expiry happens at 32 seconds.



Keep-Alive from UA Flow

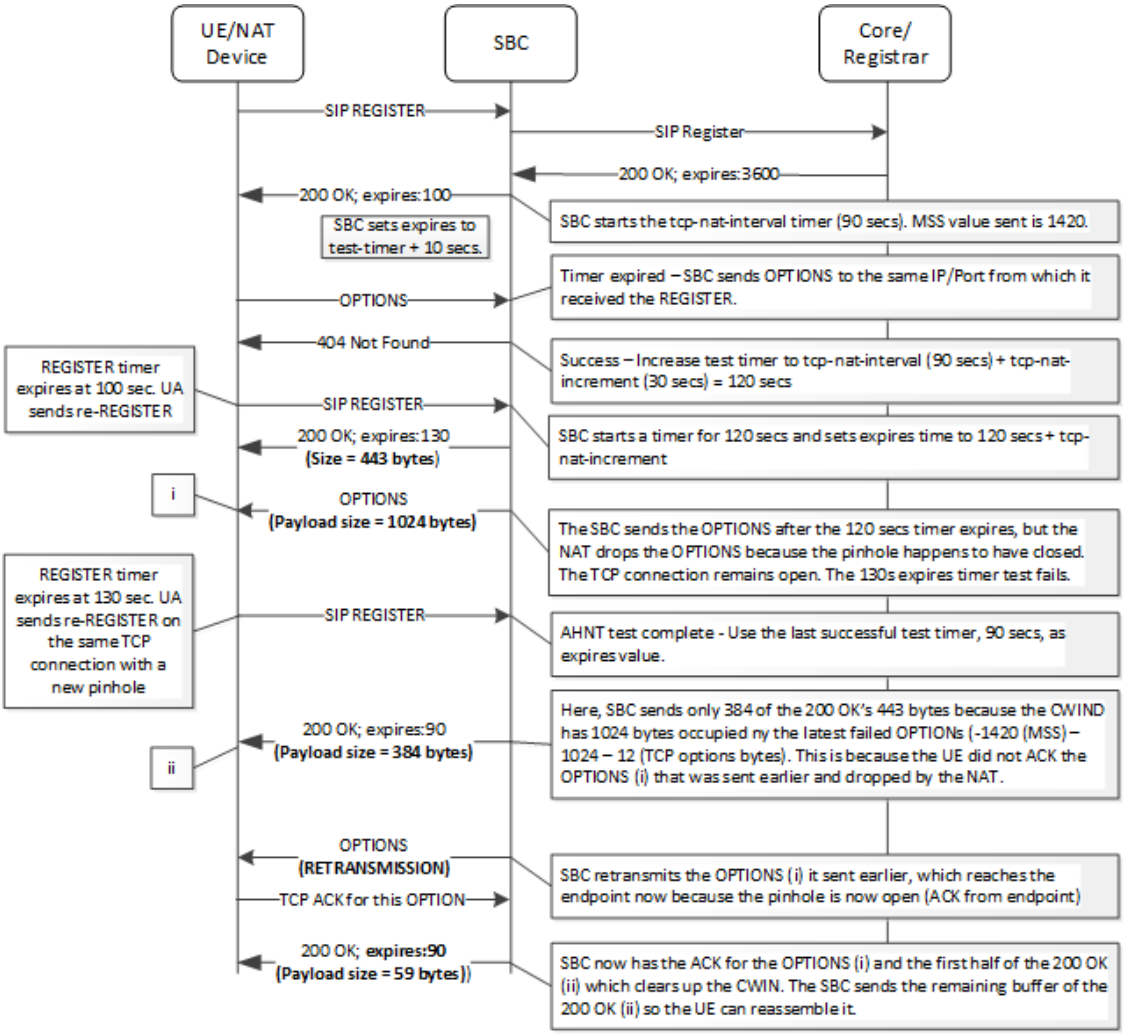
Within other use cases, the UA itself tries to keep the NAT pinhole open by sending OPTIONS or any other out of dialog SIP request for that contact from the same IP address and port number that it used for its last REGISTER. When it detects this, the SBC disables AHNT testing for that contact for 5 or more consecutive instances, and uses the last successful test time for future RE-REGISTERs expires times.



AHNT Operation in Conjunction with TCP Behavior

Some call flows applicable to this feature are subject to normal packet delivery delays that allow the NAT pinhole to close. Examples include TCP connections that experience segmented packet transfer wherein a segment may not have received an ACK, lengthening the amount of time consumed by a transmission. In these cases, the SBC persists with its AHNT behaviors, ultimately waiting out the closed pinhole and proceeding with packet reassembly after the TCP connection resumes transmission.

Consider the situation wherein the OPTIONS pings are retransmitted after a pinhole is closed and re-opened. The SBC would not be aware of whether this situation was caused by the absence of an ACK to an OPTIONS or because there was a network issue. In this case, the SBC follows standard TCP behavior and waits for a segment's ACK from an endpoint within its congestion window (CWIND) before sending the additional segments to the endpoint.



The steps below provide additional explanation on the call flow above:

1. The SBC establishes the TCP connection with TCP maximum segment value (MSS) of 1420. The SBC starts AHNT testing and establishes an expires value of 100.
2. The SBC follows its AHNT testing procedure until it finds an expires value that keeps the pinhole open.
3. In the meantime, the end station sends another REGISTER to which the SBC provides a 200 OK.
4. Notice the first 200 OK sent by the SBC is 443 bytes. The expires timer is lengthened as the AHNT testing is continuing to identify the longest window it can used without the pinhole closing.
5. After the re-REGISTER and 200 OK, the NAT device happens to close the pinhole.
6. The SBC sends an OPTIONS, with a size of 1024 bytes to continue with the AHNT test. But OPTIONS does not reach the UE because the pinhole is closed and it was dropped by the NAT. TCP keeps the connection open waiting for the ACK to the OPTIONS.
   In addition, the TCP CWIND still has 1024 bytes occupied by the most recent OPTIONS.
7. The UE sends another refresh REGISTER, resulting in the SBC completing the AHNT test and reverting to the last successful expires timer of 90 seconds. This re-REGISTER also re-opens the NAT pinhole.

8. Next, the SBC prepares to send 200 OK with expires of 90 seconds. Because the 1024 bytes of the unanswered OPTIONS still occupies the a large amount of the CWIN, the SBC can only send a part of the 200 OK, in this case 384 bytes.
9. Later, the SBC re-transmits an OPTIONS ping and receives an ACK because the pinhole is open. This ACK applies to the OPTIONS and the 384 bytes of the outstanding 200 OK.
10. The CWIN is now cleared, so the SBC is able to send the remaining 59 bytes of the 200 OK.
11. At this point, every re-REGISTER's 200 OK for this UE has an expires value set to 90 seconds.

Synchronize A-HNT Successful Timer to Standby

Adaptive HNT enables the Oracle Communications Session Border Controller to determine, through testing, an optimum SIP REGISTER expires time interval that keeps the NAT pinhole open. For an HA node, this successful time value is determined through testing by the active system and then replicated to the standby. If there is a switchover during the active system's testing process, then it will restart for that endpoint.

Adaptive HNT Configuration

You configure the SIP interface to set the state of this feature and to define the increments of time the Oracle Communications Session Border Controller uses to perform adaptive HNT. Remember that the Oracle Communications Session Border Controller uses the time you specify as the NAT interval, the supported time interval, as the basis on which to begin testing.

If you are configuring AHNT for TCP connections, the following **sip-interface** parameters perform the same functions as the equivalent UDP parameters in the procedure below:

- **tcp-sip-dynamic-hnt**
- **tcp-max-nat-interval**
- **tcp-nat-int-increment**
- **tcp-nat-test-increment**

To configure adaptive HNT:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the **session-router** path.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ```

4. **sip-dynamic-hnt**—Enable this parameter if you want to use adaptive HNT. The default value is **disabled**. The valid values are:
   - enabled | disabled

> **Note:**
>
> Updates to **sip-dynamic-hnt** applies to new registration and when the registration cache is cleared.

5. **max-nat-interval**—Set the amount of time in seconds that testing should not exceed. The Oracle Communications Session Border Controller will keep the expires interval at this value. The default value is **3600**. The valid range is:
   - Minimum—0
   - Maximum—4294967295
6. **nat-int-increment**—Set the amount of time in seconds to use as the increment in value in the SIP expires header. The default value is **10**. The valid range is:
   - Minimum—0
   - Maximum—4294967295
7. **nat-test-increment**—Set the amount of time in seconds that will be added to the test timer. The default value is **30**. The valid range is:
   - Minimum—0
   - Maximum—4294967295

SIP IP Address Hiding and NATing in XML

Adding to its topology hiding and NAT capabilities, the Oracle Communications Session Border Controller now performs those functions for pertinent IP addresses that are not part of the standard SIP message header format. Previously, such addresses were visible to the next hop in the SIP session path.

Note that this feature adds to the Oracle Communications Session Border Controller's pre-existing ability to perform this function for XML messages; this new support is specifically for the keyset-info message type.

For incoming SIP NOTIFY messages, the Oracle Communications Session Border Controller searches for the application/keyset-info+xml content type in the message. When it finds this content type, it searches further to detect the presence of <di:remote-uri> or <di:local-uri> XML tags and then NATs the IP addresses in the tags it finds. Specifically, the Oracle Communications Session Border Controller changes:

- The <di:remote-uri> IP address to be the egress SIP interface's IP address
- The <di:local-uri> IP address to be the Ip address of the next hop to which the message is being sent

Sample SIP NOTIFY with NATed XML

The following is a sample SIP NOTIFY message as it might arrive at the Oracle Communications Session Border Controller.

> **Note:**
>
> that it contains the <di:remote-uri> or <di:local-uri> XML tags on which the system will perform NAT; these lines appear in bold text.

```
NOTIFY sip:15615281021@10.152.128.253:5137;transport=udp SIP/2.0
To: 15615281021  <sip:15615281021@10.152.128.102:5080>;tag=5c93d019904036a
From: <sip:15615281021@10.152.128.102:5080>;tag=test_tag_0008347766
Call-ID: 3215a76a979d0c6
CSeq: 18 NOTIFY
Contact: <sip:15615281021@10.152.128.102:5080;maddr=10.152.128.102>
Via: SIP/2.0/UDP 10.152.128.102:5060;branch=z9hG4bK_brancha_0023415201
Event: keyset-info
Subscription-state: active;expires=2778
Accept: application/keyset-info+xml
Content-Type: application/keyset-info+xml
Content-Length: 599
Max-Forwards: 70
<?xml version="1.0"?>
<keyset-info xmlns="urn:ietf:params:xml:ns:keyset-info"
     version="16"
     entity="15615281021">
  <ki-data>
    <ki-state>"active"</ki-state>
    <ki-event>"unknown"</ki-event>
  </ki-data>
   <di:dialog id="dialog_id_201" call-
id="1395216611-1987932283256611-11-0884970552" local-
tag="test_tag_0008347790" direction="recipient">
    <di:state>trying</di:state>
    <di:duration>2778</di:duration>
    <di:local-uri>sip:15615281021@10.152.128.253:5137</di:local-uri>
    <di:remote-uri>sip:1004@10.152.128.102</di:remote-uri>
   </di:dialog>
</keyset-info>
```

Once the Oracle Communications Session Border Controller has completed the NAT process, the <di:remote-uri> and <di:local-uri> XML tags look like this

```
<di:local-uri>sip:15615281021@192.168.200.99:5137</di:local-uri>
<di:remote-uri>sip:1004@192.168.200.49</di:remote-uri>
```

because egress the SIP interface's IP address is 192.168.200.49 and the next hop's IP address is 192.168.200.99.

This feature does not require any configuration.

SIP Server Redundancy

This section explains how to configure SIP server redundancy. SIP server redundancy involves detecting that an upstream/downstream SIP signaling entity has failed, and adapting route policies dynamically to remove it as a potential destination.

Overview

You establish SIP server redundancy by creating session agents, which are virtual representations of the SIP signaling entities. These agents are then collected into a session agent group, which is a logical collection of two or more session agents that behaves as a single aggregate entity.

Rather than direct signaling messages to a single session agent (IP), the signaling message is directed to a session agent group (SAG). The group will have a set distribution pattern: hunt, round robin, proportionally distributed, and so on. Signaling is spread amongst the agents using this chosen pattern.

You direct the signaling message by configuring a route policy, known as a local policy, which determines where SIP REQUESTS should be routed and/or forwarded. The values in the To and From headers in the SIP REQUEST are matched with the content of the local policy within the constraints set by the session agent's previous hop value and SIP interface values such as the list of carriers.

To summarize, you need:

- two or more session agents
- a session group containg those session agents
- a local policy which directs traffic to the session agent group

Configuration Overview

You make a session agent group a target by using a local policy to select the next hop from the members of a session agent group. You need to set the replace URI field of the configured local policy to enabled; which causes NAT rules such as realm prefixing to be overridden. The replace URI field allows you to indicate whether the local policy's value is used to replace the Request-URI in outgoing requests. This boolean field can be set to either enabled or disabled.

When the SIP NAT's route home proxy field is set to forced, it forces the Request to be forwarded to the home proxy without using a local policy. When this option is set to either disabled or enabled and the Request-URI matches the external address of the SIP NAT, the local policy is used.

However, the local policy only replaces the Request-URI when the original Request-URI matches the SBC's IP address or hostname. This behavior is in accordance with that described in RFC 3261. The original Request-URI will be the home proxy address value (the home address of the SIP NAT into the backbone) and not the Oracle Communications Session Border Controller (SBC) address.

Using strict routing, the Request-URI would be the next hop, but the message would also include a Route header with the original Request-URI. With loose routing, the Request-URI remains unchanged and the next hop value is added as the top Route header.

Sometimes the next hop field value must replace the Request-URI in the outgoing request, even if the original Request-URI is not the SBCC. To accomplish this, an option has been added to the local policy that causes the next hop value to be used as the Request-URI and prevents the addition of Route headers. This option is the replace uri value in the local policy.

The following table lists the policy attributes for the local policy:

Parameter	Description
next hop	IP address of your internal SIP proxy. This value corresponds to the IP address of the network interface associated with the SIP proxy.
realm	Number of the port associated with the SIP port.
replace uri	Stores the transport protocol used for sending an receiving signaling messages associated with the SIP port.
allow anonymous	Indicates whether this SIP port allows anonymous connections from session agents.

> **Note:**
>
> You should also define the ping method intervals for the session agents so that the SBC can detect when the agents are back in service after failure.

SIP Server Redundancy Configuration

To enable replace URI:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements. The system prompt changes.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **local-policy** and press Enter. The system prompt changes.

   ```
   ORACLE(session-router)# local-policy
   ORACLE(local-policy)#
   ```

4. Type **policy-attributes** and press Enter. The system prompt changes.

   ```
   ORACLE(local-policy)# policy-attributes
   ORACLE(local-policy-attributes)#
   ```

   From this point, you can configure policy attributes for the local policy. To see all local policy attribute options, enter a **?** at the system prompt.

5. **action**—Set this parameter to **replace-uri**, which causes NAT rules such as realm prefixing to be overridden. The default value is **none**. Valid values are:

   - none | replace-uri | redirect

     The replace URI field allows you to indicate whether the local policy's value is used to replace the Request-URI in outgoing requests. This boolean field can be set to either enabled or disabled.

Administratively Disabling a SIP Registrar

The Oracle Communications Session Border Controller's registration cache feature is commonly used to support authorization. It also allows the Oracle Communications Session Border Controller to respond directly to SIP REGISTER requests from endpoints rather than forwarding every REGISTER message to the Registrar(s). In the Oracle Communications Session Border Controller, Registrars are frequently configured as session agents, and an association between each endpoint and its Registrar is stored with the registration cache information.

In Release 4.0.1 and later, the i**nvalidate-registrations** parameter in the session agent configuration enables the Oracle Communications Session Border Controller to detect failed Registrar session agents and automatically forward subsequent REGISTER requests from endpoints to a new Registrar. You can now perform the same behavior manually through a new ACLI command. When you use this command, the Oracle Communications Session Border Controller acts as though the registrations have expired.

For each SIP session agent, you can enable the manual trigger command, and then use the command from the main Superuser ACLI prompt. The **reset session-agent** command provides a way for you to send a session agent offline. Session agents can come back online once they send 200 OK messages the Oracle Communications Session Border Controller receives successfully.

Without using the manual trigger, session agents can go offline because of they do not respond to pings or because of excessive transaction timeouts. However, you might not want to use these more dynamic methods of taking session agents out of service (and subsequently invalidating any associated registrations). You can disable both of these mechanisms by setting the following parameters to 0:

- **ping-interval**—Frequency (amount of time in seconds) with which the Oracle Communications Session Border Controller pings the entity the session agent represents)
- **ttr-no-response**—Dictates when the SA (Session Agent) should be put back in service after the SA is taken OOS (Out Of Service) because it did not respond to the Oracle Communications Session Border Controller

However, you can still use the new SIP manual trigger even with these dynamic methods enabled; the trigger simply overrides the configuration to send the session agent offline.

Considerations for Implicit Service Route Use

When implicit service route support is enabled for a SIP interface (in IMS applications), the Oracle Communications Session Border Controller stores the Service Route URIs from the Service-Route headers that are included in 200 OK responses to REGISTER messages. Subsequently, and even when a session agent is rendered invalid, re-REGISTER messages follow the route stored in the cache instead of using the one defined in the Oracle Communications Session Border Controller.

However, you might not want to use this behavior when you send session agents offline. If you instead want use the route defined in the Oracle Communications Session Border Controller, then you need to configure the SIP interface option called **route-register-no-service-route**.

Manual Trigger Configuration

This section shows you how to enable the manual trigger for sending session agents out of service, and how to then use the trigger from the command line. This section also shows you how to verify that you have successfully put a session agent out of service.

To enable a SIP session agent to manually trigger it to go out of service:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

   If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration you want to edit.

4. **invalidate-registrations**—Set this parameter to enabled if you want to use the manual trigger to send this session agent offline (and therefore invalidate the registrations associated with it). The default is disabled.
5. Save and activate your configuration.

   To use the manual trigger that sends session agents offline:

6. Note the hostname value (typically the IP address of the endpoint) for the session agent you want to put out of service. You use this name as an argument in the ACLI command to use the manual trigger.
7. At the Superuser prompt, type **reset session-agent**, a Space, and the hostname value for the session agent. The press Enter.

   ```
   ORACLE# reset session-agent 192.168.20.45
   ```

   If you enter a session agent that does not exist, the system notifies you that it cannot carry out the reset.

Manual Trigger Confirmation

To confirm that a session agent has been sent offline:

- Use the **show sipd endpoint-ip** command to confirm the session agent state.

  ```
  ACMEPACKET# show sipd endpoint-ip 1016
  User <sip:1016@172.18.1.80>
          Contact exp=3582
  ```

```
            UA-Contact: <sip:1016@192.168.1.132:5060> UDP
                realm=access local=172.18.1.132:5060
UA=192.168.1.132:5060
    SD-Contact: <sip:1016-o3badgbbnjcq5@172.18.2.80:5060> realm=core
    Call-ID: 1-7944@192.168.1.132'
    SR=172.18.2.92
    SA=172.18.2.93
    Service-Route='<sip:test@s-cscf::5060;orig;lr>'
ACMEPACKET# reset session-agent 172.18.2.92
Accepted
Reset SA failover timer
ACMEPACKET# show sipd endpoint-ip 1016
User <sip:1016@172.18.1.80>
        Contact <invalidated> exp=3572
            UA-Contact: <sip:1016@192.168.1.132:5060> UDP
                realm=access local=172.18.1.80:5060
UA=192.168.1.132:5060
    SD-Contact: <sip:1016-o3badgbbnjcq5@172.18.2.80:5060> realm=core
    Call-ID: 1-7944@192.168.1.132'
    SR=172.18.2.92 (failed 2 seconds ago)
    SA=172.18.2.93
    Service-Route='<sip:test@s-cscf::5060;orig;lr>'
ACMEPACKET#
```

In the above ACLI example the first iteration of the **show sip endpoint-ip** command provides information for the in-service 172.18.2.92 session agent; the second command iteration displays information for the now out-of-service session agent.

> **Note:**
>
> There can be multiple users registered with the same phone number. In those cases, the **show sipd endpoint-ip <phone-number>** output is a single entry which first matches the registration cache.

Surrogate Agent Refresh on Invalidate

Surrogate agent registrations normally only re-register when nearing their expiration time. When a registrar fails, the surrogate agent will wait until the expiration time to refresh the registration with an in-service registrar.

You can configure your Oracle Communications Session Border Controller to immediately refresh the surrogate agent registrar with an in-service registrar by enabling the existing parameter **invalidate-registrations**.

Invalidate Registrations

An existing feature called **invalidate-registrations** located in the session agent keeps track of when surrogate agents go out of service. When REGISTER messages are received, registration entries that had out-of-service session agents since the last REGISTER will always allow the message through to the registrar (as opposed to responding directly from the cache).

The **invalidate-registrations** parameter in session agent configuration enables the Oracle Communications Session Border Controller to detect failed Registrar session agents.

If invalidate-registrations is enabled for the session agent, a response from a surrogate REGISTER that contains a service-route header that corresponds to a session-agent is installed to the registration cache entry.

The surrogate-agents are scanned. Surrogate agents with registration entries matching the out-of-service registrar have their timer reset to initiate a refresh. For an immediate refresh, the registration entry will only be considered when the service-route session agent goes out-of-service. The service-route session agent takes precedence and any previous registrar session agent w ill not be considered for an immediate refresh of the surrogate-agent registration.

Performance Impact

In cases with a large number of surrogate-agent registrations, there may be an impact to CPU usage when a session-agent goes out-of-service. All of the surrogate-agent registrations are scanned at that time. Refresh registrations are then sent out on timers.

Media Inactivity Timer Configuration

To disable the media inactivity timer for calls placed on hold:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **session-agent** and press Enter.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

   If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration you want to edit.

4. **invalidate-registration**—Set this parameter to **enabled** if you want to use the manual trigger to send this session agent offline (and therefore invalidate the registrations associated with it). The default is **disabled**.
5. Save and activate your configuration.

Support for Encoded Multipart Message Bodies

SIP messages and responses may arrive at the Oracle Communications Session Border Controller with encoded multipart message bodies, such that the content of the body is unreadable. This information may be encoded for the purpose of compressing the data. Normally, the Oracle Communications Session Border Controller would consider the body invalid and reject the entire message, replying to the sender with a `400 Invalid Body` error response. The user, however, can configure the **sip-config** option, **proxy-content-type-encodings**, allowing the Oracle Communications Session Border Controller to accept, process and forward messages containing these encoded parts. This configuration causes the Oracle Communications Session Border Controller to ignore the encoding, identify the end of the

message via content length, and pass the message towards its intended recipient with the multipart body fully encoded.

The condition that triggers this functionality is the Oracle Communications Session Border Controller recognizing the presence of a multipart message body and the definition of the encoding type within the message.

```
NOTIFY sip:user@example.com SIP/2.0
Via: SIP/2.0/TCP
...
Content-Type: multipart/mixed;boundary="imdn-boundary"
Content-Encoding: gzip

... Encoded multipart content ...
```

When configured, the **proxy-content-type-encodings** is simply a list of strings. The Oracle Communications Session Border Controller looks to match the string defining the content encoding with a string in the list to proceed with the functionality.

The Oracle Communications Session Border Controller only performs this procedure on messages encoded with types for which it is configured and that are properly formed. Examples of when the Oracle Communications Session Border Controller does not perform this procedure include:

- The Oracle Communications Session Border Controller receives a message with an encoded multipart message block, but **proxy-content-type-encodings** list is empty. In this case, the Oracle Communications Session Border Controller responds with a `415 Unsupported Media Type`.
- The message arrives with a multipart message body with encoding for which the **proxy-content-type-encodings** is configured, but there is no terminating boundary. In this case, the Oracle Communications Session Border Controller replies with a `400 Invalid Body error`.
- The Oracle Communications Session Border Controller receives a response with an encoded multipart message block, but **proxy-content-type-encodings** list is empty. In this case, the Oracle Communications Session Border Controller simple drops the response.

Multipart Message Encoding Support Configuration

The procedure below provides the steps needed to configure the Oracle Communications Session Border Controller for multipart message encoding support.

To have your Oracle Communications Session Border Controller proxy messages despite the presence of the specified multipart message encoding:

1. In Superuser mode, use the following command sequence to access the **sip-config** element.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# session-router
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   From this point, you can configure encoding support.

2. Configure the desired encoding types using the option followed by comma-separated coding types.

   The example below configures support for gzip and compressed encoding.

   ```
   ORACLE(sip-config)# options +proxy-content-type-encodings=gzip,compress
   ```

3. Type **done** and exit configuration mode. Save and activate your configuration.

SIP Distributed Media Release

This section explains how to configure distributed media release (DMR). SIP DMR lets you choose whether to include multi-system (multiple Oracle Communications Session Border Controllers) media release information in SIP signaling requests sent into a specific realm.

Overview

The SIP DMR feature lets RTP/RTCP media be sent directly between SIP endpoints (for example, SIP phones or user agents) without going through a Oracle Communications Session Border Controller; even if the SIP signaling messages traverse multiple Oracle Communications Session Border Controllers. It encodes IPv4 address and port information for the media streams described by the media, for example SDP.

With SIP DMR, the media realm and IPv4 address and port information from the UA's SDP is encoded into SIP messages (either in the SIP header or in the SDP) as they enter the backbone network. The information is decoded by a Oracle Communications Session Border Controller from SIP messages that come from the backbone network. The decoded address and port information is put into the SDP sent the UAs in the access (private/customer) network.

This functionality lets the RTP/RTCP flow directly between the UAs in the access network without traversing the Oracle Communications Session Border Controllers and without passing into the backbone network. The media can then flow directly between the two SIP endpoints in the same network, if it is serviced by multiple Oracle Communications Session Border Controllers.

You can enable this feature on a per-realm basis and multiple realms can be supported.

Endpoint Locations

You can configure the Oracle Communications Session Border Controller to release media when the source and destination of the call are in the same network, customer VPN, or customer LAN. In architectures that use DMR, the Oracle Communications Session Border Controller is only part of the media path for traffic that originates and terminates in different networks.

If configured to do so, the Oracle Communications Session Border Controller can release media:

- Between endpoints supported by a single Oracle Communications Session Border Controller
  In the same network/VPN

  In the same network behind the same NAT/firewall
- Between endpoints supported by multiple distributed Oracle Communications Session Border Controllers
  In the same network/VPN

Location of the Encoded Information

Encoded media release information can appear in three different places:

- SDP attribute
  Media release data can be encoded into an SDP attribute in the SIP message body (for example, media-release=sdp;acme-media). The encoded data is placed into an acme-media attribute in the SDP:

  ```
  a=acme-media:<encoded-media-interface-info>
  ```

- SIP header parameter
  Media release data can be placed in a header parameter of a SIP header (for example, media-release=Contact;acme-media). The encoded data is placed into an acme-media parameter in the Contact header:

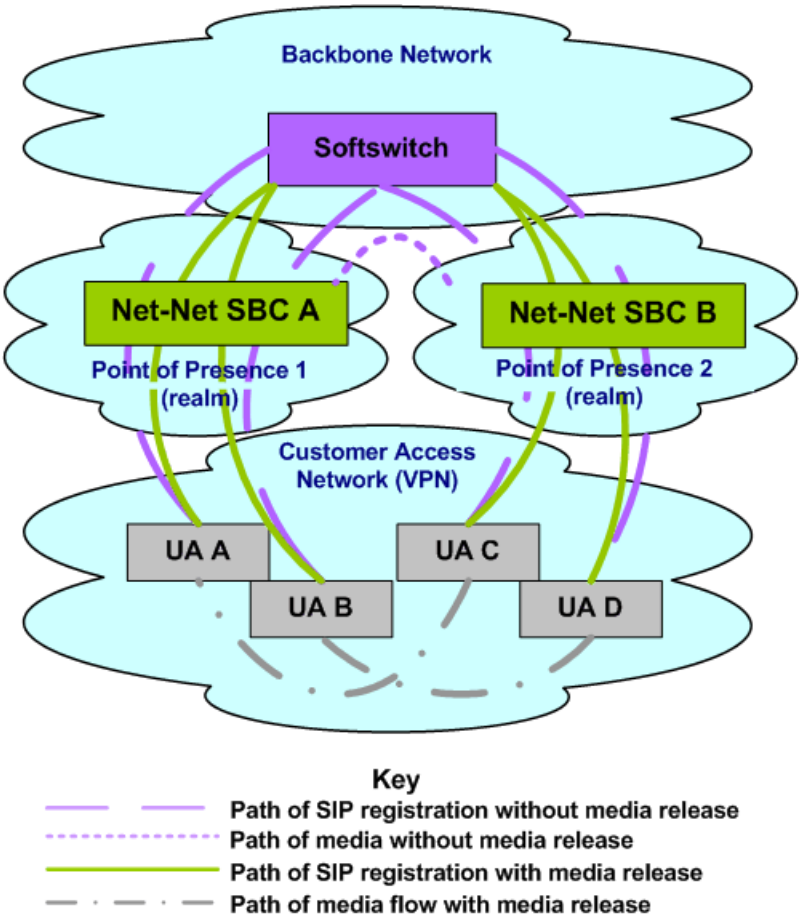
  ```
  Contact: <sip:1234@abc.com>;acme-media=<encoded-media-interface-info>
  ```

- SIP header
  Media release data can appear in a SIP header (for example, media-release=P-Media-Release). The encoded data is placed into a P-Media-Release header:

  ```
  P-Media-Release: <encoded-media-interface-info>
  ```

Example Distributed Media Release

The following example shows the network diagram for DMR in a multiple-site VPN environment supported by multiple, distributed Oracle Communications Session Border Controllers.



As shown in the network diagram, UA A and UA B register with the softswitch through Oracle Communications Session Border Controller A while UA C and UA D register with the softswitch through Oracle Communications Session Border Controller B. Without DMR, the media for calls between UA A/UA B and UA C/UA D is steered through both Oracle Communications Session Border Controller A and Oracle Communications Session Border Controller B.

With SIP DMR, the media realm and IPv4 address and port information from the UA's Session Description Protocol (SDP) is encoded into SIP messages (either in the SIP header or in the SDP) as they enter the backbone (public/service provider) network. The information is decoded from SIP messages that come from the backbone network. The decoded address and port information is put into the SDP sent to the UAs in the access (private/customer) network. This functionality allows for the RTP/RTCP to flow directly between the UAs in the access network without traversing the Oracle Communications Session Border Controllers and without passing into the backbone network.

Overview of SIP DMR Configuration

To configure SIP DMR:

1. Edit the SIP config element's option field.

   The media-release="<header-name>[;<header-param>]" option defines how the SIP distributed media release feature encodes IPv4 address and port information. If the media-release parameter is configured in the options field but no header is specified, the parameter value of P=Media-Release will be used. This parameter is optional and is not configured by default.

2. Enable SIP DMR for the entire realm by setting the realm config element's msm release field to enabled.

   The media IPv4 address and port information is encoded into outgoing SIP messages and decoded from incoming SIP messages for all of the realms (in each realm-config element) with which the SIP distributed media release will be used.

> **Note:**
>
> You can also use the realm config element's mm in network field to release the media back to a connected network that has multiple realms. This field is not specific SIP distributed media release and it is not required for the SIP DMR to work. However, if this field is set to enabled and the ingress and egress realms are part of the same network interface, it lets the Oracle Communications Session Border Controller release the media.

SIP DMR Configuration

To configure media release:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   From this point, you can configure SIP config parameters. To view all SIP config parameters, enter a **?** at the system prompt.

4. Type **options** followed by a Space.
5. After the Space, type the media release information in the following format:

   ```
   media-release="<header-name>[;<header-param>]"
   ```

   - header-name either refers to the SIP header in which to put the information or to the special header-name value of sdp to indicate the information should be put into the SDP.
   - parameter-name refers to the header parameter name in which to put the information or, in the case of the special header-name value of sdp, to the SDP attribute name in which to put the information.

     For example:

     ```
     ORACLE(sip-config)# options media-release=P-Media-Release
     ```

6. Press Enter.

> **Note:**
>
> If the media-release parameter is configured in the options field, but no header is specified, then the parameter value of P-Media-Release will be used. P-Media-Release is a proprietary header and means that the media will be encoded in the SIP header with this name.

The following example shows where the encoded information (for example, SDP data) is passed.

```
media-release="P-Media-Release"
media-release="Contact;acme-media"
media-release="sdp;acme-media"
```

Configuring the Realm

You need to set the each realm config element's msm release field to enabled for all the realms for which you want to use SIP DMR.

Although the mm in network field is not specific to the SIP distributed media release feature, it can be used to release the media back to a connected network that has multiple realms. This field does not need to be configured in order for the SIP distributed media release feature to work. However, if this field is set to enabled and the ingress and egress realms are part of the same network interface, it lets the Oracle Communications Session Border Controller release the media.

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

   From this point, you can configure realm parameters. To view all realm configuration parameters, enter a **?** at the system prompt.

4. **msm-release**—Enable DMR within this realm on this Oracle Communications Session Border Controller. The default value is **disabled**. The valid values are:
   - enabled | disabled
5. Repeat for each realm on which you want to enable DMR.

Add-On Conferencing

This section explains how to configure the add-on conferencing functionality. It also includes a description of the SIP B2BUA functionality related to the SIP add-on conferencing. This description includes information about Contact header mapping and processing and Refer-to header processing.

Overview

SIP add-on conferencing lets you:

- Use the Oracle Communications Session Border Controller's add-on conferencing feature for network architectures in which the conference initiator is located on a different network than that of the media server.
- Configure the Oracle Communications Session Border Controller to enable Contact header mapping for the Refer-To header.

Caveats

The following caveats are associated with add-on conferencing:

- Contact header mapping is not replicated on the standby Oracle Communications Session Border Controller in an HA Oracle Communications Session Border Controller pair architecture.
- Upon switchover, any conferences in progress remain in progress, but no new parties can be invited to or join the conference.
- By default, the Oracle Communications Session Border Controller does not map SIP Contact headers for reasons of performance.

Add-On Conferencing Scenario

The add-on conferencing scenario described in the following example applies to a network architecture involving the Oracle Communications Session Border Controller and a media server that is located on a different network from the other conference participants. In this scenario, the Oracle Communications Session Border Controller resides on a standalone network that connects two additional, separate networks.

Some network architectures have a media server on a different network from the one on which the phones reside. In this scenario, all requests and/or responses going from the phones (Phone A, Phone B, or Phone C) to Media Server D and vice versa are translated according to their corresponding SIP-NAT. All headers subjected to NAT are encoded and decoded properly as they traverse the Oracle Communications Session Border Controller, except for the Contact header. This exception occurs because the SIP process on the Oracle Communications Session Border Controller runs as a SIP B2BUA and not as a SIP proxy.

The SIP B2BUA re-originates the Contact headers of the User Agents (UAs) participating in SIP sessions with local Contact headers to make sure that they receive all future in-dialog requests. For an in-dialog request, the B2BUA can identify the dialog and find the Contact URI of the other leg of the call.

The Oracle Communications Session Border Controller add-on conferencing feature applies to situations when the Contact URI is used in another dialog. In such a case, the SIP B2BUA will not be able to find the correct dialog that retrieves the correct Contact URI of the other leg if it needs to replace the Contact URI.

Using the SIP add-on conferencing, the SIP B2BUA on the Oracle Communications Session Border Controller can map the Contact headers it receives to the Contact headers it creates. It can also convert the Refer-To URI to the correct value required for forwarding the REFER request.

SIP B2BUA Functionality

This section describes the role of the Oracle Communications Session Border Controller's SIP B2BUA in the add-on conferencing scenario that requires Contact header mapping for the Refer-To header.

When the Oracle Communications Session Border Controller starts up, the SIP B2BUA reads and parses the list of options in the SIP configuration. If the refer to uri prefix is an appropriate value (it is not an empty string), the Oracle Communications Session Border Controller will have a text prefix value the media server can use to denote a conference ID in its Contact header. With this information, the SIP B2BUA sets up a Contact header mapping.

You configure the Oracle Communications Session Border Controller to enable Contact header mapping for the Refer-To header by editing the SIP config options parameter. The SIP B2BUA on the Oracle Communications Session Border Controller can then map the Contact headers it receives to the Contact headers it creates.

Contact Header Processing

The Contact header mapping matches a Contact header that contains the refer to URI prefix to the corresponding Contact header that the Oracle Communications Session Border Controller's SIP B2BUA re-originates. Contact headers that do not contain the refer to URI prefix are not mapped (so that performance of the Oracle Communications Session Border Controller is minimally affected).

Only the Contact header in an INVITE request and its 200 OK response are checked for the refer to URI prefix and added to the Contact header mapping. Contact headers appearing in other SIP requests/responses are not checked.

Target Mapping and Conferences

If the Oracle Communications Session Border Controller is configured to enable Contact header mapping for the Refer-To header, then Contact header target maps are established for each individual call. The Oracle Communications Session Border Controller's SIP B2BUA uses these maps to allow the media server to connect the conference initiator with the conferenced-in parties.

Prior to terminating the call (hanging up), the conference initiator can contact other parties and invite those additional parties to join the conference. These other parties can join the existing conference because the target mapping for the conference is still in effect on the Oracle Communications Session Border Controller.

Once the conference initiator hangs up, the Oracle Communications Session Border Controller discards the mapping from the conference.

Refer-To Header Processing

When a Refer-To header is present in a REFER request that arrives at the SIP B2BUA after the incoming request is properly translated according to its SIP-NAT, the SIP B2BUA follows these steps:

1. The SIP B2BUA parses the Refer-To URI.

2. If the user part of the Refer-To URI contains the refer to URI prefix, the SIP B2BUA searches the Contact header mapping for a match of the user part of the URI.

   If the user part of the Refer-To URI does not contain the refer to URI prefix, the SIP B2BUA leaves the existing Refer-To URI unchanged.

3. If the user part of the Refer-To URI contains the refer to URI prefix and a match of the Refer-To URI is found, the SIP B2BUA replaces the existing Refer-To URI with the URI of the corresponding Contact URI stored in the matched record. This replacement enables the NAT function to properly decode the replacement URI and change it back to the form originally received by the Oracle Communications Session Border Controller. As a result, the correct conference ID is restored in the Refer-To header prior to the request being sent to its next hop.

   If the user part of the Refer-To URI contains the refer to URI prefix but a matched URI cannot be found, the SIP B2BUA will leave the existing Refer-To URI unchanged and will write a WARNING level log message to record the failure.

Add-on Conferencing Configuration

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   From this point, you can configure SIP config parameters. To view all SIP config parameters, enter a **?** at the system prompt.

4. Type **options** followed by a Space.
5. After the Space, type the add-on conferencing information in the following format:

   ```
   options refer-to-uri-prefix=”conf=”
   ```

   For example:

   ```
   ORACLE(sip-config)# options refer-to-uri-prefix=”conf”
   ```

6. Press Enter.

SIP REFER Method Call Transfer

The Oracle Communications Session Border Controller automatically converts a received REFER method into an INVITE method, thus allowing the Oracle Communications Session Border Controller to transfer a call without having to proxy the REFER back to the other UA.

This function can be configured for a specified realm or session agent. When both elements have the SIP REFER method call transfer functionality configured, the session-agent configuration takes precedence over realm-config. Furthermore, this function only works from a realm-config when the REFER request is from an end point that is not configured as a session-agent.

The Oracle Communications Session Border Controller has a configuration parameter giving it the ability to provision the handling of REFER methods as call transfers. The parameter is called refer-call-transfer. When this feature is enabled, the Oracle Communications Session Border Controller creates an INVITE message whenever it receives a REFER. The Oracle Communications Session Border Controller sends this INVITE message to the address in the Refer-To header. Included in the INVITE message is all the unmodified information contained in the REFER message. The previously negotiated codec is also still used in the new INVITE message. NOTIFY and BYE messages are sent to the UA upon call transfer completion.

If a REFER method is received containing no Referred-By header, the Oracle Communications Session Border Controller adds one, allowing the Oracle Communications Session Border Controller to support all call agent screen applications.

In addition, the SIP REFER method call transfer feature supports the following:

- Both unattended and attended call transfers
- Both successful and unsuccessful call transfers
- Early media from the Referred-To party to the transferee
- REFER method transfer from different sources within the destination realm
- The REFER event package as defined in RFC 3515. This applies for situations where multiple REFER methods are used within a single dialog.
- Third party initiated REFER method signalling the transfer of a call by associating the REFER method to the dialogue via the REFER TargetDialog.
- The Referred-To party can be both in a different realm (and thus a different steering pool) from the referrer, and in the same realm
- The associated latching should not prohibit the Referred-To party from being latched to while the referee is still sending media.

Unsuccessful Transfer Scenarios

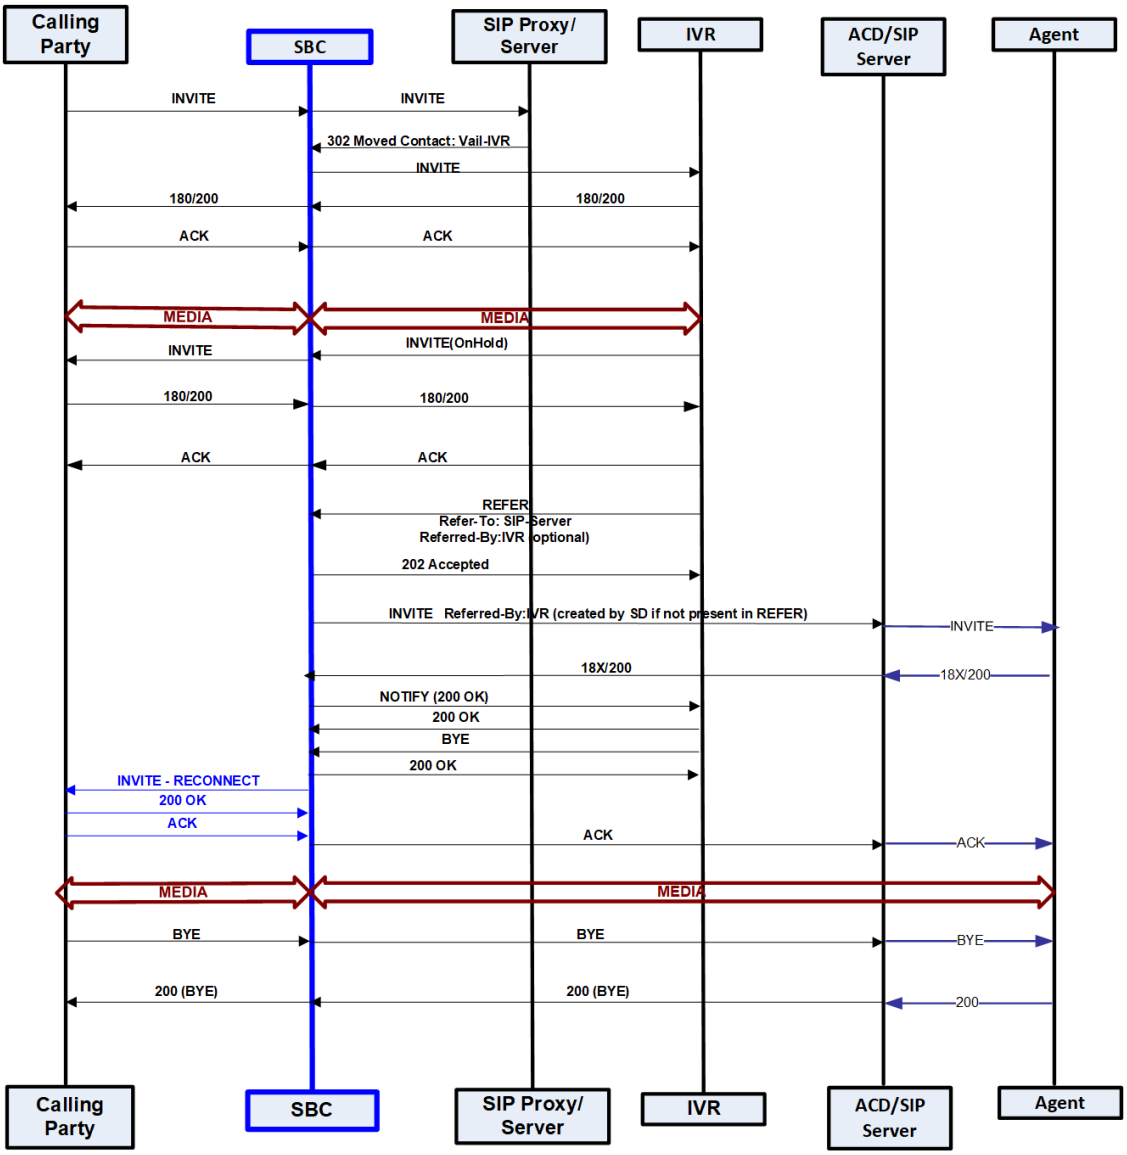
The Oracle Communications Session Border Controller does not successfully handle the following failed, unusual, and unexpected transfer scenarios:

- The new INVITE to the Referred-To party gets challenged, the Oracle Communications Session Border Controller does not answer the challenge. It is treated with the 401/407 response just as any other unsuccessful final response.
- The header of the REFER message contains a method other than INVITE or contains URI-parameters or embedded headers not supported by the Oracle Communications Session Border Controller.
- The Oracle Communications Session Border Controller shall allow the Referred-To URI that happens to resolve to the same next-hop as the original INVITE went to, to do so.
- The Oracle Communications Session Border Controller ignores any MIME attachment(s) within a REFER method.
- The Oracle Communications Session Border Controller recurses (when configured to do so) when the new INVITE sent to the Referred-To party receives a 3xx response.

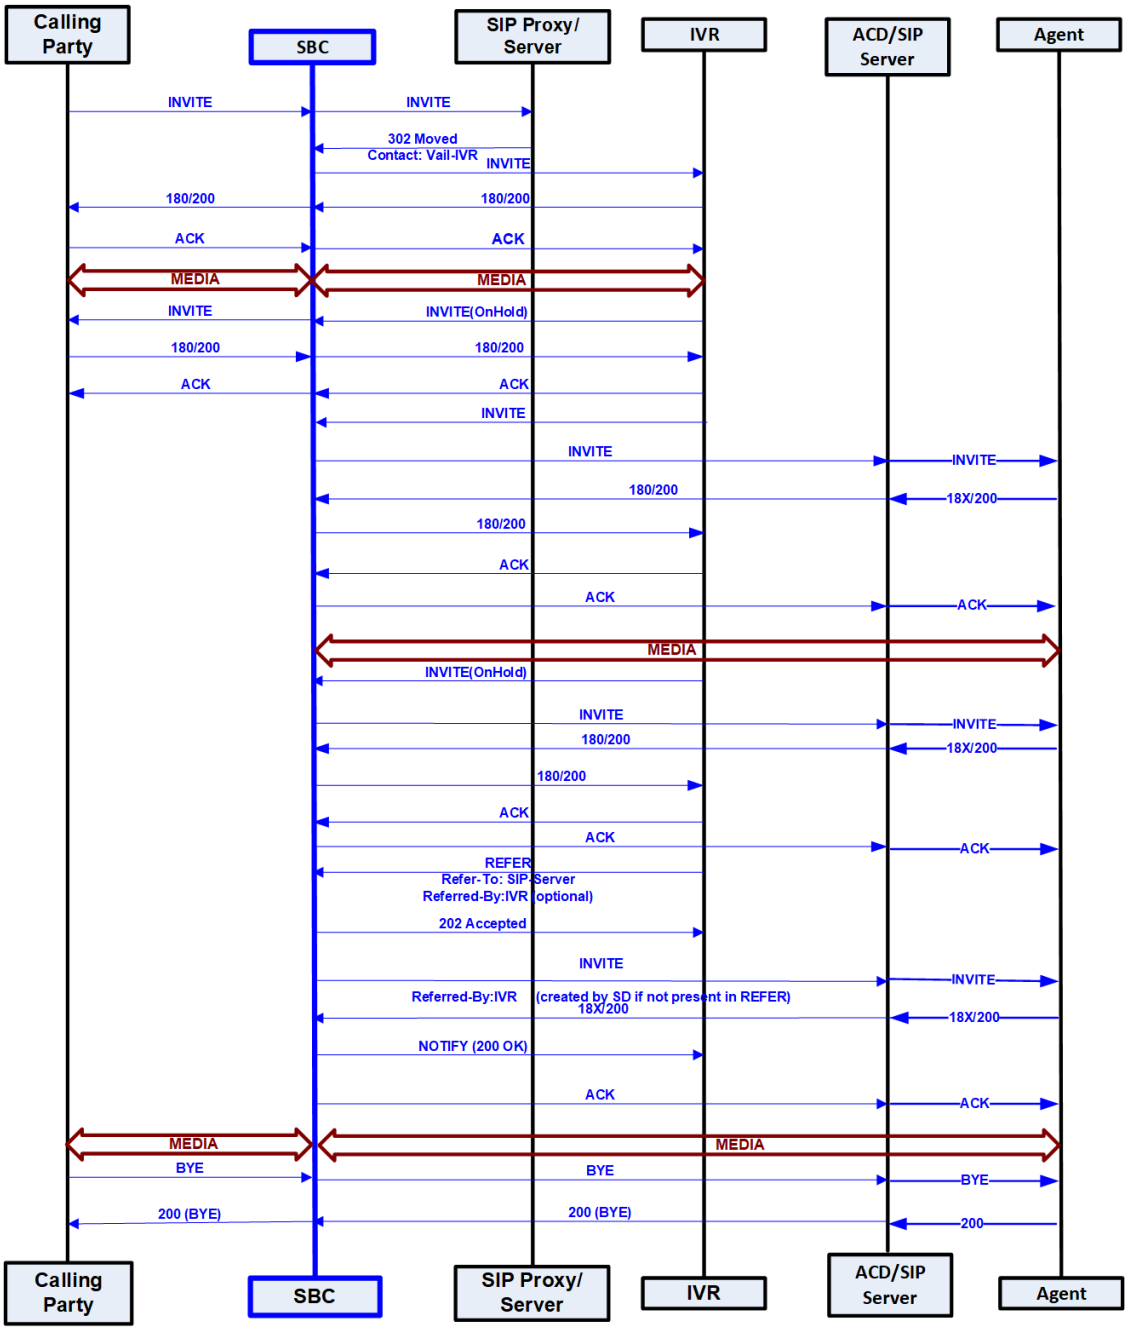
- The transferee indicated support for 100rel, and the original two parties agreed on using it, yet the Referred-To party does not support it.
- The original parties negotiated SRTP keys.
- The original parties agreed on a codec using a dynamic payload type, and the Referred-To party happens to use a different dynamic payload number for that codec.

Call Flows

The following is an example call flow for an unattended call transfer:



The following is an example call flow of an attended call transfer:



SIP REFER Method Configuration

To enable SIP REFER method call transfer in the realm-config:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. **refer-call-transfer**—Set to **enabled** to enable the refer call transfer feature. The default for this parameter is **disabled**.
5. Save and activate your configuration.

   To enable SIP REFER method call transfer in the session-agent:

6. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

7. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

8. Type **session-agent** and press Enter.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

9. **refer-call-transfer**—Set to **enabled** to enable the refer call transfer feature. The default for this parameter is **disabled**.
10. Save and activate your configuration.

REFER-Initiated Call Transfer

The Oracle Communications Session Border Controller supportes REFER-initiated call transfer either by proxying the REFER to the other User Agent in the dialog, or by terminating the received REFER and issuing a new INVITE to the referred party. These static alternate operational modes can be configured for specific SIP interfaces, realms, or session agents.

An additional operational mode can determine on a call-by-call basis whether to proxy the REFER to the next hop, or terminate the REFER and issue an INVITE in its stead.

The configuration parameter **dyn-refer-term**, and **refer-call-transfer** parameter specify call transfer modes.

With the **refer-call-transfer** parameter set to **disabled** (the default), all received REFERs are simply proxied to the peer User Agent.

With the **refer-call-transfer** parameter set to **enabled**, the Oracle Communications Session Border Controller terminates all REFERs, generates a new INVITE, and sends the INVITE to the address in the Refer-To header.

With the **refer-call-transfer** parameter set to **dynamic**, the Oracle Communications Session Border Controller determines REFER handling on a call-by-call basis as follows:

1. Check the **refer-call-transfer** value for the session agent from which the REFER was received, or for ingress realm (the realm that received the REFER).

   If the value is disabled, proxy the REFER to the peer User Agent, to complete REFER processing.

   If the value is enabled, terminate the REFER and issue an new INVITE to the referred party, to complete REFER processing.

   If the value is dynamic, identify the next hop egress realm.

2. Check the **dyn-refer-term** value for the next hop egress realm.

   If the **dyn-refer-term** value is disabled (the default), proxy the REFER to the next hop to complete REFER processing.

   If the **dyn-refer-term** value is enabled, terminate the REFER and issue an new INVITE to the referred party to complete REFER processing.

Supported Scenarios

In the basic scenario for REFER initiated call transfer, a call is established between two User Agents (Alice and Bob). User Agent Bob then sends a REFER request to transfer the call to a third User Agent Eva. With dynamic call-transfer enabled, the Oracle Communications Session Border Controller (SBC) prevents the REFER from being sent to Alice and generates the INVITE to Eva.

If the INVITE to Eva succeeds, the SBC sends a re-INVITE to Alice modifying the SIP session as described in Section 14 of RFC 3261, *SIP: Session Initiation Protocol*. At this point the SBC cancels the original dialog between the SBC and Bob.

If the INVITE to Eva fails, call disposition depends on whether or not Bob issued a BYE after the REFER call transfer. If the Oracle Communications Session Border Controller did receive a BYE from Bob (for instance, a blind transfer), it proxies the BYE to A. Otherwise, the SBC retains the original SIP session and media session, thus allowing Bob to re-establish the call with Alice by sending a re-INVITE. In this case, the SBC sets a timer (32 seconds), after which a BYE will be sent.

If a REFER method is received containing no Referred-By header, the SBC adds one, allowing the SBC to support all call agent screen applications.

In addition, the SIP REFER method call transfer feature supports the following:

- Both unattended and attended call transfers
- Both successful and unsuccessful call transfers
- Early media from the Referred-To party to the transferee
- REFER method transfer from different sources within the destination realm
- The REFER event package as defined in RFC 3515. This applies for situations where multiple REFER methods are used within a single dialog.
- Third party initiated REFER method signalling the transfer of a call by associating the REFER method to the dialogue via the REFER TargetDialog.
- The Referred-To party can be both in a different realm (and thus a different steering pool) from the referrer, and in the same realm

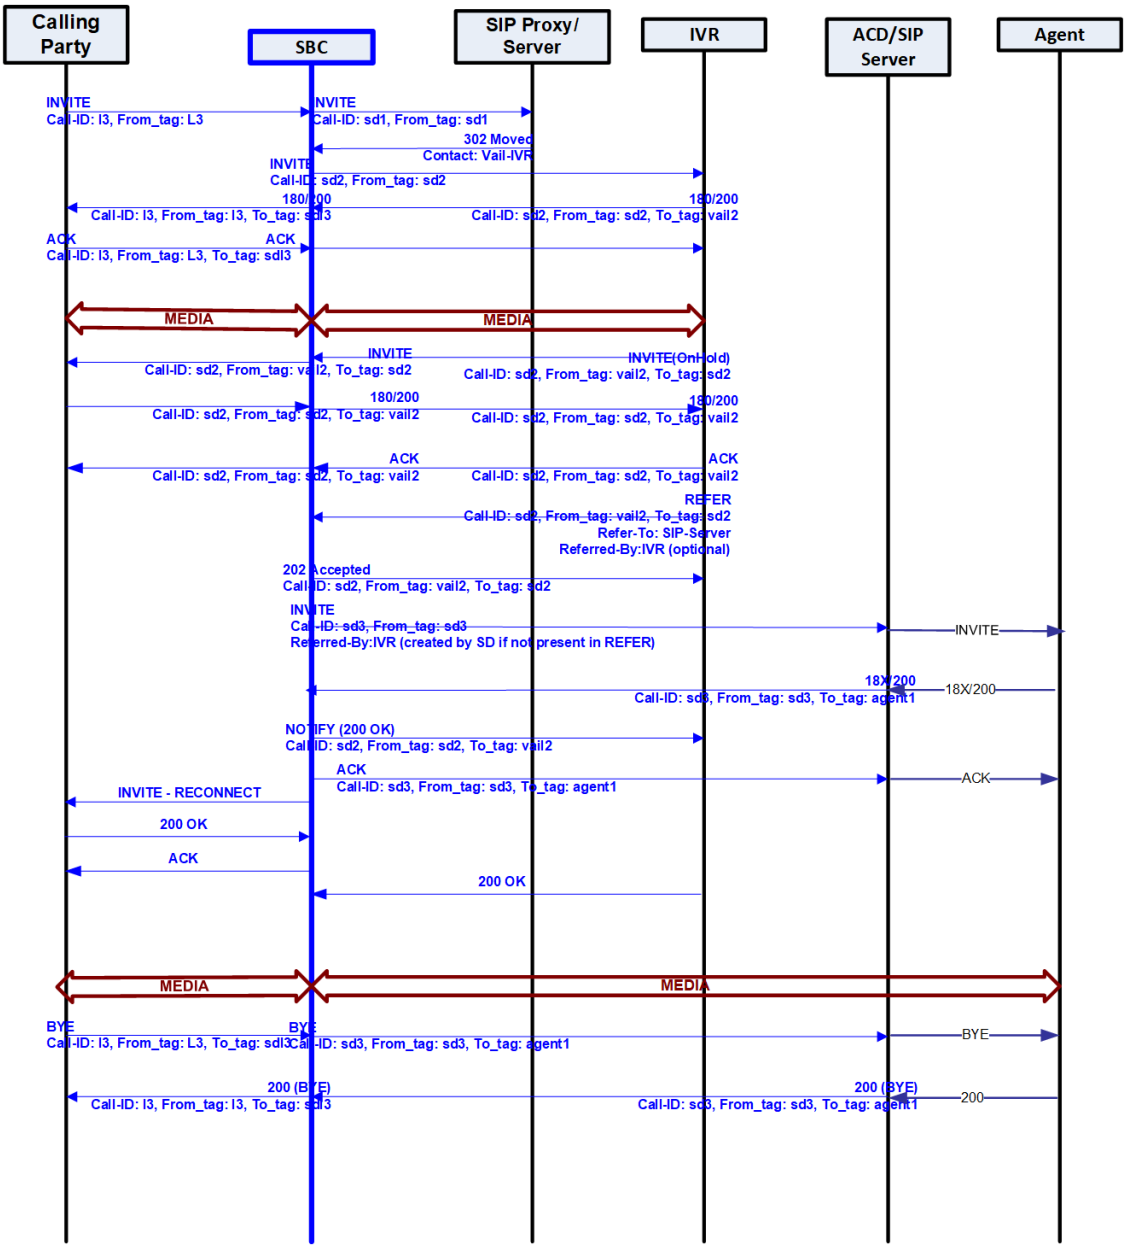
- The associated latching should not prohibit the Referred-To party from being latched to while the referee is still sending media.

The SBC does not successfully handle the following anomalous transfer scenarios:

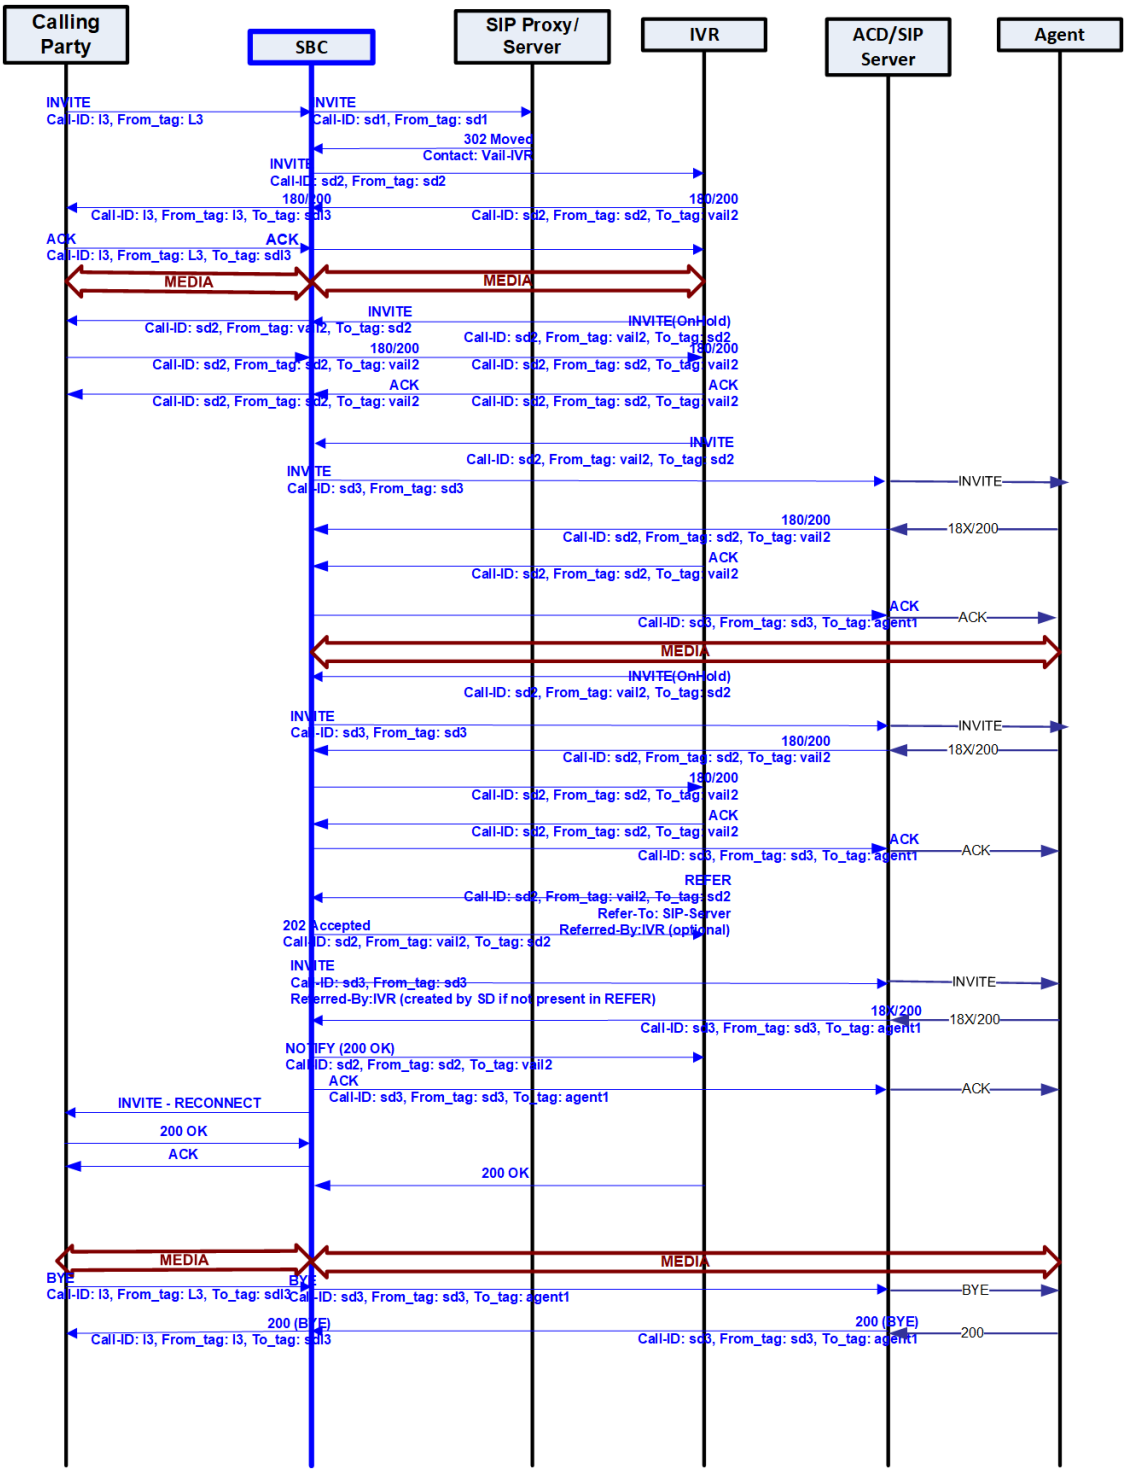
- The new INVITE to the Referred-To party gets challenged — the SBC does not answer the challenge. It is treated with the 401/407 response just as any other unsuccessful final response.
- The header of the REFER message contains a method other than INVITE or contains URI-parameters or embedded headers not supported by the SBC.
- The SBC shall allow the Referred-To URI that happens to resolve to the same next-hop as the original INVITE went to, to do so.
- The SBC ignores any MIME attachment(s) within a REFER method.
- The SBC recurses (when configured to do so) when the new INVITE sent to the Referred-To party receives a 3xx response.
- The transferee indicated support for 100rel, and the original two parties agreed on using it, yet the Referred-To party does not support it.
- The original parties negotiated SRTP keys.

Call Flows

The following is an example call flow for an unattended call transfer:



The following is an example call flow of an attended call transfer:



REFER Source Routing

If, after the conclusion of static or dynamic REFER handling, the REFER is terminated and a new INVITE issued, users now can specify a policy lookup behavior based upon either the source realm of the calling party (the INVITE originator), or the source realm of the referring party (the REFER originator).

Behavior is controlled by a new **refer-src-routing** parameter in the **sip-config** configuration element.

disabled, the default value, specifies that the Oracle Communications Session Border Controller performs a policy lookup based on the source realm of the calling party.

enabled specifies that the Oracle Communications Session Border Controller performs a policy lookup based on the source realm of the referring party. Note: Enable refer-src-routing when refer-call-transfer is set to dynamic.

REFER Source Routing Configuration

To enable realm-based REFER method call transfer:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. **refer-call-transfer** — Retain the default (**disabled**) to proxy all REFERs to the next hop. Use **enabled** to terminate all REFERs and issue a new INVITE. Use **dynamic** to specify REFER handling on a call-by-call basis, as determined by the value of the **dyn-refer-term** parameter.
5. **dyn-refer-term** (meaningful only when **refer-call-transfer** is set to dynamic) — Retain the default (**disabled**) to terminate the REFER and issue a new INVITE. Use **enabled** to proxy the REFER to the next hop.
6. Save and activate your configuration.

   To enable session-agent-based REFER method call transfer:

7. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

8. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

9. Type **session-agent** and press Enter.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

10. **refer-call-transfer** — Retain the default (**disabled**) to proxy all REFERs to the next hop. Use **enabled** to terminate all REFERs and issue a new INVITE. Use **dynamic** to specify REFER handling on a call-by-call basis, as determined by the value of the **dyn-refer-term** parameter.
11. Save and activate your configuration.

    To specify policy lookup for a newly generated INVITE:
12. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

13. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

14. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

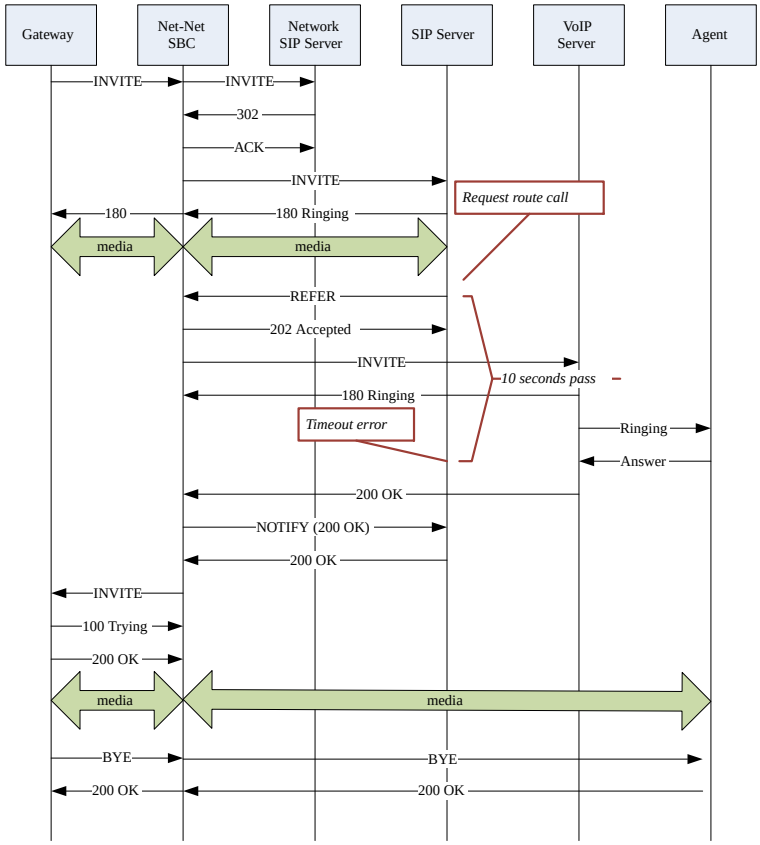
15. **refer-src-routing** — Retain the default (**disabled**) to perform a policy lookup based upon the source realm of the calling party (the issuer of the original INVITE). Use enabled to perform a policy lookup based upon the source realm of the referring party (the issuer of the REFER).
16. Save and activate your configuration.

180 & 100 NOTIFY in REFER Call Transfers

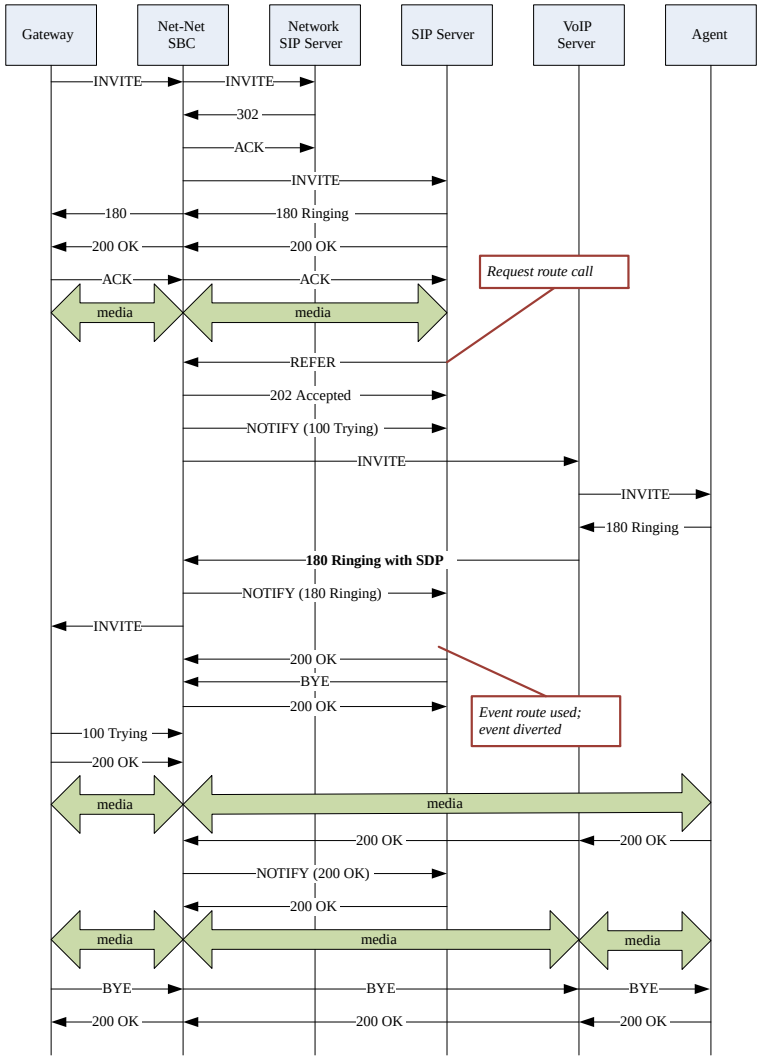
When you configure your Oracle Communications Session Border Controller to support REFER call transfers, you can enable it to send a NOTIFY message after it has sent either a 202 Accepted or sent a 180 Ringing message. If your network contains elements that comply with RFC 5589, and so expect the NOTIFY message after the 202 Accepted and each provisional 180 Ringing, you want to set the **refer-notify-provisional** to either **initial** or **all**, according to your needs.

Without this parameter changed from its default (**none**), the Oracle Communications Session Border Controller does not return send the NOTIFY until it receives the 200 OK response from the agent being called. If the time between the REFER and the NOTIFY exceeds time limits, this sequencing can cause the Oracle Communications Session Border Controller's NOTIFY to go undetected by devices compliant with RFC 5589. Failures during the routing process can result.

You can see how a sample call flow works without setting the **refer-notify-provisional** parameter.



When you compare the call flow above to the one depicting the scenario when the Oracle Communications Session Border Controller has the **refer-notify-provisional** changed from its default, you can see that the Oracle Communications Session Border Controller now response with a NOTIFY in response to the 202 Accepted and it sends another after the 180 Ringing.This causes the event to be diverted successfully.



Sample Messages

In compliance with RFC 5589, the NOTIFY message with 100 Trying as the message body looks like the sample below. Note that the expires value in the subscription state header is

populated with a value that equals 2* TIMER C, where the default value of TIMER C is 180000 milliseconds.

```
NOTIFY sips:4889445d8kjtk3@atlanta.example.com;gr=723jd2d SIP/2.0
Via: SIP/2.0/TLS 192.0.2.4;branch=z9hG4bKnas432
Max-Forwards: 70
To: <sips:transferor@atlanta.example.com>;tag=1928301774
From: <sips:3ld812adkjw@biloxi.example.com;gr=3413kj2ha>;tag=a6c85cf
Call-ID: a84b4c76e66710
CSeq: 73 NOTIFY
Contact: <sips:3ld812adkjw@biloxi.example.com;gr=3413kj2ha>
Allow: INVITE, ACK, CANCEL, OPTIONS, BYE, REFER, NOTIFY
Supported: replaces, tdialog
Event: refer
Subscription-State: active;expires=360
Content-Type: message/sipfrag
Content-Length: ...
SIP/2.0 100 Trying
```

Also in compliance with RFC 5589, the NOTIFY message with 180 Ringing as the message body looks like the sample below. Again, the expires value in the subscription state header is populated with a value that equals 2* TIMER C, where the default value of TIMER C is 180000 milliseconds.

```
NOTIFY sips:4889445d8kjtk3@atlanta.example.com;gr=723jd2d SIP/2.0
Via: SIP/2.0/TLS 192.0.2.4;branch=z9hG4bKnas432
Max-Forwards: 70
To: <sips:transferor@atlanta.example.com>;tag=1928301774
From: <sips:3ld812adkjw@biloxi.example.com;gr=3413kj2ha>;tag=a6c85cf
Call-ID: a84b4c76e66710
CSeq: 73 NOTIFY
Contact: <sips:3ld812adkjw@biloxi.example.com;gr=3413kj2ha>
Allow: INVITE, ACK, CANCEL, OPTIONS, BYE, REFER, NOTIFY
Supported: replaces, tdialog
Event: refer
Subscription-State: active;expires=360
Content-Type: message/sipfrag
Content-Length: ...
SIP/2.0 180 Ringing
```

Also in compliance with RFC 5589, the NOTIFY message with 200 OK as the message body looks like the sample below.

```
NOTIFY sips:4889445d8kjtk3@atlanta.example.com;gr=723jd2d SIP/2.0
Via: SIP/2.0/TLS 192.0.2.4;branch=z9hG4bKnas432
Max-Forwards: 70
To: <sips:transferor@atlanta.example.com>;tag=1928301774
From: <sips:3ld812adkjw@biloxi.example.com;gr=3413kj2ha>;tag=a6c85cf
Call-ID: a84b4c76e66710
CSeq: 74 NOTIFY
Contact: <sips:3ld812adkjw@biloxi.example.com;gr=3413kj2ha>
Allow: INVITE, ACK, CANCEL, OPTIONS, BYE, REFER, NOTIFY
Supported: replaces, tdialog
Event: refer
Subscription-State: terminated;reason=noresource
```

```
Content-Type: message/sipfrag
Content-Length: ...
SIP/2.0 200 OK
```

180 and 100 NOTIFY Configuration

You can apply the **refer-notify-provisional** setting to realms or to session agents. This section shows you how to apply the setting for a realm; the same steps and definitions apply to session agents.

If you do not want to insert NOTIFY messages into the exchanges that support REFER call transfers, you can leave the **refer-notify-provisional** set to **none**. This means that the Oracle Communications Session Border Controller will send only the final result NOTIFY message. Otherwise, you want to choose one of the two settings described in the instructions below.

To enable 100 and 180 NOTIFY messages in REFER call transfers:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. **refer-notify-provisional**—Choose from one of the following settings, where the Oracle Communications Session Border Controller:
   - **initial**—Sends an immediate 100 Trying NOTIFY, and the final result NOTIFY
   - **all**—Sends an immediate 100 Trying NOTIFY, plus a notify for each non-100 provisional messages the Oracle Communications Session Border Controller receives; and the final result NOTIFY

     ```
     ORACLE(realm-config)# refer-notify-provisional all
     ```

5. Save your work.

SIP REFER Re-Invite for Call Leg SDP Renegotiation

Enhancing the original implementation of SIP REFER termination introduced in Release S-C6.0.0, this change to Oracle Communications Session Border Controller behavior allows for SDP renegotiation between both parties of a transferred call.

Scenario

In a call transfer initiated by SIP REFER, a call is established between two user agents, UA-A and UA-B. UA-B then sends a REFER request to transfer the call to UA-C. The challenge is

that UA-A and UA-B had already been communicating using mutually agreed-on codec, while UA-C might not be using an entirely different codec.

To solve this problem, the Oracle Communications Session Border Controller causes a new SIP session and new media session to be created between UA-A and UA-C. The Oracle Communications Session Border Controller removes any resources allocated for use between UA-A and UA-B, and then severs its connection with UA-B. The session between UA-A and UA-C continues.

Alterations to SIP REFER

The Oracle Communications Session Border Controller sends re-INVITE with the negotiated SDP to the user agent for which the Oracle Communications Session Border Controller performs the call transfer.

More about SIP REFER

The Oracle Communications Session Border Controller makes the new call between Party A and Party C appear as though A were participating to allow the Oracle Communications Session Border Controller's natural media setup occur in the same way as if the REFER had actually been sent to A and A had sent a new INVITE.

When the Oracle Communications Session Border Controller receives a REFER request and determines it needs to handle it locally, it creates a new INVITE made to look like one from Party A. And the Oracle Communications Session Border Controller actually processes this INVITE as though it were from Party A. As a result, new SIP and new media sessions are created with new media ports for Parties A and C. When the INVITE to Party C receives a final response, the Oracle Communications Session Border Controller sends the result to Party B using a SIP NOTIFY request.

If the new INVITE succeeds, the old context and flows disappear and the new context and flows for the A-to-C connection remain in place. Because of the new media ports, the Oracle Communications Session Border Controller sends a re-INVITE to Party A, directing media to the new port and forwarded to Party C. Next, the original dialog with Party B needs to be terminated; if the Oracle Communications Session Border Controller has not received Party B's BYE, it will wait five second and then send Party B a BYE.

If the INVITE to Party C fails, the new SIP and media sessions are deleted as are the new context and flows. The Oracle Communications Session Border Controller treats Party A differently depending on whether or not a BYE was received from Party B. If a BYE was received from Party B. then the Oracle Communications Session Border Controller sends a BYE to Party A. If not, the original SIP and media sessions as well as the context and media flows remain in tact. This way, Party B can re-establish the call with Party A using a re-INVITE. In the case, the Oracle Communications Session Border Controller waits 32 second before sending a BYE.

If the Oracle Communications Session Border Controller receives a BYE while processing the INVITE to Party C, it sends a CANCEL message to Party C in an attempt to cancel the call. The BYE passes to Party B, and associated sessions, contexts, and flows terminate normally. Still, the Oracle Communications Session Border Controller waits for the final response to the INVITE to Party C. If the Oracle Communications Session Border Controller receives a successful response, it sends an ACK and then a BYE to terminate the abandoned call. If the Oracle Communications Session Border Controller receives an unsuccessful final response, it uses its normal response error handling processes. In either of these last two cases, all sessions, context, and flow are deleted.

Please note that the Oracle Communications Session Border Controller does not remove the a=sendonly attribute from the SDP it sends to Party A during the A-to-B call, and extra media ports are not allocated for the original media session.

SIP REFER with Replaces

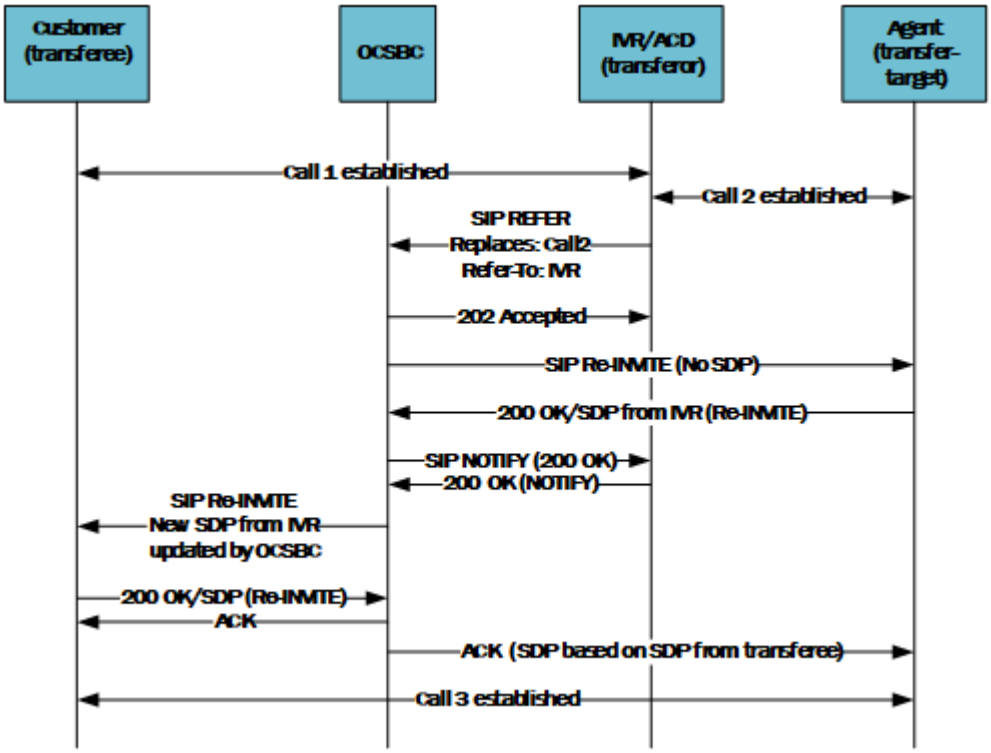
To support enterprise and call center applications, the Oracle Communications Session Border Controller (SBC) provides the ability for one party participating in a three-way call to request direct connectivity between the other two parties and to leave the call silently when that connectivity is established. SIP supports this function using the Replaces header in a REFER message, also known as REFER with Replaces.

A typical example of a refer with replaces flow includes three parties:

- Transferee—A customer who calls into a company's service department.
- Transferor—The service department's IVR/ACD, which manages the transfer.
- Transfer-Target—The agent who ultimately talks with the customer.

To support the SIP REFER, the SBC first establishes calls from the transferee to the transferor (Call 1) and from the transferor to the transfer-target (Call 2). After establishing these calls, the SBC receives a SIP REFER from the transferor and manages the SIP and SDP signaling to replace Call 2 with a new call, Call 3, which is between the transferor and the transfer-target.

As shown below, call replacement consists of SIP ReINVITEs and associated messaging to establish flows for Call 3. This setup is subject to timing, compatibility and other hurdles that could cause the REFER to fail. Assuming successful setup, the SBC subsequently issues BYEs for Call 1 and Call 2 and supports any further signaling for Call 3.



The common high-level sequence of a REFER with REPLACES application includes:

1. The transferee calls a customer service line and reaches, via the SBC, an Interactive Voice Response system/Automatic Call Distribution (IVR/ACD) system. In some architectures, these are two separate elements, but can always be understood as the transferor.

2. Based on the customer's selection from the menu of options, the IVR/ACD contacts an agent, the transfer-target, via the SBC.
3. Since the ultimate goal is for the IVR/ACD to drop out of the path, it sends a REFER with Replaces to the SBC. This message indicates the SBC should replace the IVR/ACD endpoint in the call leg with the transfer-target's endpoint.
4. The SBC processes the REFER with Replaces, issuing ReINVITEs to the transferee with the agent's parameters.
5. There are multiple significant behaviors that the SBC performs after the Re-INVITE, including:
   - Retains the original sessions and dialogs intact, supporting any subsequent REFER attempt by the transferor.
   - Manages SDP such that, in the case of attended transfer, it:
     – Sends a Re-INVITE without SDP to the transfer-target.
     – Sends Re-INVITE with updated SDP to transferee, based on 200OK SDP received from the transfer-target.
     – Sends ACK with new SDP to transfer-target, based on 200OK SDP received from the transferee. (This behavior can be changed for backward compatibility.)
   - Waits for a final success response to the Re-INVITE retaining both the transferee-to-transferor and transferor-to-transfer target call legs until it receives indications of success or failure. If there is a failure response, the SBC sends the failure response to the transferor using a SIP NOTIFY, relying on it to either issue another REFER or release the calls.

     > **Note:**
     >
     > the SBC only handles 4xx, 5xx and 6xx error responses for the REFER ReINVITE towards the Transfer Target.

     An example of such a failure is the receipt of a Re-INVITE from the transfer-target at the same time the SBC sends a Re-INVITE to the transfer-target. To manage this sequence, the SBC accepts the ensuing 491 Request Pending message from the transfer-target and:
     – Sends a SIP NOTIFY to the transferor indicating the transfer failed due to a 491 Request Pending,
     – Retains both calls, then
     – Waits for the transferor to issue a new SIP REFER in an attempt to complete the transfer.
   - If it receives a BYE from the transferee after it has sent a Re-INVITE (with SDP) to the transfer-target, the SBC sends 2 BYEs to the transferor, one for the transferee to transferor leg and one for the transferor to transfer-target leg, and also sends 1 BYE to the transfer-target for the transferor to transfer-target leg.
6. The IVR/ACD drops out of the media path once the bridged call between the transferee and the transfer-target is established.

Direct media connectivity between endpoints must be possible in order for the REFER with Replaces to be carried out properly.

For example, if both endpoints (such as the customer and agent from the example above) are behind the same firewall, direct media connectivity should be possible. However, if one endpoint is behind a firewall and the other is not, then direct media connectivity may not be possible.

Note also that the SBC complies with RFC 3264 by retaining identical o= line in the SDP when issuing an offer that modifies the session with the exception that it increments the sess-version value by one. This helps maintain SDP consistency across the dialog.

For licensing capacity purposes, note that a bridged session counts as a single call. Note also that the SBC supports attended call transfers during HA switchover.

Sending Offerless Responses to Re-Invites

By default, the SBC sends SDP in responses to Re-INVITEs to the transfer-target. This supports changes to the SDP during attended transfers. If desired, you can configure the SBC to send offer-less responses to the Re-INVITE to the transfer target. You configure this by enabling the **refer-reinvite-no-sdp** parameter on the **sip-config**. This is a global configuration

SIP REFER with Replaces Configuration

You enable SIP REFER with Replaces handling either in the realm configuration or in the session agent configuration. This section provides the steps to apply this option to a session agent. The syntax for applying this option to a realm is the same.

To enable sending ReINVITES to a referred agent on an existing session/dialog:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **session-agent** and press Enter.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

   If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **options**—Set the options parameter by typing options, a Space, and then the option name **refer-reinvite**. Then press Enter.

   ```
   ORACLE(session-agent)# options +refer-reinvite
   ```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

SDP Handling for Compatibility Configuration

You enable **refer-reinvite-no-sdp** parameter in the **sip-config** to prevent the system from including SDP in the response to the Re-INVITE it receives from the transfer-target.

To enable this parameter:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   You must select the **sip-config** using the ACLI **select** command to edit it.

4. **refer-reinvite-no-sdp**—Enable this parameter to cause the system to globally exclude SDP from re-INVITE responses sent to the transfer target.

   ```
   ORACLE(sip-config)#refer-reinvite-no-sdp enabled
   ```

SIP REFER-to-BYE

The Oracle Communications Session Border Controller's SIP REFER-to-BYE capability addresses situations when other network elements do not support the REFER method but do offer blind transfer in a SIP BYE request. The target number is encoded in a Reason header of the BYE request. In such cases, the Oracle Communications Session Border Controller terminates the REFER and passes the Refer-To number in a Reason header of the BYE.

You configure both SIP interfaces and SIP session agents with the refer-to-bye option to use this function:

- SIP interface—You add this ability to SIP interfaces facing the SIP elements that need to receive a BYE instead of a REFER. This setting only applies when the next hop is not a session agent.
- SIP session agent—The SIP session agent takes precedence over the SIP interface. You add this ability to SIP session agents that need to receive a BYE instead of a REFER. If the next hop SIP element—the remote target in the dialog—is a session agent, in other words, you need to configure the option for it. Note that when you use this option for SIP session agents, the SIP interface or realm on which the REFER is received takes precedence over the REFER-to-BYE capability.

When a REFER request arrives and the REFER-to-BYE capability applies, the Oracle Communications Session Border Controller responds to it with a 202 Accepted and sends a NOTIFY to terminate the implicit refer subscription. This NOTIFY contains a message/sipfrag body with SIP/2.0 200 OK. Upon receiving the response to this NOTIFY, the Oracle

Communications Session Border Controller sends a BYE with an added Reason header (encoded with the Refer-To number) to the other end.

The network element that does not accept REFERs takes the BYE with the Reason header and issues a new initial INVITE that initiates transfer, which the Oracle Communications Session Border Controller sees as starting a new and independent session.

SIP hold-refer-reinvite

When SIP hold-refer-reinvite is enabled for REFER with Replaces, the system queues the outgoing Invite populated from the received REFER based on the dialog state.

In a deployment where a call goes through the Oracle Communications Session Border Controller (SBC) before going to an Interactive Voice Response (IVR) server, the SBC proxies the intermediate reinvite that the IVR sends to the transfer target. If the intermediate reinvite is in either the pending state or the established state when the IVR initiates the transfer to the transfer target, the SBC terminates the call prematurely. The hold-refer-reinvite option allows the SBC to queue the Out Going INVITE from the received REFER request when the previously proxied reinvite request is in either the pending state or the established state. The result is a successful call.

Enable the SIP hold-refer-reinvite option from the ACLI command line or the Web GUI in Advanced mode.

Enable hold-refer-reinvite - ACLI

The SIP hold-refer-reinvite parameter for REFER with Replaces is a parameter that you enable to prevent premature call termination in a deployment where calls are proxied by the Oracle Communications Session Border Controller.

- Confirm that refer-reinvite is added to realm/SA/SipInterface options.
- Confirm that refer-call-transfer is enabled on realm/SA/SipInterface
- Confirm that the session agent on which you want to enable hold-refer-reinvite is configured.

To enable hold-refer-reinvite, select a configured session agent and enable the parameter on the selected agent.

1. Access the **session-agent** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# session-agent
ORACLE(session-agent)
```

2. Type **select**, and press ENTER.

   The system displays a numbered list of session-agents.

3. Type the number of the agent on which you want to enable hold-refer-invite, and press ENTER.
4. Type **hold-refer-reinvite enabled**, and press ENTER.
5. Type **done** to save the configuration.

- Enable the refer-hold-reinvite parameter in the realm configuration.
- Enable the refer-hold-reinvite parameter in the session agent configuration.

SIP Roaming

This section explains how to configure SIP roaming. SIP roaming lets subscribers move from one active SIP device to another (at the same site or multiple sites) and retain service at the last registering device.

Overview

The Oracle Communications Session Border Controller supports multiple active registrations for the same user. The softswitch makes decisions regarding the current location of the user and the handling of requests from devices that are not currently identified as the user location. When there are multiple NATs, the Oracle Communications Session Border Controller is still required to let the softswitch be able to differentiate it.

The Oracle Communications Session Border Controller's SIP roaming ability supports the following features:

- Multiple active registrations from the same user can be cached, allowing subscribers to move from one active SIP device to another (at the same site or multiple sites) and still retain service at the last registering device. With the SIP roaming feature, one person, using multiple devices, can be contacted at all of the devices. These multiple devices (with their unique contact information) register to indicate that they are available for anyone that wants to contact that one person.
- The Oracle Communications Session Border Controller can also inform network devices (such as softswitches) of private SIP device IPv4 addresses (endpoints) and the public firewall address of the user location.

Process Overview

Caller 1 wants to contact Person A. Caller 1 sends a message to persona@acmepacket.com, but Person A has configured more than one SIP-enabled device to accept messages sent to that address. These devices have unique addresses of desk@10.0.0.4 and phone2@10.0.0.5. Person A has desk@10.0.0.4 and phone2@10.0.0.5 registered with the Oracle Communications Session Border Controller for anything addressed to persona@acmepacket.com.

With the SIP roaming feature, the Oracle Communications Session Border Controller accepts and stores both registrations for persona@acmepacket.com. That way, when someone wants to get in touch with Person A, the messages are sent to both devices (desk@10.0.0.4 and phone2@10.0.0.5) until Person A answers one of them. You do not need to configure your Oracle Communications Session Border Controller for this functionality; your Oracle Communications Session Border Controller automatically provides it.

Using Private IPv4 Addresses

In addition to supporting multiple registries, the Oracle Communications Session Border Controller (SBC) can also distinguish user locations by their private IPv4 address and the IPv4 address of the public firewall. Using this information, the SBC adds private endpoint and public firewall information to Contact headers.

For example, entering this information causes a Contact header that formerly appeared as the following:

```
Contact:<sip:027411620263.67.143.217>
```

to subsequently appear as the following:

```
Contact:<sip:027411620263.67.143.217;ep=192.168.1.10;fw=10.1.10.21>
```

The SBC SIP proxy reads this information and populates the contact-endpoint and contact-firewall fields with the appropriate values.

Example 1 With a NAT Firewall

The Oracle Communications Session Border Controller (SBC) SIP proxy is configured with the following changeable parameters:

- endpoint= IP address of the SIP UA
- useradd= IP address of the Firewall Public IP address or the source layer 3 IP address of Register message
- userport= IP address port number of the Firewall Public IP address or the source layer 3 IP address port of Register message
- SBC address=63.67.143.217
- firewall public address=10.1.10.21
- firewall public address port=10000
- SIP endpoint behind firewall=192.168.1.10

SIP message Contact header:

```
Contact:<sip:027411620263.67.143.217; endpoint=192.168.1.10;
useradd=10.1.10.21; userport=10000; transport=udp>
```

Example 2 Without a NAT Firewall

The Oracle Communications Session Border Controller SIP proxy is configured with the following changeable parameters:

- useradd= IP address of the SIP UA or the source layer 3 IP address of Register message
- userport= IP address port number of the SIP UA or the source layer 3 IP address port of Register message
- Oracle Communications Session Border Controller address=63.67.143.217
- SIP endpoint=192.168.1.10
- SIP endpoint IP address port=5060

SIP message Contact header:

```
Contact:<sip:027411620263.67.143.217; useradd=192.168.1.10; userport=5060;
transport=udp>
```

For SIP, the softswitch responsibility is that the URI SD put in the Contact of the REGISTER message should be reflected in the 200-OK response to the REGISTER request. The Contact header of the response should have an expires header parameter indicating the lifetime of the registration.

The following example shows a Oracle Communications Session Border Controller Send:

```
Contact: <sep: 027411620263.67.143.217 endpoint=192.168.1.10;
useradd=10.1.10.21; userport=10000>;
```

The following examples shows the softswitch Respond:

```
Contact: <sep: 027411620263.67.143.217 endpoint=192.168.1.10;
useradd=10.1.10.21; userport=10000>;  expires=360
```

The contact field for endpoint and firewall parameters only appear in the following:

- Contact header of a REGISTER request sent from the Oracle Communications Session Border Controller to the softswitch server
- Contact header of a REGISTER response sent from the softwitch server to the Oracle Communications Session Border Controller
- Request-URI of an initial INVITE sent from the UT CSA server to the Oracle Communications Session Border Controller

An active endpoint is deleted when it does not register within the registration-interval setting or receives a 401 Unauthorized.

SIP Roaming Configuration

You can configure the SIP configuration's options parameter to indicate that you want to use the private IP address of the SIP device that the user is using and/or the public firewall address that identifies the location of the device. If defined, these options will be added as parameters to all Contact headers.

You can identify the endpoint and/or firewall information using the following options:

- contact-endpoint=<value> where <value> is the endpoint address or label
- contact-firewall=<value> where <value> is the firewall address or label

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

From this point, you can configure SIP config parameters. To view all SIP config parameters, enter a **?** at the system prompt.

4. Type **options** followed by a Space.
5. After the Space, type the information for an endpoint or a firewall, or both:

```
contact-endpoint=”<label>
contact-firewall=”<label>
"contact-endpoint="<label>",contact-firewall="<label>""
```

6. Press Enter.

   For example, if you want your Oracle Communications Session Border Controller to add private endpoint and public firewall information to Contact headers, and you want to label this information as ep and fw, you would enter the following information in the ACLI.

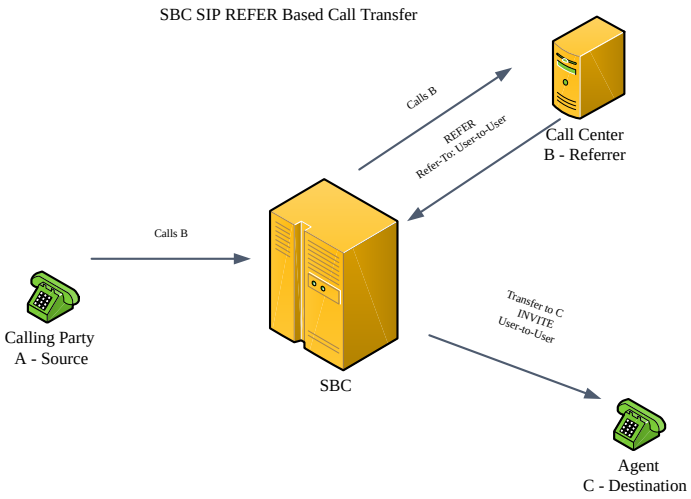
```
ORACLE(configure)# session-router
ORACLE(session-router)# sip-config
ORACLE(sip-config)# options "contact-endpoint="ep",contact-firewall="fw""
```

SIP REFER Call Transfer UUI Relay

The SIP REFER Call Transfer **User to User Information (UUI)** Relay option assists in the transfer of caller details through using the information in the "Refer-To" header in a new "User to User" header in the INVITE to the Referred-to party. This feature only works when the **refer-call-transfer** option is enabled on the realm or session agent where the REFER is received. This behavior change is enabled by default. This option can be used by a Call Center application to transfer a call with user information to an agent.

A new INVITE is sent with the information about the calling user to the agent by way of the "Refer-To" header using the **User to User Information.** The product variable needs to relay this UUI as a separate header in the INVITE message while transferring the call to the destination. In this scenario, the product terminates the REFER message having captured the UUI and then sends an INVITE with the UUI to the agent. This feature works only when the **refer-call-transfer** option is enabled on the Realm or Session Agent where REFER is received. By default this option is enabled and thus needs to be specifically disabled in the configuration if not wanted.

The following illustration shows the path of the call from the source to the destination by way of the product utilizing the **User to User Information** relay



SIP REFER UUI Relay

Refer-To Header

The Oracle Communications Session Border Controller supports the format of **User-to-User** in the "Refer-To" header in the REFER message. The following example shows the new text after the IP address and port in the second to last line.

```
REFER sip:7325550000@192.168.28.10:5060 SIP/2.0
Via: SIP/2.0/UDP 192.168.29.1:5060;branch=z9hG4bK-10659-1-4
From: 7325550000 <sip:7325550000@192.168.29.1:5060>;tag=1
To: 7321110000 <sip:732111000@192.168.28.19:5060>;tag=1
Call-ID: 1-10679@192.168.28.1
...
Refer-To: <sip:9785550000@192.168.29.1:6062?User-to-
User=56a390f3d2b7310023a%3Bencoding%3Dhex%3Bpurpose%3Disdn-
interwork%3Bcontent%3Disdn-uui
Content-Length:0
```

User to User Parameter in INVITE

If the UUI is received in the "Refer-To" header in the REFER message, the Oracle Communications Session Border Controller adds the new UUI header in the INVITE message to the destination party. The system encodes the INVITE message as shown in the following example. All the escape characters received in the UUI parameter converts to plain text and all

the UUI header parameters are relayed. In the example below, note the new UUI content below **Content-Length** and in the **Supported** fields.

```
INVITE sip:9785550000@192.168.29.1:6062 SIP/2.0
Via: SIP/2.0/UDP 192.168.29.20:5060;branch=z9hG4bKgkm8110090jmlvcfk80.1
From: 7321110000 <sip:7321110000@192.168.28.1:5060>;tag=1
To: <sip:9785550000@192.168.29.1:6062>

```

INVITE Message Details

The Oracle Communications Session Border Controller adds the UUI parameter to the **Supported** header in the INVITE message to the **Referred-to** party. The Oracle Communications Session Border Controller encodes only one instance of the UUI header in the INVITE message to the **Referred-to** party. The Oracle Communications Session Border Controller will only process the first UUI parameter received in the "Refer-To" header. The

Oracle Communications Session Border Controller supports a maximum of 128 octets hex content in the UUI header field, excluding parameters. The overall length of the header complies with RFC 3261. If the header length exceeds the maximum, the Oracle Communications Session Border Controller discards the UUI header and cannot relay the call.

SIP REFER Call Transfer UUI Relay Configuration

The SIP REFER Call Transfer **User to User Information** Relay is enabled by default. To disable UUI relaying on a configured realm:

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Select the **realm-config** object to edit.

```
ORACLE(realm-config)# select
identifier:
1: realm01 left-left:0 0.0.0.0

selection: 1
ORACLE(realm-config)#
```

3. **options**—Set the options parameter by typing options, a space, **disable-refer-to-uui=yes**. You may prepend the option name with a plus to add and not replace this option to the existing **realm-config** option list.

```
ORACLE#options +disable-refer-to-uui=yes
```

4. Type **done** to save your configuration.

Embedded Header Support

This section explains how to configure embedded header support. The Oracle Communications Session Border Controller supports methods of extracting an embedded P-Asserted-Identity header from a contact header to support E911 when integrated with certain vendor's systems. See RFC 3455 *Private Header (P-Header) Extensions to the Session Initiation Protocol (SIP) for the 3rd-Generation Partnership Project (3GPP)* for more information.

The embedded header support feature watches for a specified embedded header contained in a Contact header received in a 3XX message. When the specified embedded header is found, the full <header=value> pair is inserted as a unique header in a redirected INVITE message that exits the Oracle Communications Session Border Controller. If the outgoing INVITE message were to contain the specified header, regardless of the use of this feature, the value extracted from the 3XX message replaces the INVITE message's specified header value.

If an incoming Contact header in a 3XX message looks like:

```
Contact: <ESRN@IPv4_Intrado_GW;user=phone?P-Asserted-Identity=%3Csip:+1-
ESQK@IPv4_My_EAG;user=phone%3E>
```

Then, if you configure your Oracle Communications Session Border Controller to parse for the embedded P-Asserted-Identity header to write as a unique header in the outgoing invite message, the outgoing INVITE and P-Asserted-Identity headers will look like:

```
INVITE SIP: ESRN@IPv4_Intrado_GW;user=phone
P-Asserted-Identity: +1-ESQK@IPv4_My_EAG;user=phone
```

Embedded Header Support Configuration

Embedded header support is enabled in the session agent configuration.

To configure embedded header support:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

4. Select the session agent where you want this feature.

   ```
   ORACLE(session-agent)# select
   <hostname>:
   1: asd          realm=      ip=1.0.0.0
   2: SIPSA        realm=      ip=10.10.102.1
   selection:2
   ORACLE(session-agent)#
   ```

5. **request-uri-headers—Enter a list of embedded headers extracted from the Contact header that will be inserted in the re INVITE message.** To configure this parameter for multiple headers, enclose the headers in double quotes and separate them with spaces. This completes the configuration of embedded header support.

   ```
   ORACLE(session-agent)# request-uri-headers P-Asserted-Identity
   ```

Dialog Transparency

This section explains how to configure dialog transparency, which prevents the Oracle Communications Session Border Controller from generating a unique Call-ID and modifying dialog tags.

Overview

With dialog transparency enabled, the Oracle Communications Session Border Controller is prevented from generating a unique Call-ID and from modifying the dialog tags; the Oracle

Communications Session Border Controller passes what it receives. Therefore, when a call made on one Oracle Communications Session Border Controller is transferred to another UA and crosses a second Oracle Communications Session Border Controller, the second Oracle Communications Session Border Controller does not note the context of the original dialog, and the original call identifiers are preserved end to end. The signalling presented to each endpoint remains in the appropriate context regardless of how many times a call crosses through a Oracle Communications Session Border Controller or how many Oracle Communications Session Border Controllers a call crosses.

Without dialog transparency enabled, the Oracle Communications Session Border Controller's SIP B2BUA rewrites the Call-ID header and inserted dialog cookies into the From and To tags of all messages it processes. These dialog cookies are in the following format: SDxxxxxNN-. Using these cookies, the Oracle Communications Session Border Controller can recognize the direction of a dialog. However, this behavior makes call transfers problematic because one Oracle Communications Session Border Controllers' Call-ID might not be properly decoded by another Oracle Communications Session Border Controller. The result is asymmetric header manipulation and failed call transfers.

Dialog Transparency Configuration

You set one parameter in your SIP configuration to enable dialog transparency.

- For new configurations, this feature defaults to enabled
  To enable SIP dialog transparency:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the **session-router** path.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ```

4. Use the ACLI **select** command so that you can work with the SIP configuration.

   ```
   ORACLE(sip-config)# select
   ```

5. **dialog-transparency**—Enter the state of SIP dialog transparency you require for your Oracle Communications Session Border Controller. The default value is **enabled**. The valid values are:
   - enabled | disabled

Route Header Removal

This section explains how to enable the Oracle Communications Session Border Controller to disregard and strip all SIP Route headers. You set an option in a SIP interface configuration to strip all Route headers for SIP requests coming from this interface.

When the Oracle Communications Session Border Controller with this option configured receives an INVITE from an interface, it removes the route headers. However, although it

removes the headers, the Oracle Communications Session Border Controller maintains backward compatibility with RFC 2543 nodes. To do so, it normalizes the request to an RFC 3261 loose routing form before it removes the headers.

Route Header Removal Configuration

The following information explains how to remove SIP route headers.

To configure SIP route header removal:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. Type **options strip-route-headers** and press Enter. This completes the configuration of SIP route header removal.

   ```
   ORACLE(sip-interface)# options strip-route-headers
   ```

SIP Via Transparency

This section explains the inbound Via header transparency feature, which enables the Oracle Communications Session Border Controller to insert its Via header on top of the top-most Via header received from user equipment (UE). It then forwards it on to the IP Multimedia Subsystem (IMS) core with the original Via header now located as the bottom-most Via header.

The Oracle Communications Session Border Controller still replaces the Contact and other header addresses with its own, and does not pass on the core's Via headers in outbound requests.

This feature is targeted for the Telecoms & Internet converged Services & Protocols for Advanced Networks (TISPAN) with SIP hosted NAT traversal support. It works with SIP NAT bridged, local-policy routed, and non-SIP NAT configurations, regardless of registration handling.

Some equipment acts as Proxy-CSCF (P-CSCF) and Serving-CSCF (S-CSCF) nodes, with the Oracle Communications Session Border Controller is located between the equipment and user endpoints. The equipment needs to see the each user endpoint's original Via header in order to perform some implicit authentication, admission, and control functions in a TISPAN-compliant model.

You enable Via header transparency on the access SIP interface. Received Via headers are saved for inclusion in requests going out another interface or session agent that does not have the parameter set, in other words, the core side. For any received SIP message where the inbound previous hop interface was enabled for Via header transparency, theOracle

Communications Session Border Controller adds its own Via header as it forwards it, and it also copies the received top-most Via as the new bottom-most Via, if the outbound next hop interface/session agent is not enabled for Via header transparency. The Oracle Communications Session Border Controller also adds a received= parameter to the copied Via header, per the SIP RFC 3261.

Any message received from an interface without Via header transparency enabled, does not have the received Via header copied over to any other direction.

For HNT, where the original top-most (and only) Via header from a UE is a private/false address, the SD should still copy that false address into the core-side, and the received= parameter will contain the real Layer-3 addressing.

SIP Via Transparency Configuration

You can configure SIP Via header transparency for the access SIP interface using the ACLI.

To configure SIP Via header transparency for an access interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the media-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. You can either add support to a new SIP interface configuration or to an existing SIP interface configuration:

   For a new SIP interface configuration, you can add the option by typing options, a Space, and then via-header-transparency.

   ```
   ORACLE(sip-interface)# options via-header-transparency
   ```

   For an existing SIP interface configuration without options configured, select the SIP interface, type options followed by a Space, and then via-header-transparency.

   ```
   ORACLE(sip-interface)# select
   ORACLE(sip-interface)# options via-header-transparency
   ```

   For an existing SIP interface configuration with options configured, select the SIP interface, type options followed by a Space, the plus sign (+), and the via-header-transparency option.

   ```
   ORACLE(sip-interface)# select
   ORACLE(sip-interface)# options +via-header-transparency
   ```

5. Save your work using the ACLI **save** or **done** command.

Symmetric Latching

Symmetric latching, or forced HNT, ensures that symmetric RTP/RTCP is used for a SIP endpoint. Symmetric RTP/RTCP means that the IP address and port pair used by an outbound RTP/RTCP flow is reused for the inbound flow. The IP address and port are learned when the initial RTP/RTCP flow is received by the Oracle Communications Session Border Controller. The flow's source address and port are latched onto and used as the destination for the RTP/RTCP sourced by the other side of the call. The IP address and port in the c line and m line respectively in the SDP message are ignored.

If your network is configured with nested realms in order to separate signalling from media, make sure that the symmetric latching feature is enabled on the signaling realm.

> **Note:**
>
> This description is applicable to RTCP only when you also enable the HNT RTCP option in the media-manager configuration. Do not enable symmetric latching on core-facing interfaces.

Symmetric Latching Configuration

To configure symmetric latching:

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Select the **realm-config** object to edit.

```
ORACLE(realm-config)# select
identifier:
1: realm01 left-left:0 0.0.0.0

selection: 1
ORACLE(realm-config)#
```

3. **symmetric-latching** — identifies whether and how to enable symmetric latching on the SBC. This completes the configuration of forced Hosted NAT Traversal (HNT). The default value for this parameter is **disabled**. The valid values are:
   - **disabled** —
   - **enabled** —
   - **pre-emptive** —

```
ORACLE(realm-config)# symmetric-latching pre-emptive
```

4. Type **done** to save your configuration.

Enabling RTCP Latching

To enable RTCP symmetric latching:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **media-manager** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# media-manager
   ORACLE(media-manager-config)#
   ```

4. Select the media manager configuration so that you can enable HNT RTCP.

   ```
   ORACLE(media-manager-config)# select
   ```

5. **hnt-rtcp —** Enable support of RTCP when the SBC performs HNT. The default value is **disabled**. The valid values are:

   - enabled | disabled

   ```
   ORACLE(media-manager-config)# hnt-rtcp enabled
   ```

6. Save your work using either the ACLI **save** or **done** command.

SIP Pre-emptive Symmetric Media Latching

The Oracle Communications Session Border Controller (SBC) supports symmetric media latching within a realm. However, when two SBCs are in different realms and both realms are configured for symmetric latching, then both will wait for received media packets from the other before transmitting, which results in dropped calls. This feature lets the user configure the SBC to transmit its RTP packets pre-emptively to the peer SDP connection address and then to re-latch the peer RTP source address after receiving the first RTP packet from that peer.

In a call forwarding scenario where a media server (MS) behind Network Address Translation (NAT) is between two SBCs, both SBCs will detect NAT, so both will wait to receive RTP packets before latching to the RTP source address. This feature prevents this by adding the new value **pre-emptive** to the configuration option parameter **symmetric-latching** in the configuration element **realm-config**. When the value is set to **pre-emptive**, the SBC sends the RTP packets to the received SDP connection address without waiting on the latch. Once the RTP packets are received from the peer endpoint, the SBC detects the NAT address mapping; if there is a change in the RTP source address, the SBC re-latches to the new RTP source address. Subsequent RTP packets are then sent to the peer RTP source address. This is also the behavior when there is an UPDATE or reINVITE with the SDP message.

Pre-emptive Symmetric Media Latching Configuration

1. Access the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

2. Select the **realm-config** object to edit.

```
ORACLE(realm-config)# select
identifier:
1: realm01 left-left:0 0.0.0.0

selection: 1
ORACLE(realm-config)#
```

3. **symmetric-latching** — identifies whether and how to enable symmetric latching in the realm. The default value is **disabled**.
   - **disabled**
   - **enabled**
   - **pre-emptive** — symmetric latching is enabled but the SBC sends RTP packets to the received SDP connection address without waiting on the latch
4. Type **done** to save your configuration.

SIP Number Normalization

This section explains the SIP number normalization feature that applies to the SIP To URI. (Currently the Oracle Communications Session Border Controller supports number normalization on From and To addresses for both inbound and outbound call legs.) Number normalization includes add, delete, and replace string functions that result in consistent number formats.

Number normalization is supported for the following call types:

- SIP to SIP
- H.323 to SIP

Number normalization applies to the SIP To URI. It occurs on ingress traffic, prior to the generation of accounting records or local policy lookups. RADIUS CDR attributes are populated with the normalized numbers. Local policy matching is based on the normalized numbers.

Terminology

The following lists explains the terminology used later.

- X is any digit having the value 0 through 9
- N is any digit having the value 2 through 9
- 0/1 is a digit having the value of either 0 or 1

- NXX is a form of Numbering Plan Area (NPA).
- CC is a 1, 2, or 3 digit country code used in international dialing
- NN is a national number that can be a four to fourteen digit national number used in international dialing, where the combination of CC+NN is a 7 to 15 digit number.
- + symbol in E.164 indicates that an international prefix is required
- E.164 numbers are globally unique, language independent identifiers for resources on Public Telecommunication Networks that can support many different services and protocols.
- N11 number is any of the three-digit dialing codes in the form N11 used to connect users to special services, where N is a digit between 2 and 9

Calls from IP Endpoints

The Oracle Communications Session Border Controller uses the following number normalization rules:

- North American Numbering Plan (NANP) calls: where a number with the format 1NPANXXXXXX is received, the Oracle Communications Session Border Controller adds a plus sign (+) as a prefix to the NANP number. The Oracle Communications Session Border Controller also adds the string ;user=phone after the host IP address in the SIP URI. For example:

  ```
  sip:+1NPANXXXXXX@ipaddr;user=phone
  ```

- International NWZ1 calls: Oracle Communications Session Border Controller receives an international call with the format 011CCNN. The Oracle Communications Session Border Controller deletes the 011 prefix and adds a plus sign (+) as a prefix to CC+NN; and also adds the string ;user=phone after the host IP address in the SIP URI. For example:

  ```
  sip:+CCNN@ipaddr;user=phone
  ```

- Private number calls: when a private number with the format nxxxx (where n=2 through 9) is received, no number normalization is applied by the Oracle Communications Session Border Controller.
- Calls to numbers such as N11, 0-, 0+, 00-, and 01+: the Oracle Communications Session Border Controller adds ;phone-context=+1 after the number and also adds the string ;user=phone after the host IP address in the SIP URI. For example:

  ```
  sip:N11;phone-context=+1@ipaddr;user=phone
  sip:01CCNN;phone-context=+1@ipaddr;user=phone
  ```

- Calls with numbers that are already normalized are not modified by the Oracle Communications Session Border Controller.

Calls from IP Peer Network

For calls received from external peer networks, the Oracle Communications Session Border Controller uses the following number normalization rules:

- Global numbers such as NANP and international E.164 numbers should have already been normalized. If not, the Oracle Communications Session Border Controller applies the same number normalization rules listed in the prior section.

- Calls to numbers such as N11, 0-, 0+, 00-, and 01+: the Oracle Communications Session Border Controller adds ;phone-context=+1 after the number and also adds the string ;user=phone (if absent) after the host IP address in the SIP URI.

SIP Number Normalization Configuration

You can configure SIP number normalization for the realm and session agent using the ACLI.

Realm

To configure SIP number normalization for a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. You can either add SIP number normalization support to a new session agent configuration or to an existing session agent configuration:

   - For a new realm configuration, add the option by typing **options**, a Space, and then **number-normalization**.

     ```
     ORACLE(realm-config)# options number-normalization
     ```

   - For an existing realm configuration without any options already configured, select the realm, type **options** followed by a Space, and then **number-normalization**.

     ```
     ORACLE(realm-config)# select
     ORACLE(realm-config)# options number-normalization
     ```

   - For an existing realm configuration with other options, select the realm, type **options** followed by a Space, the plus sign (**+**), and the **number-normalization** option.

     ```
     ORACLE(realm-config)# select
     ORACLE(realm-config)# options +number-normalization
     ```

5. Save your work using the ACLI **save** or **done** command.

Session Agent

To configure SIP number normalization for a session agent:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the media-level configuration elements.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

4. You can either add SIP number normalization support to a new session agent configuration or to an existing session agent configuration:
   - For a new a session agent configuration, add the option by typing **options**, a Space, and then **number-normalization**.

     ```
     ORACLE(session-agent)# options number-normalization
     ```

   - For an existing session agent configuration without any options already configured, select the session agent, type **options** followed by a Space, and then **number-normalization**.

     ```
     ORACLE(session-agent)# select
     ORACLE(session-agent)# options number-normalization
     ```

   - For an existing session agent configuration with other options, select the session agent, type **options** followed by a Space, the plus sign (**+**), and the **number-normalization** option.

     ```
     ORACLE(session-agent)# select
     ORACLE(session-agent)# options +number-normalization
     ```

5. Save your work using the ACLI **save** or **done** command.

SIP Port Mapping

This section contains information about the SIP port mapping feature. SIP port mapping lets you allocate a unique SIP signaling transport address (IP address and UDP port) on the Oracle Communications Session Border Controller in the provider network for each registered endpoint (user agent).

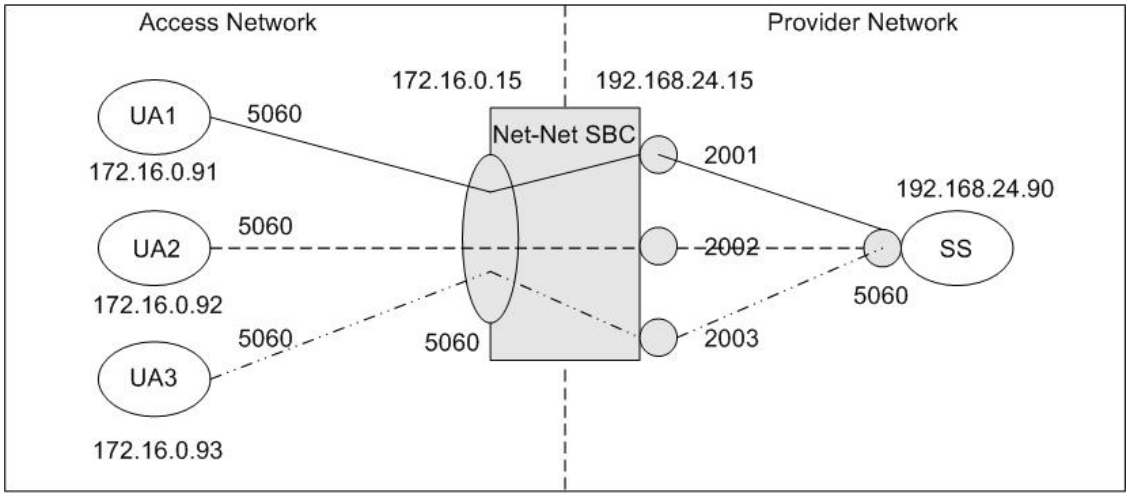
About SIP Port Mapping

You might need to provide a unique signaling transport address for each registered endpoint for admission control, if required by your softswitch vendor. If you have questions about your softswitch, contact the vendor for assistance.

When a Oracle Communications Session Border Controller resides between the endpoints and the softswitch, the softswitch sees the same transport address (that of the Oracle Communications Session Border Controller) for all endpoints. By allocating a unique UDP port

for each endpoint, the Oracle Communications Session Border Controller provides each of them a unique transport address.

The following example illustrates the SIP port mapping feature.



The diagram shows UA1, UA2, and UA3 are endpoints within the access network and that the SIP interface for the access network is 172.16.0.15:5060. On the provider network, the SIP interface is at 192.168.24.15, with the SIP port mapping feature enabled. The softswitch/ registrar is also located on the provider network at 192.168.24.90:5060.

The diagram shows that port 2001 on the provider network is allocated to UA1 on the access network, port 2002 is allocated to UA2, and port 2003 is allocated to UA3. Because of this allocation, all SIP signaling messages sent from the endpoints in the access network to the softswitch on the provider network travel through an allocated signaling port. For example, all signaling messages between UA1 and the softswitch use 192.168.24.15:2001 as the transport address.

How SIP Port Mapping Works

The Oracle Communications Session Border Controller (SBC) allocates SIP port mapping (signaling) ports during a REGISTER request that has registration caching applied. When you define a range of signaling ports for the SIP interface, you create a pool of signaling ports that can be allocated during the REGISTER request.

The SBC allocates a signaling port from the pool when it creates the registration cache entry for a Contact in a REGISTER request. It allocates a separate signaling port for each unique Contact URI from the access side. The registration cache Contact entry contains the mapping between the Contact URI in the access/endpoint realm (the UA-Contact) and the Contact URI in the registrar/softswitch realm (the SD-Contact).

The SD-Contact is the allocated signaling port. The signaling port gets returned to the pool when the Contact is removed from the registration cache. The removal can occur when the cache entry expires; or when the endpoint sends a REGISTER request to explicitly remove the Contact from the registrar. When a signaling port returns to the pool it gets placed at the end of pool list; in a least-recently-used allocation method for signaling ports

When the SBC forwards the REGISTER request to the softswitch, it replaces the UA-Contact with SD-Contact. For example, if UA1 sends a REGISTER request with a Contact URI of sip:ua1@172.16.0.91:5060, it is replaced with sip:192.168.24.15:2001 when the REGISTER request is forwarded to the registrar.

The same translation occurs when UA1 sends that same URI in the Contact header of other SIP messages. SIP requests addressed to the allocated signaling transport address (SD-Contact) are translated and forwarded to the registered endpoint contact address (UA-Contact).

> **Note:**
>
> The maximum number of registered endpoints cannot exceed the number of signaling ports available. If no signaling ports are available for a new registration, the REGISTER request receives a 503 response.

The SBC still processes requests received on the configured SIP port address. Requests sent into the registrar/softswitch realm that are not associated with a registered user will use the configured SIP port address.

Using SIP port mapping with SIPconnect—where unique ports are used for each registered PBX—hinders the SBC from routing incoming calls to the corresponding PBX because the SBC uses DN for the PBX's parent during registration, but the incoming INVITE from the softswitch contains the child DN in its Request URI. Thus the SBC cannot find a matching SBC-Contact because the username of the Request URI contains the child DN, but the username of the SBC-Contact contains the parent DN.

You can enable SIPconnect support in either the realm configuration or session agent for the SIP access network by setting the **sip-connect-pbx-reg** option. With this option set and the destination realm configured for port mapping, the SBC inserts a special search key in the registration table. Rather than adding the SD-Contact as the key as with regular (non-SIPconnect) registrations, the SBC strips user information and instead uses the host and port information as the registration key. The SBC still forwards the registration message with an intact contact username.

SIP Port Mapping Based on IP Address

Some registrars need to know that multiple contacts represent the same endpoint. The extension to this feature answers the expectation from registrars that an endpoint registering multiple AoRs will use a single core-side mapped port to show that the AoRs really represent a single endpoint.

When you enable SIP port mapping based on IP Address, the Oracle Communications Session Border Controller supports core-side UDP port mapping based on the endpoint's IP address. It ignores the username portion of the AoR or Contact.

The Oracle Communications Session Border Controller performs the port mapping allocation and lookup based on all requests using the via-key from the SIP Request. The via-key is a combination of Layer 3 and Layer 5 IP information in the message. The Oracle Communications Session Border Controller performs an additional lookup in the registration table to determine if a via-key already exists. If it does, then the Oracle Communications Session Border Controller uses the port already allocated and does not allocate a new one.

About NAT Table ACL Entries

To enable SIP signaling messages to reach the host processor, the Oracle Communications Session Border Controller adds NAT table ACL entries for each SIP interface. With UDP

without SIP port mapping applied, it adds a single ACL entry for each SIP port in the SIP interface configuration. For example:

```
untrusted entries:
intf:vlan source-ip/mask:port/mask dest-ip/mask:port/mask   prot type    index
0/0:0     0.0.0.0                  172.16.1.15:5060         UDP  static  10
0/3:0     0.0.0.0                  192.168.24.15:5060       UDP  static  16
0/1:0     0.0.0.0                  192.168.50.25:5060       UDP  static  17
```

Using SIP Port Mapping

When you use SIP port mapping, one or more ACL entries are added to the NAT table to enable the range of ports defined. The NAT table does not support the specification of port ranges. However, it does support masking the port to enable ranges that fall on bit boundaries. For example, an entry for 192.168.24.15:4096/4 defines the port range of 4096 through 8191.

The algorithm for determining the set of ACLs for the port map range balances the need to represent the range as closely as possible, with the need to minimize the number of ACL entries. For example, a range of 30000 through 39999 would result in the following set of ACLs.

```
untrusted entries:
intf:vlan source-ip/mask:port/mask dest-ip/mask:port/mask   prot type    index
0/3:0     0.0.0.0                  192.168.24.15:30000/4    UDP  static  13
0/3:0     0.0.0.0                  192.168.24.15:32768/4    UDP  static  14
0/3:0     0.0.0.0                  192.168.24.15:36864/4    UDP  static  15
```

However, the first entry actually enables ports 28672 though 32767 and the last entry allows port 36864 through 40959. If SIP messages are received on ports outside the configured range (28672 through 29999 or 40000 through 40959 in this case), they are ignored.

Oracle recommends you use port map ranges that fall on bit boundaries to ensure the fewest possible ACL entries are created and only the configured ports are allowed by the ACLs. For example, a range of 32768 to 49151 provides for 16,384 signaling ports in a single ACL entry (192.168.24.15:32768/2).

> **Note:**
>
> If the ACLs added for the port map range do not include the SIP port configured in the SIP interface; the normal SIP ACL entry for the SIP port is also added.

Dynamic Configuration

Dynamic configuration of SIP port mapping can cause disruption in service for existing registration cache entries; depending on the changes made to the defined port map range. If the range of mapping ports is reduced, it is possible that SIP signaling messages from the registrar/softswitch realm will no longer be sent to the host processor because of the changes in the NAT Table ACL entries.

When the range of mapping ports is changed, any signaling ports in the free signaling port pool not allocated to a registration cache entry are removed from the pool. When an allocated signaling port that is no longer part of the defined mapping port range is released, it is not returned to the pool of free steering ports.

The administrator is warned when the changed configuration is activated after the port map range of a SIP interface has been changed.

Registration Statistics

The SIP registration cache statistics include counters for free and allocated signaling ports. You can issue a show registration command to display the statistics:

```
17:36:55-190
SIP Registrations          -- Period -- -------- Lifetime --------
                  Active     High   Total       Total   PerMax     High
User Entries           4        4       0           7        4        4
Local Contacts         4        4       0           7        4        4
Free Map Ports     12284    12284       0       12291    12288    12288
Used Map Ports         4        4       0           7        4        4
Forwards               -        -       1          22        4
Refreshes              -        -       3          43        3
Rejects                -        -       0           0        0
Timeouts               -        -       0           1        1
Fwd Postponed          -        -       0           0        0
Fwd Rejected           -        -       0           0        0
Refr Extension         0        0       0           0        0        0
Refresh Extended       -        -       0           0        0
```

The labels for the first two items reflect the restructured registration cache:

- User Entries: counts the number of unique SIP addresses of record in the cache. Each unique address of record represents a SIP user (or subscriber). The address of record is taken from the To header in the REGISTER request. There might be one or more registered contacts for each SIP user. The contacts come from the Contact header of the REGISTER request.
- Local Contacts: counts the number of contact entries in the cache. Because the same user can register from multiple endpoints (user agents); the number of Local Contacts might be higher than the number of User Entries.
- Free Map Ports: counts the number of ports available in the free signaling port pool.
- Used Map Ports: counts the number of signaling ports allocated for registration cache entries. The value of Used Map Ports will equal the number of Local Contacts when the port mapping feature is used for all registrar/softswitch realms in the Oracle Communications Session Border Controller.

SIP Port Mapping Configuration

You configure the SIP port mapping feature on a per-realm basis using the SIP interface configuration. Configure the port map range on the SIP interface for the realm where the registrar/softswitch resides. Port mapping is only applied when the access/ingress realm has registration caching and/or HNT enabled.

The range of SIP mapping ports must not overlap the following:

- Configured SIP port, which might be used for signaling messages not associated with a registered endpoint.
- Port range defined for steering pool configuration using the same IP address as the SIP interface. If overlap occurs, the NAT table entry for the steering port used in a call prevents SIP messages from reaching the host processor.

To configure SIP port mapping:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the session-router path.

```
ORACLE(configure)# session-router
```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

4. **port-map-start**—Set the starting port for the range of SIP ports available for SIP port mapping. The valid range is 1025 through 65535. The default values is **0** and when this value is set, SIP port mapping is disabled. The valid range is:
   - Minimum: 0, 1025
   - Maximum: 65535

```
ORACLE(sip-interface)# port-map-start 32768
```

5. **port-map-end**—Set the ending port for the range of SIP ports available for SIP port mapping. The valid range is 1025 through 65535. If you set the value to the default **0**, SIP port mapping is disabled. The valid range is:
   - Minimum—0, 1025
   - Maximum—65535

> **Note:**
>
> If not set to zero (0), the ending port must be greater than the starting port.

```
ORACLE(sip-interface)# port-map-end 40959
```

6. **options**—If you want to use SIP port mapping based on IP address, set the options parameter by typing **options**, a Space, the option name **reg-via-key** with a plus sign in front of it, type the equal sign and the word **all**. Then press Enter.

```
ORACLE(sip-interface)# options +reg-via-key=all
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

7. Save your work using the ACLI **done** command.

The following example shows SIP port mapping configured for a SIP interface:

```
sip-interface
        state                           enabled
        realm-id                        backbone
        sip-port
                address                         192.168.24.15
                port                            5060
                transport-protocol              UDP
                allow-anonymous                 all
        sip-port
                address                         192.168.24.15
                port                            5060
                transport-protocol              TCP
                allow-anonymous                 all
        carriers
        proxy-mode
        redirect-action
        contact-mode                    none
        nat-traversal                   none
        nat-interval                    30
        registration-caching            enabled
        min-reg-expire                  120
        registration-interval           3600
        route-to-registrar              enabled
        teluri-scheme                   disabled
        uri-fqdn-domain
        trust-mode                      agents-only
        max-nat-interval                3600
        nat-int-increment               10
        nat-test-increment              30
        sip-dynamic-hnt                 disabled
        stop-recurse                    401,407
        port-map-start                  32768
        port-map-end                    40959
        last-modified-date              2005-09-23 14:32:15
```

SIP Port Mapping for TCP and TLS

In releases prior to S-C6.2.0, the Oracle Communications Session Border Controller (SBC) supports SIP port mapping for UDP and now you can enable this feature for SIP sessions using TCP and TLS. Port mapping enables the SBC to allocate a unique port number for each endpoint registering through it by giving it a transport address (or hostport) in the registered Contact.

When you enable this feature for TCP and TLS, the SBC designates a port from a configured range for each endpoint that registers with SIP servers in the SIP interface's realm. You establish that range of ports using the **port-map-start** and **port-map-end** parameters. Unlike its behavior with UDP port mapping—where the SBC sends requests on the SIP interface from the allocated port mapping, the SBC sends all requests over an existing connection to the target next hop for TCP/TLS port mapping. If a connection does not exist, the system creates one. So for TCP/TLS port mapping, only the Contact header contains the transport address of the mapping port (i.e., the transport address of the configured SIP port). And the system refuses TCP and TLS connections on the allocated mapping port.

With TCP/TLS port mapping enabled, the SBC sends the Path header with the transport address in Register requests, unless you specify that it should not do so. Standards-conformant SIP servers (that support RFC 3327) might attempt to send requests to the allocated mapping port if the Path header is absent.

> **Note:**
>
> ACL entries in the NAT table that permit TCP/TLS signaling for a SIP port configuration with TCP/TLS port mapping are the same as they would be for a TCP/TLS SIP port without port mapping enabled. Additional ACL entries that need to be set up for UDP port mapping are not required for TCP/TLS port mapping.

RTN 1684

SIP Port Mapping Configuration for TCP TLS

You enable TCP/TLS port mapping in a per-realm basis using the SIP interface configuration; setting the **tcp-port-mapping** value in the **options** parameter enables the feature. Enabling this parameter turns on the port mapping feature for UDP as well.

By default, the Oracle Communications Session Border Controller includes the Path header in Register requests it sends from that SIP interface. If you do not this header to be included, however, you can set the value as **tcp-port-mapping=nopath**.

To enable TCP/TLS port mapping for a SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter. If you are adding this feature to a pre-existing configuration, you will need to select and edit it.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. **options**—Set the options parameter by typing options, a Space, the option name **tcp-port-mapping** with a plus sign in front of it, and then press Enter.

   ```
   ORACLE(sip-interface)# options +tcp-port-mapping
   ```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the realm configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save your work.

SIP Configurable Route Recursion

When the Oracle Communications Session Border Controller routes SIP requests from a UAC to a UAS, it might determine that there are multiple routes to try based on a matching local policy. The Oracle Communications Session Border Controller recurses through the list of routes in a specific order according to your configuration and the quality of the match. There are other scenarios when a UAS replies with a 3xx Redirect response to the Oracle Communications Session Border Controller, the 3xx response can include multiple Contacts to which the request should be forwarded in a specific order. In both cases, the Oracle Communications Session Border Controller needs to recurse through a list of targets.

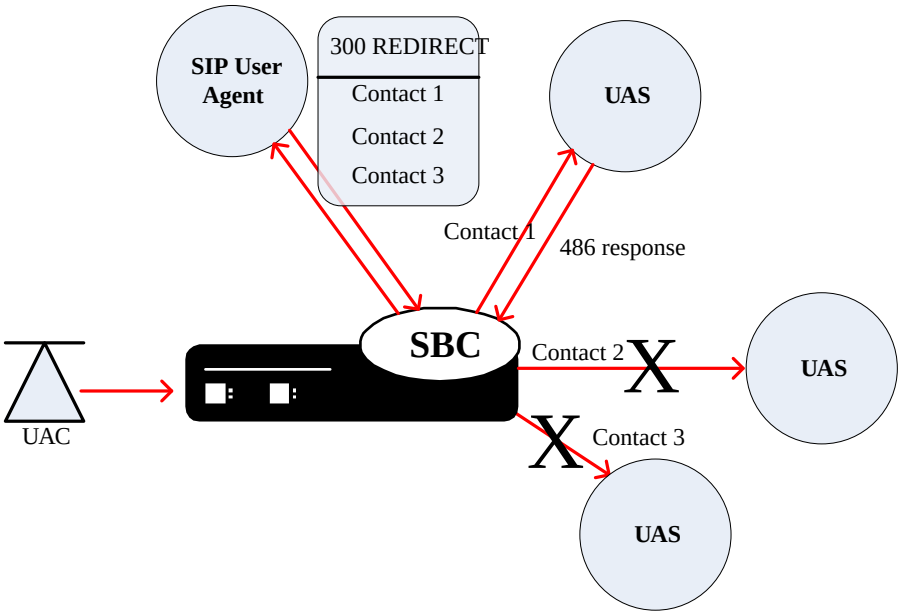
When the Oracle Communications Session Border Controller receives a non-successful (or non-6xx response) final response from the UAS, and there are multiple targets for the original request, the Oracle Communications Session Border Controller will forward the request to the next target and wait for a response. While the process of forwarding the request to multiple targets as explained in the previous paragraph is called serial forking, and the process of forwarding the request to contacts received in redirect responses is called recursion, the term recursion is used for both processes in this notice.

Use the SIP Route Recursion feature when you want the Oracle Communications Session Border Controller to forward a response to the UAC and stop recursing through the target list immediately after receiving the 3xx, 4xx, or 5xx response code that you configure. When this feature is disabled, the Oracle Communications Session Border Controller only stops recursing when it receives a message with a 401 or 407 response code. Using this feature, you can configure a specific message or range of messages to stop recursing on when received. The Oracle Communications Session Border Controller retains its default behavior to stop recursing on a 401 or 407 response code when SIP Route Recursion is configured on a SIP interface. The Oracle Communications Session Border Controller will always stop recursing when it receives a global failure (6xx); this behavior is not configurable.

You can disable response recursion for either a SIP interface or for a SIP session agent, providing you with flexibility for various network architectures. For instance, a PSTN gateway might be the only hop to reach a given endpoint, whereas several session agents might need to be contacted if multiple devices map to a contacted address of record.

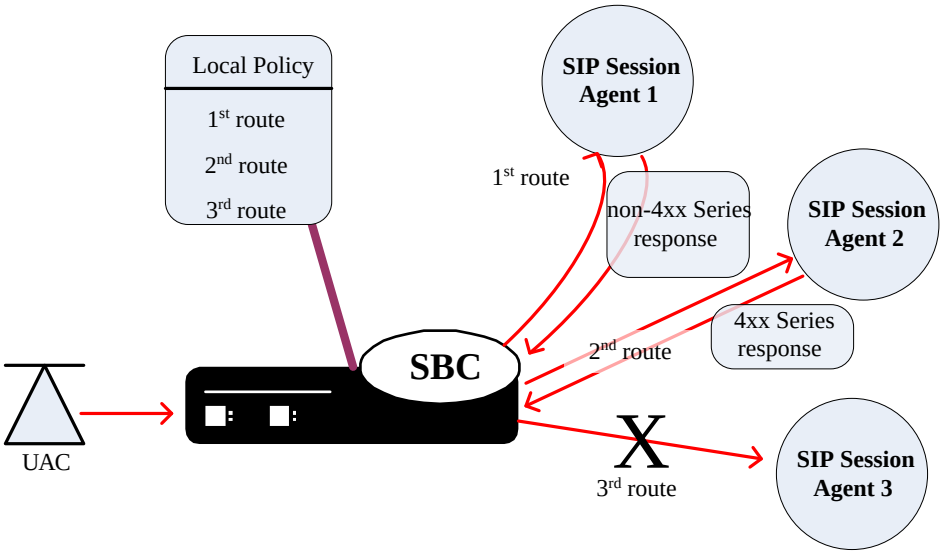
Example 1

A more detailed example is when a softswitch might return a list of contacts for multiple PSTN gateways in a Redirect message. If the PSTN target number contacted on redirection is busy, a 486 response will be sent to the Oracle Communications Session Border Controller. Since the single target is located in the PSTN, a subsequent request through a different gateway will yield another 486 response. The Oracle Communications Session Border Controller should be configured to return the 486 response to the UAC immediately. No other SIP requests should be sent to applicable targets/contacts that were enumerated in the redirect list. See the following example:



Example 2

The Oracle Communications Session Border Controller might determine from a local policy lookup that several routes are applicable for forwarding a SIP message. The Oracle Communications Session Border Controller will try each route in turn, but the SIP response recursion disable feature can be implemented to stop the route recursion when a configured responses message is received by the Oracle Communications Session Border Controller. See the following example:



There are a few conditions on the parameter used to configure response recursion:

- SIP Route Recursion is configurable for either the SIP interface or session agent.
- 401 and 407 are preconfigured for all configured SIP interfaces. They are not configured for session agents.
- The format is a comma-separated list of response codes or response code ranges: 404, 484-486.

- Only response codes that fall within the 3xx, 4xx, and 5xx range may be specified.

SIP Route Recursion Configuration

You enable SIP route recursion either in the session agent or the SIP interface configuration.

Configuring a Session Agent for SIP Route Recursion

To configure SIP Route recursion for an existing session agent:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-router path.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

4. Select the session agent where you want this feature.

   ```
   ORACLE(session-agent)# select
   <hostname>:
   1: asd          realm=      ip=1.0.0.0
   2: SIPSA        realm=      ip=10.10.102.1
   selection:2
   ORACLE(session-agent)#
   ```

5. **stop-recurse**—Enter list of returned response codes that this session agent will watch for in order to stop recursion on the target's or contact's messages. This can be a comma-separated list or response code ranges.

   ```
   ORACLE(session-agent)# stop-recurse 404,484-486
   ```

6. Save and activate your changes.

Configuring a SIP Interface for SIP Route Recursion

To configure SIP route recursion for an existing SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the **session-router** path.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

4. Select the SIP interface to which you want to apply this feature.

```
ORACLE(sip-interface)# select
<realm-id>:
1: Acme_Realm
selection:1
ORACLE(sip-interface)#
```

5. **stop-recurse**—Enter a list of returned response codes that this SIP interface will watch for in order to stop recursion on the target's or contact's messages. This list can be a comma-separated list of response codes or response code ranges.

```
ORACLE(sip-interface)# stop-recurse 404,484-486
```

6. Save and activate your changes.

SIP Event Package Interoperability

Service providers often deploy a Oracle Communications Session Border Controller on the border of an access network, where it sits between the SIP endpoints (user agents) and the service provider's application server. The application server and the user agents sometimes use various SIP event packages to exchange and maintain state information. The SUBSCRIBE and NOTIFY methods are used to establish subscriptions to the event packages and to report state changes to the subscribing entity.

The SIP global contact option addresses interoperability in the Dialog and Presence event packages that are used in hosted PBX and IP Centrex offerings. State information is passed in the message body of a NOTIFY request; this message body is encoded in an XML format described by the Content-Type header. The Oracle Communications Session Border Controller needs to update certain fields in the body to account for dialog mapping and SIP NAT functionality between the access and service provider realms. Often the subscriptions are established using URIs learned from Contact headers in the user agent registrations or dialog establishment (INVITE/SUBSCRIBE). For this, a Oracle Communications Session Border Controllerrequires a Contact URI that is usable and routable outside of an existing dialog.

The SIP global contact option enables persistent URIs in the Contact headers inserted into outgoing SIP messages. If this option is not used, URIs placed in the Contact header of outgoing messages are only valid within the context of the dialog to which the message is associated.

RFCs associated with this feature are:

- A. B. Roach, *Session Initiation Protocol (SIP)-Specific Event Notification*, RFC 3265, June 2002
- J. Rosenberg, *A Presence Event Package for the Session Initiation Protocol (SIP)*, RFC 3856, August 2004
- J. Rosenberg, et al. *Data Format for Presence Using XML*, http://www.iptel.org/info/players/ietf/presence/outdated/draft-rosenberg-impp-pidf-00.txt, Work In Progress (expired), June 2000

- J.Rosenberg, H. Schulzrinne, R. Mahy, *An INVITE Initiated Dialog Event Package for the Session Initiation Protocol (SIP)*, draft-ietf-sipping-dialog-package-06.txt, Work In Progress, April 2005
- H. Sugano, et al., *Presence Information Data Format (PIDF)*, RFC 3863, August 2004

SIP Event Package Interoperability Configuration

This feature is applicable to the global SIP configuration.

To configure SIP event package interoperability:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

4. **options**—Add SIP event package interoperability support to a new SIP configuration or to an existing SIP configuration:

   If you do not currently have an SIP configuration, you can add the option by typing options, a Space and then global-contact.

   ```
   ORACLE(sip-config)# options global-contact
   ```

   Select the SIP configuration so that you can add SIP event package interoperability support to it. Then, to add this option to a list of options that you have already configured, type options followed by a Space, the plus sign (+), and the global-contact option.

   ```
   ORACLE(sip-config)# select
   ORACLE(sip-config)# options +global-contact
   ```

   If you type options global-contact without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

5. Save and activate your changes.

SIP Proxy Subscriptions

When the Oracle Communications Session Border Controller operates in dialog mode (i.e., as a B2BUA), it creates and maintains dialog state for subscription dialogs created with SUBSCRIBE/NOTIFY messages and for INVITE-initiated dialogs. Since there can be a very large number of subscriptions per user in a Rich Communication Services (RCS) environment (especially for presence subscriptions), Oracle Communications Session Border Controller resources can quickly become depleted.

To alleviate this consumption of resources, you can configure your **Oracle Communications Session Border Controller** to operate in proxy mode for event packages that you define using the **proxy-sub-event** parameter in the global SIP configuration. When you define event packages in this list and the operation mode for the SIP configuration is dialog or session, the **Oracle Communications Session Border Controller** processes all SUBSCRIBE and NOTIFY requests and responses for the designated event packages in transaction stateful mode.

Topology Hiding

So that it can perform topology hiding, the Oracle Communications Session Border Controller retains necessary routing information (such as the Contact or Record-Route header values) and it encodes certain data from the messages it receives in the messages it sends. To be more specific, the Oracle Communications Session Border Controller encodes the original URI hostport and the ingress realm name into a gr parameter it adds to the URI. The hostport information is replaced with the IP address and port of the SIP interface from which the message is sent (the egress interface). Without this information, subsequent in-dialog messages cannot be routed correctly because the Oracle Communications Session Border Controller does not retain dialog state (i.e., the route-set or remote-target).

For example, the URI sip:td@192.168.24.121:5060 might be encoded as sip:td@192.168.24.121:5060; gr=vjml9qtd175bhmhvhkgp0jov81popvbp000040.

The Oracle Communications Session Border Controller also performs URI encoding on the message body for Content-Type application/pdif+xml. this contains a Presence Information Data Format document (or PIDF) in PUBLISH and NOTIFY requests so subsequent SIP requests using the URIs in the PIDF document can be routed correctly.

The Oracle Communications Session Border Controller performs URI encoding in outgoing SIP messages after SIP=NAT is applied and before outbound HMR occurs. And the system decodes URIs in SIP messages after inbound HMR takes place and before SIP-NAT is applied.

In the event a URI is encoded several times (as is the case in spiral and hairpin calls), the encoded realm+hostport values are separated by a plus sign (+), as in the following:

```
sip:td@192.168.24.121:5060; gr=vjml9qtd175bhmhvhkgp+dhfhb0jov81opvbp
```

When the Oracle Communications Session Border Controller receives any of the following requests, it matches the contents of the request's Event header with the list you configure in the proxy-sub-events parameter:

- PUBLISH
- SUBSCRIBE
- NOTIFY
- REFER

This is provided the operation-mode for the SIP configuration is set to either **session** or **dialog**. If it finds a match, the Oracle Communications Session Border Controller marks the request for processing in transaction-stateful mode rather than in B2BUA mode.

> **Note:**
>
> Although PUBLISH is not a dialog-creating request, topology hiding needs to be applied to the PIDF so that subsequent NOTIFY requests containing portions of the published PIDF can be decoded properly.

When the Oracle Communications Session Border Controller forwards the request, it will have encoded all Contact and Record-Route header information using the ingress realm. The hostport value of the URIs then has egress SIP interface's IP address and port. The Via headers in the requested the Oracle Communications Session Border Controller received are not included in the outgoing request.

Then PUBLISH, SUBSCRIBE, NOTIFY, and REFER responses are compared to the request that was sent to determine if the response should receive transaction-stateful proxy treatment. The Oracle Communications Session Border Controller decodes any encoded Record-Route headers back to their original values for the outgoing response. Any Record-Route headers added downstream from the Oracle Communications Session Border Controller are encoded using the original request's egress realm (meaning the realm from which the response was received). In addition, the Contact header is encoded using the request's egress realm and ingress SIP interface and port.

Feature Interaction

When using this feature, the Oracle Communications Session Border Controller does not keep dialog or subscription state. Therefore the Per-user SUBSCRIBE Dialog Limit feature—configured in the **enforcement-profile** configuration—will not function properly when a subscription is handled in proxy mode.

SIP Proxy Subscription Configuration

This section shows you how to configure a list of SIP event packages to cause the Oracle Communications Session Border Controller to act in proxy mode.

> **Note:**
>
> The operation-mode parameter for the global SIP configuration must be set to either dialog or session in order for this feature to function as designed.

To configure a list of SIP event packages to enable SIP proxy subscriptions:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **proxy-sub-events**—Enter a list of SIP event package names that you want to enable the SIP proxy subscriptions feature. You can enter more than one value by enclosing multiple values in quotations marks, as in the following example.

```
ORACLE(sip-config)# proxy-sub-events presence winfo
```

SIP REGISTER Forwarding After Call-ID Change

This feature addresses the case when an endpoint reboots and performs a third party registration before its old registration expires. During this reregistration, the contact header is the same as it was pre-reregistration. As a consequence of the reboot, the SIP Call-ID changes. In this situation, the Oracle Communications Session Border Controller does not forward the REGISTER to the registrar, because it believes the endpoint is already registered, based on a previous registration from the same Contact: header URI.

To remedy this problem, the Oracle Communications Session Border Controller now keeps track of the Call-ID in its registration cache. The **forward-reg-callid-change** option in the global SIP configuration element forces the Oracle Communications Session Border Controller to forward a REGISTER message to the registrar when the Call-ID header changes in a REGISTER message received from a reregistering UAC.

SIP REGISTER Forwarding Configuration

To configure SIP REGISTER forwarding after a Call-ID change:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. **options—**Add this feature to a new or an existing SIP configuration:

   If you do not currently have a SIP configuration, you can add the option by typing options, a Space, and then forward-reg-callid-change.

```
ORACLE(sip-config)# options forward-reg-callid-change
```

For an existing SIP configuration, select the SIP configuration so that you can add this feature to it. Then, to add this option to a list of options that you have already configured, type options, a Space, the plus sign (+), and the forward-reg-callid-change option.

```
ORACLE(sip-config)# options +forward-reg-callid-change
```

If you type options forward-reg-callid-change without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

5. Save and activate your changes.

SIP Local Response Code Mapping

The SIP local response code mapping feature enhances the SIP response code mapping. The SIP response code map feature lets you establish a table that maps SIP response-received messages (entries) to response-to-send messages (entries).

SIP local response code mapping is used with the SIP responses generated by the Oracle Communications Session Border Controller towards a specific SIP session agent. This feature lets you provision the mapping of the response codes used by the Oracle Communications Session Border Controller when it generates the responses towards a session agent.

You create the SIP local response code map using the existing mapping functionality, and then assigning that map to a session agent or to a SIP interface.

> **Note:**
>
> The configured response map is not used when the Oracle Communications Session Border Controller is acting as proxy for the responses to this session agent.

The parameters **method** and **register-response-expires** enable a SIP registration response mapping feature that allows you to configure the Oracle Communications Session Border Controller to remap a SIP failure response—which it receives from another network device or that it generates locally—to a 200 OK. You might want the Oracle Communications Session Border Controller to perform this type of mapping for circumstances where non-malicious endpoints continually attempt registration, but will stop (and still not be registered) when they receive a 200 OK. This response mapping does not actually register the client with the Oracle Communications Session Border Controller, meaning that there is neither a registration cache entry or a CAM ACL for it.

For the 200 OK it generates, the Oracle Communications Session Border Controller removes any Reason or Retry-After header in the 200 OK and sets the expires time. By default, the expires time is the Retry-After time (if there is one in the response) or the expires value in the Register request (if there is no Retry-After expires time). You can also set this value using the **register-response-expires** parameter, but the value you set should never exceed the Register request's expires time.

SIP Local Response Code Mapping Configuration

The following instructions explain how to create the SIP response code map and then how to assign it to a specific session agent.

Creating a SIP Response Code Map

To create a SIP local response code map:

1. Access the **sip-response-map** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-response-map
ORACLE(sip-response-map)#
```

2. **name**—Enter the name of the SIP response map you want to configure.

   This value is required and must be unique.

```
ORACLE(response-map)# name busy
```

3. **entries**—Configure the entries for this mapping.

   Typing a question mark will show you the response code entry parameters that you can configure.

```
ORACLE(response-map)# entries
ORACLE(response-map-entries)#
```

   a. **recv-code**—Enter original SIP response code for the recv-mode parameter.

      The valid range is:

      - Minimum—100
      - Maximum—699

```
ORACLE(response-map-entries)# recv-mode 486
```

   b. **xmit-code**—Enter the SIP response code into which you want the original response code to be translated.

      This valid range is:

      - Minimum—100
      - Maximum—699

```
ORACLE(response-map-entries)# xmit-mode 600
```

   c. **reason**—Enter a reason for the translated code into the reason parameter.

      This response comment is sent with the translated code. Make your entry in quotation marks.

```
ORACLE(response-map-entries)# reason "Busy Everywhere"
```

   d. **method**—Enter the name of the received SIP failure response message you want to map to a 200 OK.

> **Note:**
>
> There is no default for this parameter, and leaving the parameter empty turns off the SIP registration response mapping feature.

e. **register-response-expires**—Enter the time you want to use for the expires time what mapping the SIP method you identified in the **method** parameter.

   The maximum is 999999999. By default, the expires time is the Retry-After time (if there is one in the response) or the expires value in the Register request (if there is no Retry-After expires time). Any value you configure in this parameter (when not using the defaults) should never exceed the Register request's expires time.

4. Note the name that you gave the SIP response code map so that you can use it when you configure a session agent to support SIP response code mapping.
5. Save and activate your changes.

Assigning SIP Response Code Maps to Session Agents

To assign a SIP local response code map to a session agent:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

4. **local-response-map—Enter the name of the configured SIP response map that you want to use for this session-agent** and press Enter.

```
ORACLE(session-agent)# local-response-map busy
```

5. Save and activate your configuration.

Assigning SIP Response Code Maps to SIP Interfaces

To apply SIP response codes maps to a SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

4. **local-response-map**—Enter the name of the configured SIP response map that you want to apply to this SIP interface for locally-generated SIP responses. This parameter is blank by default.
5. Save and activate your configuration.

Specific Reason Headers in 503 Response

The Oracle Communications Session Border Controller issues a 503 Service Unavailable SIP response code when it fails to fulfill an apparently valid request because it is undergoing maintenance or is temporarily overloaded and so cannot process the request. This feature changes the reason phrase in the SIP response from the generic “Service Unavailable” to one that specifies the overload condition when exceeding provisioned session capacity, transcoding sessions, or DSP resources.

The Oracle Communications Session Border Controller sends SIP responses with the values of **status-code** and **sip-reason** in the **local-response-map-entries** configuration element as status text when the provisioned session capacity, transcoding sessions, or DSP resource capacity has reached its maximum limit and the capacity has been noted in the **local-error** parameter of the **local-response-map-entries** configuration element. The SBC issues the generic “Service Unavailable” when the capacity has not been noted in the in the **local-response-map-entries** configuration element. Additionally, this feature adds the values of **q.850-cause** and **q.850-reason** in the **local-response-map-entries** configuration element to the reason header when the value of **add-reason header** in the **sip-config** configuration element is **enabled**.

> **Note:**
>
> When SBC reaches the session-capacity, by default SBC sends “503 licensed-session-capacity-reached”.

Specific Reason Headers in 503 Response Configuration

1. Access the **entries** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# local-response-map
ORACLE(local-response-map)# local-response-map-entries
ORACLE(local-response-map-entries)#
```

2. Select the **entries** object to edit.

```
ORACLE(local-response-map-entries)# select

ORACLE(local-response-map-entries)#
```

3. Type **local-error** followed by a space and then one of the following phrases:
   - **transcoding-licensed-session-capacity-reached** — changes the sip-reason field in the SIP response from “Service Unavailable” to "SIP_LOCAL_ERROR_TRANSCODING_LICENSED_SESSION_CAPACITY_REACHED" when there are no more available transcoding licenses.
   - **dsp-resource-limit-reached** — changes the sip-reason field in the SIP response from “Service Unavailable” to "SIP_LOCAL_ERROR_DSP_RESOURCE_LIMIT_REACHED" when there are no more available DSP resources.
4. Type **done** to save your configuration.

Session Agent Ping Message Formatting

You can configure the user portions of the Request-URI and To: headers that define the destination of a session agent ping message, and the From: header that defines the source of a session agent ping message. These headers are sent to Oracle Communications Session Border Controller session agent. This feature is required for interoperability with certain E911 servers.

In the following example of a session agent ping-type message, you can set the user portion of the Request-URI (the text bob in the OPTIONS method line) and the user portion of the From: header (the text bob in the From: header) to the same new value. You can also set the user portion of the To: header (the text anna in the To: header) to its own new value.

```
OPTIONS sip:bob@sip.com SIP/2.0
From: UA1 <sip:bob@sip.com>
To: NUT <sip:anna@gw.sip.com>
Call-ID: 123abc@desk.sip.com
CSeq: 1 OPTIONS
Contact: <sip:UA1@client.sip.com>
Accept: application/sdp
Content-Length: 0
```

If you do not enable this feature, then the session agent ping-type message contains the text ping in all cases.

Session Agent Ping Message Formatting Configuration

1. Access the **session-agent** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# session-agent
ORACLE(session-agent)
```

2. Select the **session-agent** object to edit.

```
ORACLE(session-agent)# select
<hostname>:
1: 192.168.100.101:1813

selection: 1
ORACLE(session-agent)#
```

3. **ping-from-user-part**—Set the user portion of the From: header that defines the source of a session agent ping message.

```
ORACLE(session-agent)# ping-from-user-part bob
```

4. **ping-to-user-part**—Set the user portions of the Request-URI and To: headers that define the destination of a session agent ping message.

```
ORACLE(session-agent)# ping-to-user-part anna
```

5. Type **done** to save your configuration.

SIP Session Agent Continuous Ping

You can configure the Oracle Communications Session Border Controller to use either a keep-alive or continuous method for pinging SIP session agents to determine their health—i.e., whether or not the SBC should route requests to them.

To summarize the two methods:

- keep-alive— SBC sends a ping message of a type you configure to the session agent in the absence of regular traffic.
- continuous—The SBC sends a ping message regardless of traffic state (regular or irregular); the SBC regularly sends a ping sent based on the configured ping interval timer.

By sending ping messages, the SBC monitors session agents' health and can determine whether or not to take a session out of service (OOS), leave it in service, or bring it back into service after being OOS.

When you set it to use the keep-alive mode of pinging, the SBC starts sending a configured ping message to a session agent when traffic for that session agent has become irregular. The SBC only sends the ping if there are no SIP transactions with a session agent over a configurable period of time, to which the session agent's response can have one of the following results:

- Successful response—A successful response is either any SIP response code or any response code not found in the **out-service-response-codes** parameter; these leave the session agent in service. In addition, any successful response or any response in the **ping-in-service-response-codes** parameter can bring a session agent from OOS to in-service status.
- Unsuccessful response—An unsuccessful response is any SIP response code configured in the **out-service-response-codes** parameter and takes the session agent sending it OOS. Because this parameter is blank by default, the SBC considers any SIP response code successful.
- Transaction timeout—A transaction timeout happens when the session agent fails to send a response to the SBC's request, resulting in the session agent's being taken OOS.

Despite the fact that the keep-alive ping mode is a powerful tool for monitoring session agents' health, you might want to use the continuous ping method if you are concerned about the SBC not distinguishing between unsuccessful responses from next-hop session agents and ones from devices downstream from the next-hop session agent. For example, if a SIP hop beyond the session agent responds with a 503 Service Unavailable, the SBC does not detect whether a session agent or the device beyond it generated the response.

When you use the continuous ping method, only the next-hop session agent responds—preventing the request from being sent to downstream devices. The SBC also sends the ping in regular traffic conditions when in continuous ping mode, so it is certain the response comes from the next hop associated with the session agent. And in continuous ping mode, only entries for the **ping-out-service-response-codes** parameter and transaction timeouts bring session agents OOS.

> **Note:**
>
> The SBC also brings a Session Agent from OOS to in-service if it receives any SIP request from the session agent device.

By default, if the SBC does not receive a response to the ping from the session-agent, it marks it as out-of-service. You can configure the number of ping failures that the SBC can receive before it marks the session-agent as out-of-service. This is achieved by configuring the OPTIONS parameter in the session-agent with a ping-failure value, where value is the number of ping response failures. This is true for both the keep-alive and continuous-ping modes.

For example, set the Options parameter by typing **options**, followed by a Space, the option name: **ping-failure-count=N** (where N is the number of ping response failures before the SA is set to OOS) and press Enter. You may prepend the option parameter with a plus sign to add and not replace this option to the existing realm-config option list.

```
ORACLE (session-agent) #options +ping-failure-count=3
```

The session-agent is set out of service after the third ping response failure.

To remove the ping-failure-count option configuration, enter options **-ping**

```
ORACLE (session-agent) #options -ping
```

SIP SA Continuous Ping Configuration

You can set the ping mode in the session agent or session constraints configuration. The default for the ping-send-mode parameter is keep-alive.

Configure Ping Mode for Session Agents

1. Access the session-agent configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# session-agent
ORACLE(session-agent)
```

2. If you are adding to an existing configuration, then you will need to select the configuration you want to edit.
3. **ping-send-mode**—If to want to use continuous ping mode to send ping messages to session agents in regular traffic conditions, set this parameter to **continuous**. If you want to use the keep-alive mode, leave this parameter set to **keep-alive** (default).
4. Save and activate your configuration.

Configure Ping Mode for Session Constraints

1. Access the **session-constraints** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# session-constraints
ORACLE(session-agent)
```

2. If you are adding to an existing configuration, then you will need to select the configuration you want to edit.
3. **ping-send-mode**—If to want to use continuous ping mode to send ping messages to session agents in regular traffic conditions, set this parameter to **continuous**. If you want to use the keep-alive mode, leave this parameter set to **keep-alive** (default).
4. Save and activate your configuration.

SIP PAI Stripping

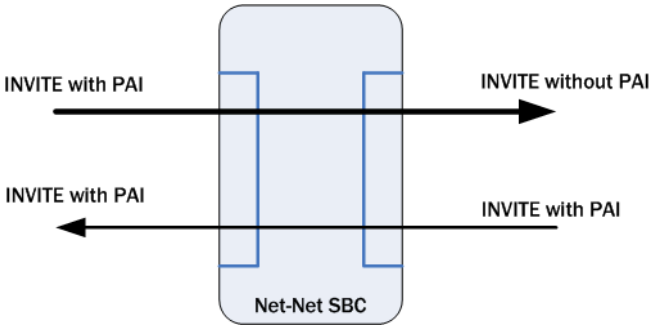
The Oracle Communications Session Border Controller now has the ability to strip P-Asserted-Identity (PAI) headers so that service providers can ensure an extra measure of security against malicious users pretending to be legitimate users. To pretend to represent another account, the malicious users simply send an INVITE with an imitation PAI. This feature allows real-time detection of such fraudulent use.

This feature uses a combination of:

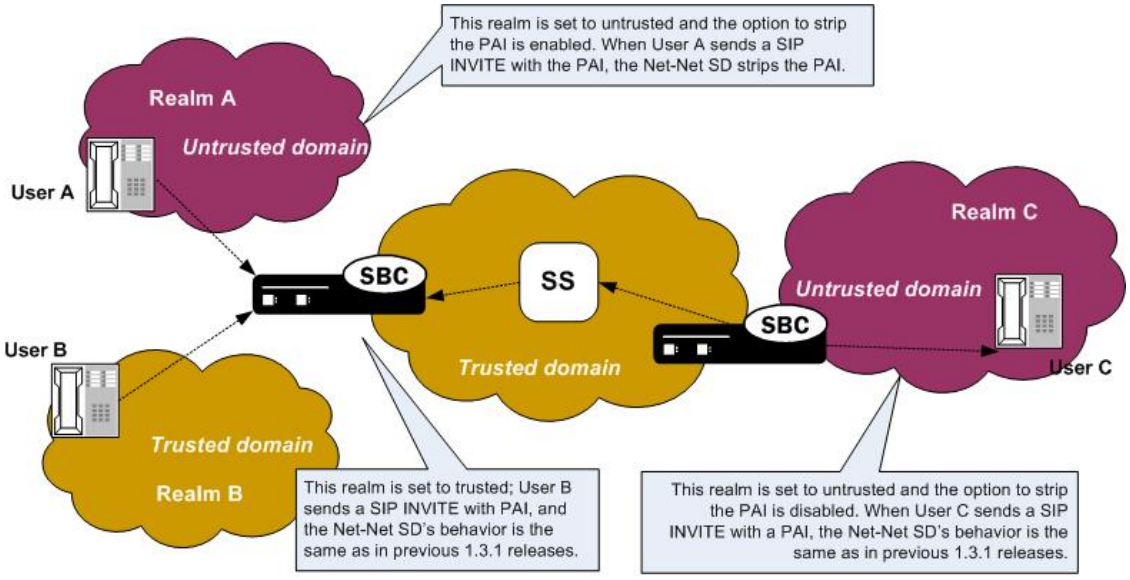
- DoS protection applied on a per-realm basis
- SIP PAI header stripping

The combination of these settings can produce different results for the SIP PAI stripping feature.

- SIP PAI header stripping enabled for an untrusted realm—If the PAI stripping parameter is set to enabled in a realm that is untrusted, then the Oracle Communications Session Border Controller strips the PAI headers from SIP INVITEs that are received from the external address, regardless of the privacy type. The Oracle Communications Session Border Controller then sends the modified INVITE (without the PAI). If the INVITE comes from a trusted realm, then the Oracle Communications Session Border Controller does not strip the PAI header and the system behaves as it does when you are using previous 1.3.1 releases.



- Multiple SIP PAIs in a SIP INVITE—The Oracle Communications Session Border Controller removes all PAIs when there are multiple PAIs set in SIP INVITEs that come from untrusted realms.
- Oracle Communications Session Border Controller behavior bridging trusted and untrusted realms—The following graphics shows you how Oracle Communications Session Border Controllers can be positioned and configured to handle PAI stripping between trusted and untrusted realms.

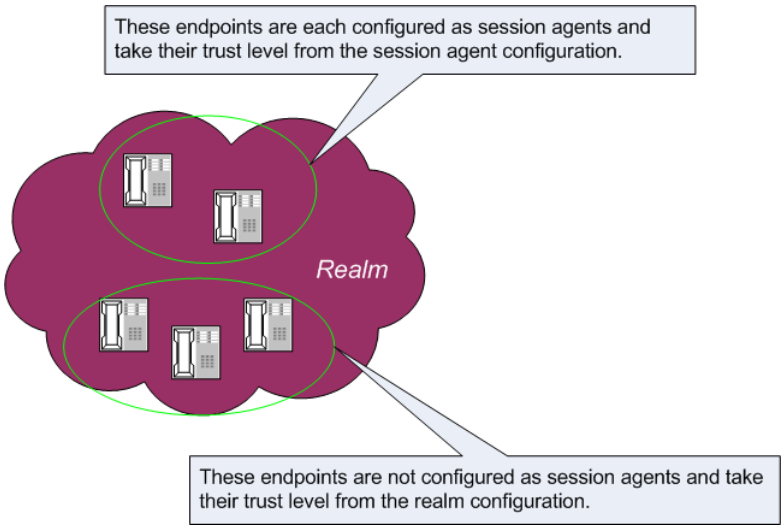


Realm Configuration Settings	REALM A	REALM B	REALM C
Realm designation trusted or untrusted (trust-me)	Disabled	Enabled	Enabled
SIP PAI stripping (pai-strip)	Enabled	Enabled or disabled	Disabled
SBC's behavior	Strip PAI regardless of privacy type	Same as behavior for SIP privacy support in previous 1.3.1 releases	Same as behavior for SIP privacy support in previous 1.3.1 releases

SIP PAI Stripping Configuration

When you configure this feature, please note how the Oracle Communications Session Border Controller behaves when you combine the designation of a realm as trusted/untrusted and SIP PAI stripping is enabled. Enter the choices for the ACLI **trust-me** and **pai-strip** parameters accordingly.

Be aware that trust is also established in the session agent configuration, and that the trust level set in a session agent configuration overrides the trust set in a realm configuration. For example, a realm might have several endpoints, some of which are associated with session agents and some of which are not. The endpoints that have configured session agent will take their trust level from the session agent parameters you set; the other endpoints, ones that are not associated with session agents, take their trust level from the realm parameters you set.



Take this relationship into consideration when you configure SIP PAI header stripping, or this feature will not work as designed.

For the sample configuration cited below, the desired Oracle Communications Session Border Controller behavior is to always strip the PAI regardless of privacy type.

To configure SIP PAI stripping for an existing realm using the ACLI:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-manager path.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. Select the realm to which you want to apply this feature.

```
ORACLE(realm-config)# select
identifier:
1: acmePacket <none>           192.168.20.0/24
2: realm1     <none>           0.0.0.0
selection:2
ORACLE(realm-config)#
```

5. **pai-strip**—Enable PAI stripping. The default is **disabled**. Valid values are:
   - enabled | disabled

```
ORACLE(realm-config)# pai-strip enabled
```

6. Save your work using the ACLI **save** or **done** command.

SIP Statuses to Q.850 Reasons

This section explains the Oracle Communications Session Border Controller's ability to map Q.850 cause values with SIP responses, a feature used in SIP calls and calls that require IWF.

RFC 3326 defines a header that might be included in any in-dialogue request. This reason header includes cause values that are defined as either a SIP response code or ITU-T Q.850 cause values. You can configure the Oracle Communications Session Border Controller to support sending and receiving RFC 3326 in SIP messages for:

- Mapping H.323 Q.850 cause values to SIP responses with reason header and cause value
- Mapping SIP response messages and RFC 3326 reason header and cause
- Locally generated SIP response with RFC 3326 reason header and cause

As specified in RFC 3326, the Oracle Communications Session Border Controller sends SIP responses to the softswitch that contain the received Q.850 cause code and the reason.

Though the Oracle Communications Session Border Controller can generate RFC 3326 headers, the default behavior for this feature is disabled. Furthermore, the Oracle Communications Session Border Controller can receive and pass SIP error messages (4xx, 5xx, and 6xx) that contain the SIP reason header with a Q.850 cause code and reason (as specified in RFC 3326). If the system receives an error message without the Reason header, then the Oracle Communications Session Border Controller is not required to insert one.

In calls that require IWF, the Q.850 cause generated in the SIP response are the same as the cause received in the following H.225 messages: Disconnect, Progress, Release, Release Complete, Resume Reject, Status, and Suspend Reject. In addition, the Q.850 cause codes that the Oracle Communications Session Border Controller receives in RFC 3326 headers are passed to the H.323 part of the call unmodified; the H.323 call leg uses this cause code for releasing the call.

SIP-SIP Calls

The SIP Reason header might appear in any request within a dialog, in a CANCEL request, and in any response where the status code explicitly allows the presence of this header field. The syntax of the header follows the standard SIP parameter:

```
Reason: SIP;cause=200;text="completed elsewhere"
Reason: Q.850;cause=16;text="Terminated"
```

This feature attends to the following possible SIP call scenarios:

- When the Oracle Communications Session Border Controller receives a SIP request or SIP response that contains the Reason header, the Oracle Communications Session Border Controller passes it without modification.
- When it generates a SIP response, the Oracle Communications Session Border Controller includes the RFC 3326 Reason header containing a Q.850 cause code and reason. This is the case for all local conditions and for all internally generated error responses (4xx, 5xx, and 6xx) to an initial SIP INVITE.
  Possible local error scenarios are:
  - invalid-message
  - cpu-overloaded
  - media-released
  - media-not-allocated

Configure Reason and Cause Mapping for SIP-SIP Calls

To configure reason-cause mapping for SIP-SIP calls, you must set up the ACLI local-response-map configuration with appropriate entries to generate the SIP response and the Q.850 cause code value used for particular error scenarios. If you want to add a Reason header, you must enable that capability in the global SIP configuration.

In the following procedure use the method parameter and the register-response-expires parameter to enable a SIP registration response mapping feature that allows you to configure the system to remap a SIP failure response to a 200 OK. The failure response can come from another network device or the system can generate the response locally. You might want the system to perform such mapping when a non-malicious endpoint continually attempts registration, but stops when the system sends a 200 OK. The failure response mapping does not register the client with the system, which leaves neither a registration cache entry nor a CAM ACL for the entry.

For the 200 OK it generates, the system removes any Reason or Retry-After header in the 200 OK and sets the expires time. By default, the expires time is the Retry-After time (if there is one in the response) or the expires value in the Register request (if there is no Retry-After expires time). You can also set this value using the register-response-expires parameter, but the value you set should never exceed the Register request's expires time.

1. Access the **entries** configuration element.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# session-router
   ORACLE(session-router)# local-response-map
   ```

```
ORACLE(local-response-map)# local-response-map-entries
ORACLE(local-response-map-entries)#
```

2. (Optional) Type **?** to see the entire menu for the local response map entries configuration.
3. **local-error**—Set the local error that triggers the use of this local response map. No default.

> **Note:**
>
> The Enterprise and Service Provider systems both display the full list, but some items do not apply to both systems. Such items are noted.

4. Type **local-error ?** to see the entire list of local errors that you can configure.
5. **sip-status**—Set the SIP response code to use. No default value. Range: 100-699.
6. **sip-reason**—Set the SIP reason string you want to use for this mapping. No default value. If the value contains spaces between the characters, you must surround the entry with quotation marks.
7. **q850-cause**—Set the Q.850 cause. No default value. Range: 0-2147483647.
8. **q850-reason**—Set the Q.850 reason string that you want to use for this mapping. No default value. If your value has spaces between characters, then your entry must be surrounded by quotation marks.
9. method—Enter the name of the received SIP failure response message you want to map to a 200 OK.

   No default. Leave the parameter empty to turn off the SIP registration response mapping feature.
10. register-response-expires—Enter the time you want to use for the expires time you identified in the method parameter.

    The maximum is 999999999. By default, the expires time is the Retry-After time (if there is one in the response) or the expires value in the Register request (if there is no Retry-After expires time). Any value you configure in this parameter (when not using the defaults) should never exceed the Register request's expires time.
11. (Optional) Repeat this process to create the number of local response map entries that you need.
12. Save and activate the configuration for changes to take effect.

Configure the System to Add Reason Headers

To enable the SBC to add the Reason header:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type session-router and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type sip-config and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. add-reason-header—Enable this parameter to add the Reason header(s) to responses and CDRs.

   The default value is disabled. The valid values are:

   - enabled | disabled

5. Save and activate your configuration for changes to take effect.

Calls Requiring IWF

For interworking calls between SIP and H.323, you can configure:

- Mappings for SIP status codes to Q.850 values
- Mappings for particular Q.850 cause codes to SIP status codes

If it cannot find the appropriate mapping, then the Oracle Communications Session Border Controller uses default mappings defined in the Default Mappings table below.

The following describes how the Oracle Communications Session Border Controller handles different IWF call scenarios:

- SIP request containing a Reason header—When it receives a request containing a Reason header, the Oracle Communications Session Border Controller determines if the request is a SIP BYE or SIP CANCEL message. RFC 3326 states that the Reason header is mainly used for these types of requests. If there is a Reason header and it contains the Q.850 cause value, then the Oracle Communications Session Border Controller releases the call on the H.323 side using the specified cause value.
- SIP response—When it receives the error response to an initial SIP INVITE, the Oracle Communications Session Border Controller uses its SIP-Q.850 map to determine the Q.850 that it will use to release the call. If there is not a map entry, then the Oracle Communications Session Border Controller uses the default mappings shown in the Default Mappings table.
- Active call released from the H.323 side—If an active call is released from the H.323 side, the Oracle Communications Session Border Controller checks the outgoing realm (the SIP side) to see if the addition of the Reason header is enabled. If it is, then the Oracle Communications Session Border Controller adds the Reason header in the SIP BYE request with the Q.850 value it received from the H.323 side.
- Error during setup of the call on the H.323 side—In the event of an error during setup on the H.323 side of the call, the system needs to send:
  - An error response, if this is a SIP to H.323 call
  - A SIP CANCEL, if this is a H.323 to SIP call and the H.323 side hangs up before the call is answered on the SIP side
    In this case, the Oracle Communications Session Border Controller checks to see if adding the Reason header is enabled in the IWF configuration. If it is, then the Oracle Communications Session Border Controller adds the Reason header with the Q.850 cause value it received from the H.323 side.
- Call released due to a Oracle Communications Session Border Controller error—If the call is released due a Oracle Communications Session Border Controller error and adding the Reason header is enabled in the IWF configuration, the error response to the initial INVITE

contains the Reason header. The Oracle Communications Session Border Controller checks the SIP to Q.850 map configurations to determine whether or not the SIP error response code it is generating is configured. If it is, then the Oracle Communications Session Border Controller maps according to the configuration. If if it not, the Oracle Communications Session Border Controller derives cause mapping from the default table.

Like the configuration for SIP-only calls that enable this feature, you can set a parameter in the IWF configuration that enables adding the Reason header in the SIP requests or responses.

Default Mappings

This table defines the default mappings the Oracle Communications Session Border Controller uses when it cannot locate an appropriate entry that you have configured.

Q.850 Cause Value Number	Q.850 Cause Value Number	SIP Status Number	SIP Status Text	Comments
1	Unallocated number	404	Not found	N/A
2	No route to specified transit network	404	Not found	N/A
3	No route destination	404	Not found	N/A
16	Normal calling clearing	N/A	BYE message	A call clearing BYE message containing cause value 16 normally results in the sending of a SIP BYE or CANCEL request. However, if a SIP response is to be sent to the INVITE request, the default response code should be used.
17	User busy	486	Busy here	N/A
18	No user responding	408	Request timeout	N/A
19	No answer from the user	480	Temporarily unavailable	N/A
20	Subscriber absent	480	Temporarily unavailable	N/A
21	Call rejected	603	Decline (if location filed in Cause information element indicates user; otherwise 403 Forbidden is used)	N/A
22	Number changed	301	Moved permanently (if information in diagnostic field of Cause information element is suitable for generating SIP Contact header; otherwise 410 Gone is used)	N/A
23	Redirection to new destination	410	Gone	N/A
25	Exchange routing error	483	Too many hops	N/A
27	Destination out of order	502	Bad gateway	N/A
28	Address incomplete	484	Address incomplete	N/A

Q.850 Cause Value Number	Q.850 Cause Value Number	SIP Status Number	SIP Status Text	Comments
29	Facility rejected	501	Not implemented	N/A
31	Normal, unspecified	480	Temporarily unavailable	N/A
34	No circuit, channel unavailable	503	Service unavailable	N/A
38	Network out of order	503	Service unavailable	N/A
41	Temporary failure	503	Service unavailable	N/A
42	Switching equipment congestion	503	Service unavailable	N/A
47	Resource unavailable unspecified	503	Service unavailable	N/A
55	Incoming calls barred with CUG	403	Forbidden	N/A
57	Bearer capability not authorized	403	Forbidden	N/A
58	Bearer capability not presently available	503	Service unavailable	N/A
65	Bearer capability not implemented	488	Not acceptable here	N/A
69	Requested facility not implemented	501	Not implemented	N/A
70	Only restricted digital information available	488	Not acceptable here	N/A
79	Service or option not implemented, unspecified	501	Not implemented	N/A
87	User not member of CUG	403	Forbidden	N/A
88	Incompatible destination	503	Service unavailable	N/A
102	Recovery on timer expiry	504	Server time-out	N/A

SIP Status

To configure a SIP status to Q.850 Reason with cause mapping:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-q850-map** and press Enter.

```
ORACLE(session-router)# sip-q850-map
ORACLE(sip-q850-map)#
```

4. Type **entries** and press Enter.

```
ORACLE(sip-q850-map)# entries
ORACLE(sip-q850-map-entry)#
```

From here, you can view the entire menu for the SIP status to Q.850 Reason with cause mapping entries configuration by typing a **?**.

5. **sip-status**—Set the SIP response code that you want to map to a particular Q.850 cause code and reason. There is no default, and the valid range is:
   - Minimum—100
   - Maximum—699
6. **q850-cause**—Set the Q.850 cause code that you want to map to the SIP response code that you set in step 5. There is no default. Range: 0-2147483647.
7. **q850-reason**—Set the Q.850 reason corresponding to the Q.850 cause code that you set in step 6. There is no default. If your value has spaces between characters, then your entry must be surrounded by quotation marks.
8. Repeat this process to create the number of local response map entries that you need.
9. Save and activate your configuration for changes to take effect.

To configure a Q.850 cause to a SIP status with reason mapping:

10. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

11. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
```

12. Type **sip-q850-map** and press Enter.

```
ORACLE(session-router)# q850-sip-map
ORACLE(q850-sip-map)#
```

13. Type **entries** and press Enter.

```
ORACLE(q850-sip-map)# entries
ORACLE(q850-sip-map-entry)#
```

From here, you can view the entire menu for the Q.850 cause to a SIP response code with reason mapping entries configuration by typing a **?**.

14. **q850-cause**—Set the Q.850 cause code that you want to map to a SIP status with reason. There is no default.
15. **sip-status**—Set the SIP response code to which you want to map the Q.850 cause that you set in step 5. There is no default, and the valid range is:

- Minimum—100
- Maximum—699

16. **sip-reason**—Set the reason that you want to use with the SIP response code that you specified in step 6. There is no default. If your value has spaces between characters, then your entry must be surrounded by quotation marks.
17. Repeat this process to create the number of local response map entries that you need.
18. Save and activate your configuration for changes to take effect.

    To enable the Oracle Communications Session Border Controller to add the Reason header for calls that require IWF:

19. In Superuser mode, type **configure terminal** and press Enter.

    ```
    ORACLE# configure terminal
    ```

20. Type **session-router** and press Enter.

    ```
    ORACLE(configure)# session-router
    ```

21. Type **iwf-config** and press Enter.

    ```
    ORACLE(session-router)# iwf-config
    ACMEPACKET(iwf-config)#
    ```

22. **add-reason-hdr**—Enable this parameter to add the Reason header. The default is **disabled**. The valid values are:

    - enabled | disabled

23. Save and activate your configuration for changes to take effect.

Trunk Group URIs

The Oracle Communications Session Border Controller's trunk group URI feature, applicable for SIP and IWF signaling services, enables the capabilities related to trunk groups that are described in this section. This implementation follows the IPTEL draft Representing Trunk Groups in Tel/SIP Uniform Resource Identifiers (URIs) (draft-ietf-iptel-trunk-group-06.txt), and also supports more customized approaches.

- For a typical access call flow scenario, when the calling party's call arrives at the Oracle Communications Session Border Controller, the Oracle Communications Session Border Controller formulates a SIP INVITE message that it sends to a softswitch. The Oracle Communications Session Border Controller now supports a new URI contact parameter in the SIP request message so that service providers need to be able to:
  - Determine from where the Oracle Communications Session Border Controller received the call
  - Signal information about the originating gateway from a Oracle Communications Session Border Controller to a softswitch (e.g., an incoming trunk group or a SIP gateway to a Oracle Communications Session Border Controller)
- This feature supports the signaling of routing information to the Oracle Communications Session Border Controller from network routing elements like softswitches. This information tells the Oracle Communications Session Border Controller what egress route (or outgoing trunk groups) it should choose for terminating next hops/gateways. For this purpose, new SIP URI parameters in the Request-URI are defined. Additional URI

parameters include the network context to identify the network in which the originating or terminating gateway resides.

- Especially important for large business applications, this feature can free Oracle Communications Session Border Controller resources by reducing the number of local policy, session agent, and session agent group configurations. By enabling the trunk group URI feature, the Oracle Communications Session Border Controller instead uses a routing scheme based on signaled SIP URI information.

Terminology

The following IPTEL terms are used in the descriptions of and instructions for how to configure this feature:

- Trunk—In a network, a communication path connecting two switching systems used in the establishment of an end-to-end connection; in selected applications, it may have both its terminations in the same switching system
- Trunk group—A set of trunks, traffic engineered as a unit, for the establishment of connections within or between switching systems in which all of the paths are interchangeable except where sub-grouped
- Trunk group name—Provides a unique identifier of the trunk group; referred to as tgrp
- Trunk group context—Imposes a namespace by specifying a domain where the trunk groups are; also referred to simply as context

Trunk Group URI Parameters

Trunk group URI parameters identify originating and terminating trunk group information in SIP requests.

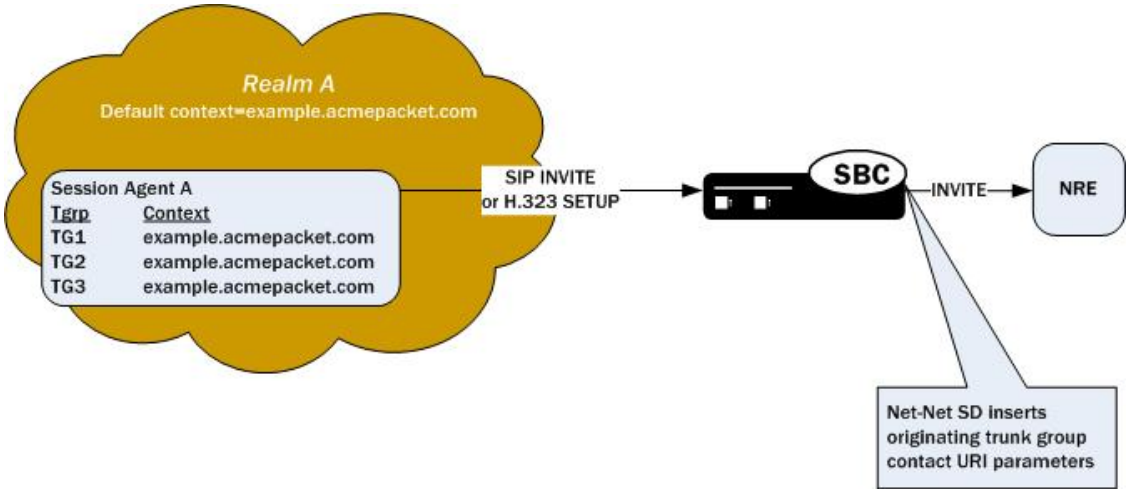
In the absence of official SIP standards for transporting trunk groups between signaling elements, the Oracle Communications Session Border Controller allows you to define URI parameters for use with originating and terminating trunk group URIs.

Originating Trunk Group URI Parameters and Formats

You can configure session agents and session agents groups on the Oracle Communications Session Border Controller to insert trunk group URI parameters in the SIP contact header. When SIP gateways comply with the IPTEL draft, they include the originating URI parameter in the SIP contact header. For those SIP and H.323 gateways that are not compliant, the Oracle Communications Session Border Controller inserts SIP trunk group URI parameters on the gateway's behalf.

When there are no applicable session agent or session agent group configurations, the Oracle Communications Session Border Controller uses the source IP address of the endpoint or gateway as the trunk group name (tgrp) parameter in the originating trunk group URI.

The following diagram shows a scenario where the Oracle Communications Session Border Controller inserts originating trunk group URI parameters.



There are two available formats for the originating trunk group URIs:

1. In compliance with the IPTEL draft, the first format has two parameters: tgrp (identifier of the specific trunk group) and trunk-context (defines the network domain of the trunk group). These appear in the following formats:
   - tgrp=”trunk group name”
   - trunk-context=”network domain”

     The URI BNF for would appear as it does in the example directly below, where the tgrp is tg55 and the trunk-context is trunk-context is telco.example.com:

     ```
     tel:+15555551212;tgrp=tg55;trunk-context=telco.example.com
     ```

2. The second format is customized specifically for access URIs and contains two provisioned parameters: tgrp (or tgname) and context (or provstring). This appears as tgrp.context, where these definitions apply:
   - tgrp (tgname)—Provisioned trunk group name for the originating session agent; this value must have at least one alphabetical character, cannot contain a period (.), and can contain a hyphen (-) but not as the first or the last character
   - context (provstring)—Name of the originating trunk group context; this value must have at least one alphabetical character in the top label

     This format conforms to format for a hostname in the SIP URI as specified in RFC 3261, such that a trunk group identifier would appear as:

     ```
     custsite2NY-00020.type2.voip.carrier.net
     ```

     where the tgrp is custsite2NY-00020, and the context is type2.voip.carrier.net.

     The BNF for an access URI conforms to the following:

     SIP-URI = "sip:" [userinfo] hostport uri-parameters [headers]

     uri-parameters = *(";" uri-parameter)

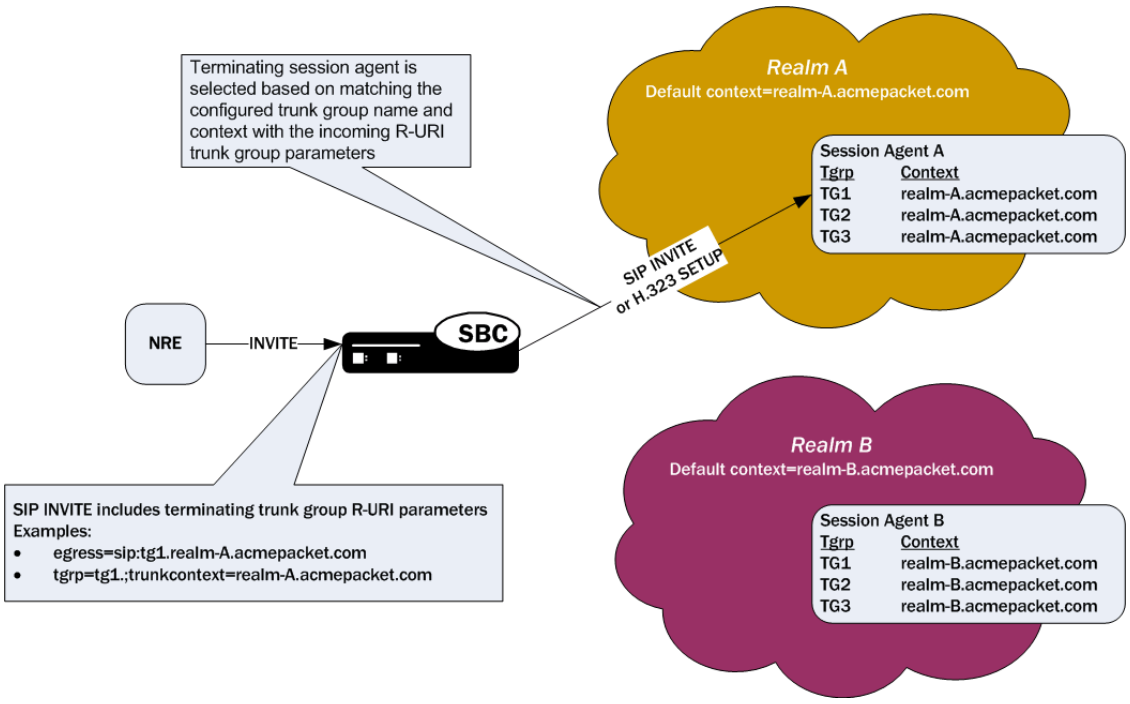
     uri-parameter = transport-param / user-param / method-param

/ ttl-param / maddr-param / lr-param / other-param

```
other-param = accessid / pname [ '=' pvalue ]
accessid = "access=" accessURI
accessURI = scheme tgname ["." provstring]
scheme = "sip:" / token
tgname = ALPHA / *(alphanum) ALPHA *(alphanum / "-") alphanum /
    alphanum *(alphanum / "-") ALPHA *(alphanum) # up to 23 characters
provstring = *(domain ".") toplabel # up to 24 characters
toplabel = ALPHA / ALPHA *( alphanum / "-" ) alphanum
domain = alphanum/ alphanum *( alphanum / "-" ) alphanum
```

Terminating Trunk Group URI Parameters and Formats

Terminating trunk group URI parameters appear in the R-URI, and they can be included in by a network routing element to instruct the Oracle Communications Session Border Controller which egress trunk groups to use. By matching the trunk group URI parameter with configured session agents or session agent groups, the Oracle Communications Session Border Controller can locate the terminating gateway. The trunk group name can also be expressed as the IP address of the terminating gateway.



In the absence of official SIP standards for transporting trunk groups between signaling elements, the Oracle Communications Session Border Controller allows you to define the URI parameters used in terminating trunk groups.

There are two available formats for the terminating trunk group URIs:

1. In compliance with the IPTEL draft, the first format has two parameters: tgrp (which can be either a trunk group name or an IP address) and trunk-context (defines the network domain of the trunk group). These appear in the following formats:
   - tgrp=”trunk group name”

- trunk-context=”network domain”

  An example R-URI with terminating trunk group parameters appears as follows, where the tgrp is TG2-1 and the context is isp.example.net@egwy.isp.example.net:

```
INVITE sip:+15555551212;tgrp=TG2-1;trunk-
context=isp.example.net@egwy.isp.example.net SIP/2.0
```

2. The second format is customized specifically for egress URIs and contains two provisioned parameters: tgrp (or tgname) and context (or tgdomain). This appears as tgrp.context (or tgname.tgdomain), where definitions apply:

   - tgrp (tgname)—Provisioned trunk group name for the originating session agent; this value must have at least one alphabetical character, cannot contain a period (.), and can contain a hyphen (-) but not as the first or the last character
   - context (tgdomain)—Name of the terminating trunk group context; this value can be up to twenty-four characters

     The use of multiple terminating trunk groups is not supported.

     The BNF for a single, egress URI with trunk group information conforms to:

```
SIP-URI = "sip:" [userinfo ] hostport uri-parameters [headers ]
uri-parameters = *( ";" uri-parameter )
uri-parameter = transport-param / user-param / method-param
            / ttl-param / maddr-param / lr-param / other-param
other-param = egressid  / pname [ '=' pvalue ]
egressid = "egress=" egressURI
egressURI = scheme tgname ["." tgdomain]
scheme = "sip:" / token
tgname = ALPHA / *(alphanum) ALPHA *(alphanum / "-") alphanum /
    alphanum *(alphanum / "-") ALPHA *(alphanum) # up to 23 characters
tgdomain = *(domain ".") toplabel # up to 24 characters
toplabel = ALPHA / ALPHA *( alphanum / "-" ) alphanum
domain = alphanum/ alphanum *( alphanum / "-" ) alphanum
```

     For all trunk group URI support, you must set the appropriate parameters in the SIP manipulations configuration and in the session agent or session agent group configurations.

     In the originating trunk group URI scenario, a call arrives at the Oracle Communications Session Border Controller from a configured session agent or session agent group. If this session agent or session agent group has the appropriate trunk group URI parameters and inbound manipulation rules configured, the Oracle Communications Session Border Controller then looks to the SIP manipulations configuration and add the trunk group URI information according to those rules. Those rules tell the Oracle Communications Session Border Controller where and how to insert the trunk group URI information, and the system forwards the call.

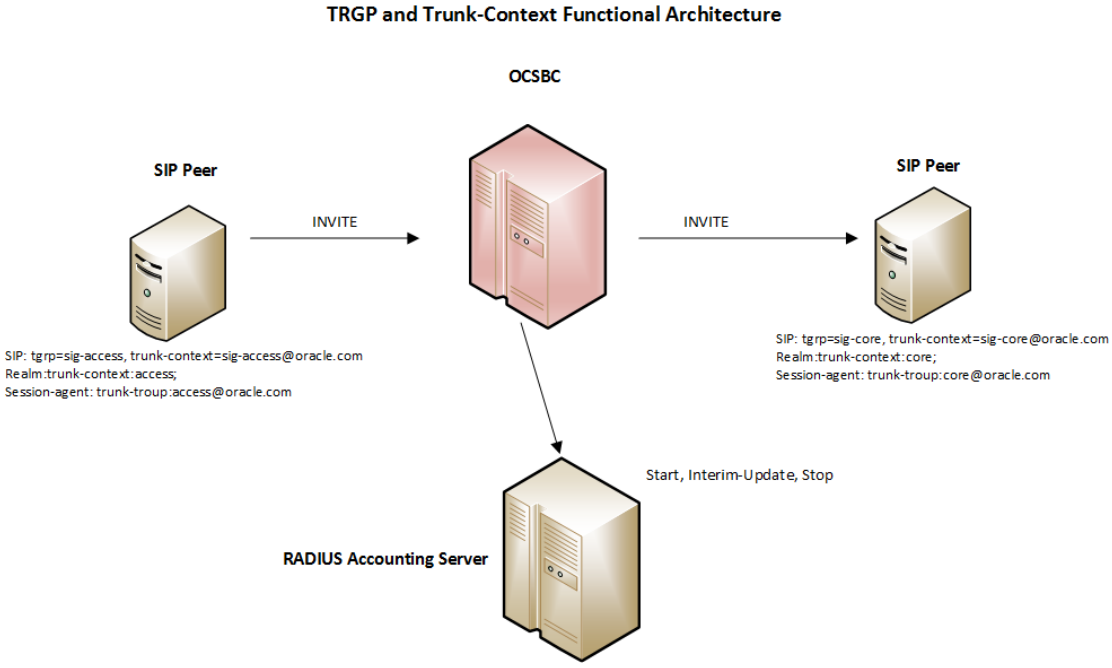
     In the terminating trunk group scenario, a call arrives at the Oracle Communications Session Border Controller from, for instance, a call agent. This call contains information about what trunk group to use. If the information matches a session agent or session agent group that has outbound manipulation rules configured, the Oracle Communications Session Border Controller will then look up the SIP manipulations configuration and strip information according to those rules. Those rules tell the Oracle Communications Session Border Controller where and how to remove the information, and the Oracle Communications Session Border Controller forwards the call.

Trunk Group Signaling Parameters

The Oracle Communications Session Border Controller supports a dynamic reading of the initial INVITE message of the session Contact header and Request URI tag parameter. This facilitates populating the Trunk Group and Trunk Context parameters into the existing AVPs.

For Ingress messages, if the **trunk-group** and the **trunk-context** parameters are configured in the session agent and the realm-configuration respectively, the Oracle Communications Session Border Controller populates these values in the Acme-Originating-Trunk-Group and the Acme-Originating Trunk-Context AVPs of the START/INTERMIDIATE/STOP accounting records. Similarly for an Egress session, if the trunk-group and the trunk-context parameters are configured in the session agent and the realm-configuration respectively, the Oracle Communications Session Border Controller populates these values in the Acme-Terminating-Trunk-Group and the Acme-Terminating-Trunk-Context AVPs of the START/INTERIM/STOP accounting records.

The following diagram shows the functional architecture of a typical access call flow scenario with Trunk Group and Trunk-Context parameters



The received SIP signaling URI trunk group parameters can be populated into the accounting AVP parameters for ingress and egress legs by adding the **populate-signaling-tgrp** option in the session-agent.

```
ORACLE#(session-agent) options +populate-signaling-tgrp
```

In the absence of the **trunk-group** and **trunk-context** parameters from the session-agent and realm-configuration respectively of the Ingress Session, if the session-agent is configured with the option **populate-signaling-tgrp**, the Oracle Communications Session Border Controller will decode the tgrp and trunk-context parameters received in the initial INVITE message 'Contact header' of the session and cache these values for the session duration. SBC will then populate these received parameter values in Acme-Originating-Trunk-Group and Acme-

Originating-Trunk-Context AVPs of START/INTERMEDIATE/STOP accounting records. Similarly for the egress session, the SBC will decode the tgrp and trunk-context parameters received in first INVITE message 'Request-URI' of the session and cache these values for the session duration. SBC will then populate these received parameter values in Acme-Terminating-Trunk-Group and Acme-Terminating-Trunk-Context AVPs of START/INTERIM/STOP accounting records.

Oracle Communications Session Border Controller will cache and populate only if both tgrp and trunk-context and present in the Contact header. In the absence of even one of the parameters the system will discard the received parameter and will not populate the parameter to the corresponding AVP.

SIP Header and Parameter Manipulation

SIP header and parameter manipulation is its own configuration where you can set up rules for the addition, removal, and modification of a SIP header or the elements of a SIP header. For example, you can set up the configuration to add a URI parameter to the URI in a SIP header or replace an FQDN with in IP address. For trunk group URI support, this configuration tells the Oracle Communications Session Border Controller where and how to manipulate the SIP message to use originating (access) and terminating (egress) trunk group URI parameters.

These manipulations can be applied at the realm or at the session agent level.

Trunk Group Routing

You can configure SIP interfaces (using the ACLI **term-tgrp-mode** parameter) to perform routing based on the trunk group information received in SIP requests. There are three options: none, IPTEL, and egress URI.

- If you leave this parameter set to none (its default), the Oracle Communications Session Border Controller will not look for or route based on terminating trunk group URI parameters
- When you set this parameter to either **iptel** or **egress-uri** and the incoming request has the trunk group parameter of this type (IPTEL or egress URI), the Oracle Communications Session Border Controller will select the egress next hop by matching the “tgrp” and trunk context with a configured session agent or session agent group.
  If the received terminating trunk group URI parameters include an IP address, the egress next hop is the IP address specified. The Oracle Communications Session Border Controller determines the egress realm by matching the trunk context it receives with the trunk context you configure for the realm.
- If the incoming request does not have trunk group parameters or it does not have trunk group parameters of the type that you configure, the Oracle Communications Session Border Controller uses provisioned procedures and/or local policy for egress call routing.

The Oracle Communications Session Border Controller returns errors in these cases:

- If the terminating trunk group URI parameters do not identify a local Oracle Communications Session Border Controller session agent or session agent group, then the Oracle Communications Session Border Controller returns a SIP final response of 488 Not Acceptable Here.
- If the Oracle Communications Session Border Controller receives a SIP INVITE with terminating trunk group URI parameters that do not match the specified syntax, the Oracle Communications Session Border Controller returns a 400 final response with the reason phrase Bad Egress=Parameters.

Trunk Group URIs and SIP Registration Caching

For calls where SIP registration caching is used, you will need to set certain parameters that enable the Oracle Communications Session Border Controller to preserve trunk group URI parameters on the outgoing side.

- For SIP-SIP calls, you set the preserve-user-info **option** in the SIP interface configuration.
- For SIP-H.323 calls requiring IWF, you set the preserve-user-info-sa **option** in the session agent configuration.

Trunk Group URI Configuration

Before you configure your Oracle Communications Session Border Controller to support trunk group URIs, you need to determine:

- How you want to manipulate SIP headers (entered in the SIP header manipulations configuration)
- For terminating trunk group routing, the trunk group mode you want to use (none, IPTEL, or egress URI); this decides routing based on trunk group information
- The trunk group name and context to use entered in a session agent or session agent group configuration
- Whether you are using originating or terminating trunk group URIs (entered in the session agent configuration)
- The trunk group context for use in a realm configuration, in case the trunk group name in the session agent or session agent group does not have a context

Precedence Used for Trunk Group Configurations

The Oracle Communications Session Border Controller (SBC) can insert trunk-group/trunk-context URIs into applicable SIP messages when the upstream SIP or H.323 gateways do not. The values inserted are dependent on SBC configuration and use configuration precedence when configurations conflict.

The SBC uses the following precedence when choosing these element's trunk-group and trunk-context configuration values for routing.

1. **session-agent** (SA)
2. **session-group** (SAG)
3. **realm**

> **Note:**
>
> Do not configure a trunk context without a trunk-group.

The examples below present configurations for SA, SAG and realm and the resulting trunk group and context values to be inserted. Examples also include an explanation for the result.

Example 1 (Result—trgp1:contextg)

- SA Configuration: **trunk-group** tgrp1

- SAG Configuration: **trunk-group** tgrp2:context2
- Realm Configuration: **trunk-context** contextg

The SBC selects SA trunk-group value. The SA has no context, so the SBC uses the realm's context value.

Example 2 (Result—trgp1:context1)

- SA Configuration: **trunk-group** tgrp1:context1
- SAG Configuration: **trunk-group** tgrp2:context2
- Realm Configuration: **trunk-context** contextg

The SBC selects the SA trunk-group and context values.

Example 3 (Result—trgp2:context2)

- SA Configuration: **trunk-group** [null]
- SAG Configuration: **trunk-group** tgrp2:context2
- Realm Configuration: **trunk-context** contextg

The SBC selects the SAG trunk-group and context values.

Example 4 (Result—trgp2:contextg)

- SA Configuration: **trunk-group** [null]
- SAG Configuration: **trunk-group** tgrp2
- Realm Configuration: **trunk-context** contextg

The SBC selects the SAG trunk-group's value. The SAG has no context, so the SBC uses the realm's context value.

Example 5 (Result—none)

- SA Configuration: **trunk-group** [null]
- SAG Configuration: **trunk-group** [null]
- Realm Configuration: **trunk-context** contextg

The SBC has no configured trunk-group value and cannot support a context without a group.

Example 6 (Result—ABC)

- SA Configuration: **trunk-group** [null]
- SAG Configuration: **trunk-group** ABC
- Realm Configuration: **trunk-context** [null]

The SBC selects the SAG trunk-group's value, and does not use a context.

Configuring SIP Manipulations

When you configure the SIP header manipulations to support trunk group URIs, take note of:

- The name of the configuration, so that you can use it when you apply the manipulations in a session agent for the inbound or outbound manipulations
- The **new-value** parameter, which specifies the trunk group and trunk group context that you want to manipulate; the possible values that apply to trunk group URI configurations are $TRUNK_GROUP and $TRUNK_GROUP_CONTEXT

Setting the Trunk Group URI Mode for Routing

To set the mode for routing for terminating trunk group URIs:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. **term-tgrp-mode**—Set the mode that you want to use for routing for terminating trunk group URIs. The default is **none**. Your choices are:
   - **none**—Disables routing based on trunk groups
   - **iptel**—Uses trunk group URI routing based on the IPTEL formats
   - **egress-uri**—Uses trunk group URI routing based on the egress URI format

Configuring a Session Agent for Trunk Group URIs

In a session agent, you can configure the outbound or inbound SIP header manipulation rules to use, as well as a list of trunk group names and contexts. For the trunk group names and contexts, you can use either the IPTEL or the custom format.

To configure a session agent for trunk group URIs:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-agent** and press Enter.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

4. **out-manipulationid**—Enter the name of the SIP header manipulations configuration that you want to apply to the traffic exiting the Oracle Communications Session Border Controller via this session agent. There is no default.
5. **in-manipulationid**—Enter the name of the SIP header manipulations configuration that you want to apply to the traffic entering the Oracle Communications Session Border Controller via this session agent. There is no default.
6. **trunk-group**—In either IPTEL or custom format, enter the trunk group names and trunk group contexts to match. If you do not set the trunk group context, then the Oracle

Communications Session Border Controller will use the one you set in the realm for this session agent.

Your ACLI entries for this list must be one of these formats: tgrp:context or tgrp.context.

To make multiple entries, surround your entries in parentheses and separate them from each other with spaces. For example:

```
ORACLE(session-agent)# trunk-group (tgrp1:context1 tgrp2:context2)
```

7. **options**—If you want to configure trunk group URIs for SIP-H.323 calls that use the IWF and you are using SIP registration caching, you might need to add the preserve-user-info-sa to your list of session agent options.

   If you are adding this option to a new session agent, you can just type **options**, a Space, and **preserve-user-info-sa**.

   If are adding this to an existing session agent, you must type a plus (+) sign before the option or you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign: options +preserve-user-info-sa.

Configuring a Session Agent Group for Trunk Group URIs

In a session agent group, you can configure the outbound or inbound SIP header manipulation rules to use, as well as a list of trunk group names and contexts. For the trunk group names and contexts, you can use either the IPTEL or the custom format.

To configure a session agent group for trunk group URIs:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-group** and press Enter.

   ```
   ORACLE(session-router)# session-group
   ORACLE(session-agent-group)#
   ```

4. **trunk-group**—In either IPTEL or custom format, enter the trunk group names and trunk group contexts to match. If you do not set the trunk group context, then the Oracle Communications Session Border Controller will use the one you set in the realm for this session agent group.

   Your ACLI entries for this list must take one of these formats: tgrp:context or tgrp.context.

   To make multiple entries, surround your entries in parentheses and separate them from each other with spaces. For example:

   ```
   ORACLE(session-agent-group)# trunk-group (tgrp1:context1 tgrp2:context2)
   ```

Setting a Trunk Group Context in a Realm

You can set trunk group contexts at the realm level, which will be used by all session agents and session agent groups if there is no context specified in their configurations.

The realm trunk group URI context accommodates the IPTEL and the custom format.

To configure a trunk group context for a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm-config** and press Enter.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. **trunk-context**—Enter the trunk group context to use for this realm. There is no default.

Using this Feature with a SIP Interface

If you are using the trunk group URIs feature with SIP interface that has registration caching enabled, then you need to configure the preserve-user-info option for that SIP interface.

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-group** and press Enter.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. **options**—Add support for trunk group URIs with SIP interface that uses registration caching.

   If you are adding this option to a new SIP interface, you can just type **options**, a Space, and **preserve-user-info**.

   If are adding this to an existing SIP interface**, you must type a plus (+) sign before the option or you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign: options +preserve-user-info**.

Example 1 Adding Originating Trunk Group Parameters in IPTEL Format

This ACLI sample shows you how the ACLI SIP manipulations might appear in a case where you want to add originating trunk parameters in IPTEL format.

```
sip-manipulation
        name                            add_iptel
        header-rule
                name                            contact
                action                          manipulate
                match-value
                msg-type                        any
                element-rule
                        name                            tgrp
                        type                            uri-user-param
                        action                          add
                        match-val-type                  any
                        match-value
                        new-value                       $TRUNK_GROUP
element-rule
                        name                            trunk-context
                        type                            uri-user-param
                        action                          add
                        match-val-type                  any
                        match-value
                        new-value                       $TRUNK_GROUP_CONTEXT
```

Example 2 Adding Originating Trunk Group Parameters in Custom Format

This ACLI sample shows you how the ACLI SIP manipulations might appear in a case where you want to add originating trunk parameters in custom format.

```
sip-manipulation
        name                            add_att
        header-rule
                name                            contact
                action                          manipulate
                match-value
                msg-type                        any
                element-rule
                        name                            egressURI
                        type                            uri-param
                        action                          add
                        match-val-type                  any
                        match-value
                        new-value
"sip:"+$TRUNK_GROUP+"."+$TRUNK_GROUP_CONTEXT
```

Example 3 Removing IPTEL Trunk Group Names

This ACLI sample shows you how the ACLI SIP manipulations might appear in a case where you want to remove IPTEL trunk groups names.

```
sip-manipulation
        name                            strip_iptel
        header-rule
                name                            request-uri
                action                          manipulate
                match-value
                msg-type                        any
                element-rule
                        name                            tgrp
                        type                            uri-user-param
                        action                          delete-element
                        match-val-type                  any
                        match-value
                        new-value
element-rule
                        name                            trunk-context
                        type                            uri-user-param
                        action                          delete-element
                        match-val-type                  any
                        match-value
                        new-value
```

Example 4 Removing Custom Trunk Group Names

This ACLI sample shows you how the ACLI SIP manipulations might appear in a case where you want to remove custom trunk groups names.

```
sip-manipulation
        name                            strip_egress
        header-rule
                name                            request-uri
                action                          manipulate
                match-value
                msg-type                        any
                element-rule
                        name                            egressURI
                        type                            uri-param
                        action                          delete-element
                        match-val-type                  any
                        match-value
                        new-value
```

Emergency Session Handling

The Oracle Communications Session Border Controller provides a mechanism to handle emergency sessions from non-allowed endpoints. An endpoint is designated as non-allowed if

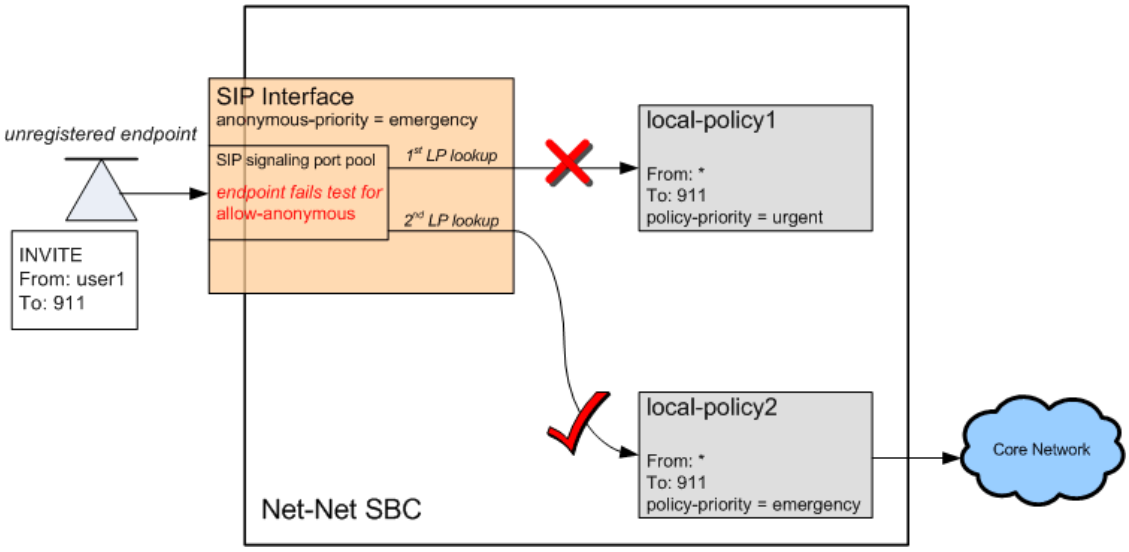
it fails the admission control criteria specified by the allow-anonymous parameter in the SIP Ports configuration element.

When the Oracle Communications Session Border Controller receives a non-allowed emergency request, it performs a local policy lookup for a matching local policy. An emergency local policy could be configured to match if the To: header in a SIP message was addressed to 911.

An emergency policy priority selection criteria has been added to both the SIP interface and the local policy configuration elements. In the SIP interface, the parameter is called anonymous-priority. In the local policy, the parameter is called policy-priority.

For the Oracle Communications Session Border Controller to choose a local policy to route an emergency call, the emergency policy priority value on the local policy must be equal to or greater than the emergency policy priority value on the SIP interface where the emergency message was received. In this scheme, an emergency policy priority value of none is the lowest value and an emergency policy priority value of emergency is the highest.

When a match is made between all existing local policy criteria and the emergency policy priority, the emergency call will be sent to the core network according to the chosen local policy. In addition, the policy priority value of the chosen local policy is inserted into the Priority header of the core-bound SIP message..



Emergency Session Handling Configuration Procedures

Note the value of the allow-anonymous parameter in the SIP interface's SIP Ports for the incoming interface you are configuring. When an incoming emergency call from an unregistered endpoint can not be characterized by this setting, the Oracle Communications Session Border Controllerwill use the following means to route the call.

Set the anonymous-priority parameter in the incoming SIP interface. This parameter specifies that for an INVITE received from an anonymous endpoint, the Oracle Communications Session Border Controller will choose a local policy of equal or greater policy priority for outbound routing.

Next, set the policy-priority parameter located in the local-policy configuration element. Most likely, this local policy will route messages to SIP devices that act on emergency calls. The

local policy is selected when its value (or above) matches the anonymous-priority parameter in the sip-interface that receives the incoming phone call from an unregistered endpoint.

The enumerated values for both the anonymous-priority and policy-priority are: none, normal, non-urgent, urgent, emergency.

Emergency Session Handling Configuration

To set the anonymous priority for a message received in a SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. Type **select** and the number of the SIP interface you want to configure.

   ```
   ORACLE(sip-interface)# select 1
   ```

5. **anonymous-priority—Set the policy priority for this SIP interface. It is used to facilitate emergency sessions from unregistered endpoints. This value is compared against the policy-priority parameter in the local-policy configuration element. The default is none. The valid values are:**

   - none | normal | non-urgent | urgent | emergency

     This completes the configuration.

     ```
     ORACLE(sip-interface)# anonymous-priority emergency
     ```

6. Save your work using the ACLI **done** command.

Setting Policy Priority

To set the policy priority for a local policy:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **local-policy** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# local-policy
ORACLE(local-policy)#
```

4. Type **select** and the number of the local policy you want to configure.

```
ORACLE(local-policy)# select 1
```

5. **policy-priority—Enter the policy priority for this local policy. It is used to facilitate emergency sessions from unregistered endpoints. This value is compared against the anonymous-priority parameter in the sip-interface configuration element. The default is none. The valid values are:**
   - none | normal | non-urgent | urgent | emergency

   This completes the configuration.

```
ORACLE(local-policy)# policy-priority emergency
```

6. Save your work using the ACLI **done** command.

Fraud Prevention

The Oracle Communications Session Border Controller can constrain outgoing SIP messages to a maximum size in bytes in order to support fraud prevention techniques. If a message does exceed the configured size, it is dropped. A SIP message can be constrained from 0 to 65535 bytes, with a default value of 4096 bytes.

Fraud Prevention Configuration

To set a maximum SIP message size:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. Type **select** to configure the existing sip config.

```
ORACLE(sip-config)# select
```

5. **sip-message-len**—Set the size constraint in bytes of a SIP message. The default is **4096**. The valid range is:

- Minimum—0
- Maximum—65535

  This completes the configuration.

```
ORACLE(sip-config)# sip-message-len 5000
```

6. Save your work using the ACLI **done** command.

Early Media Support

The Oracle Communications Session Border Controller (SBC) supports early media features, including SIP early media suppression, the Private Early Media (PEM) header, and multiple dialog management. This support complies with 3GPP TS 24.628, TS 24.182 and RFC 5009 behavior for sessions supporting early media.

Early media are the RTP/RTCP packets sent to or from the caller before a session is fully established by the receipt of a 200 OK. There are a variety of devices, including IVRs, that may generate this media. When the SBC receives an INVITE message with SDP, it can forward media packets conforming to that SDP to the calling endpoint as soon as it forwards the INVITE to the next hop. It can also forward media packets received from the calling side toward the called endpoint as soon as it receives SDP in a SIP response to the INVITE. These responses are usually provisional messages. This allows for any early media to be played, such as remote ringback or announcements.

Early media can be unidirectional or bidirectional, and can be generated by the caller, the callee, both, or by interim AS components. Important early media concepts for which the SBC provides feature support includes:

- Private Early Media (PEM) Header Support
- Early Media Suppression
- Early Media Support for Multiple Early Dialog Scenarios
- Selecting SDP within Multi-Dialog Call Scenarios

P-Early-Media SIP Header Support

Version S-CZ7.2.0 provides support for the SIP P-Early-Media that can be used in SIP INVITES, PRACKS, and UPDATES to request and authorize the use of early media. It offers an alternative to policy-based early media support.

The P-Early-Media SIP header is defined in RFC 5009, Private Header (P-Header) Extension to the Session Initiation Protocol (SIP) for Authorization of Early Media. RFC 5009 defines the use of the P-Early-Media header within SIP messages in certain SIP networks to authorize the cut-through of backward (server-to-client) and/or forward (client-to-server) early media when permitted by the early media policies of the networks involved. The P-Early-Media header field is intended for use in a SIP network, such as a 3GPP IMS that has the following characteristics: its early media policy prohibits the exchange of early media between end users; it is interconnected with other SIP networks that have unknown, untrusted, or different policies regarding early media; and it has the capability to gate (enable/disable) the flow of early media to/from user equipment.

P-Early-Media SIP Header

The P-Early-Media SIP header is defined in RFC 5009, Private Header (P-Header) Extension to the Session Initiation Protocol (SIP) for Authorization of Early Media. RFC 5009 defines the use of the P-Early-Media header within SIP messages in certain SIP networks to authorize the cut-through of backward (server-to-client) and/or forward (client-to-server) early media when permitted by the early media policies of the networks involved. The P-Early-Media header field is intended for use in a SIP network, such as a 3GPP IMS that has the following characteristics: its early media policy prohibits the exchange of early media between end users; it is interconnected with other SIP networks that have unknown, untrusted, or different policies regarding early media; and it has the capability to gate (enable/disable) the flow of early media to/from user equipment.

A SIP network containing both PSTN gateways and SIP end devices, for example, can maintain such an early media policy by gating "off" any early media with a SIP end device acting as UAS, gating "on" early media with a SIP end device acting as UAC, and gating "on" early media at each PSTN gateway. This is what we have been doing for years with the SIP early media suppression feature, which allows determining who can send early media and in what direction.

Unfortunately, in SIP interconnection scenarios there is no means of assuring that the interconnected network is implementing a compatible early media policy, thus allowing the exchange of user data within early media under some circumstances. For example, if a network "A" allows all early media with user equipment as UAC and an interconnected network "B" allows all early media with user equipment as UAS, any session established between user equipment as UAC in "A" and user equipment as UAS in "B" will allow bidirectional user data exchange as early media.

The P-Early-Media header is used for the purpose of requesting and authorizing requests for backward and/or forward early media. It's sent from UAS to UAC to indicate authorization for early media.

P-Early-Media-Header Usage

The syntax of the P-Early-Media header field is as follows.

```
P-Early-Media = "P-Early-Media" HCOLON[ em-param *(COMMA em-param) ]
       em-param  = "sendrecv" / "sendonly" / "recvonly" / "inactive" /
"gated" /
      "supported" / token
```

The P-Early-Media header is used for requesting and authorizing requests for backward and/or forward early media. The P-Early-Media header field in an INVITE request contains the "supported" parameter. If P-CSCF is part of the trusted domain, then it must decide whether to insert or delete the P-Early-Media header field before forwarding the INVITE. The P-CSCF upon receiving the P-Early-Media header field in a message towards the UAC needs to verify that the early media request comes from an authorized source. If a P-Early-Media header field arrives from either an untrusted source, a source not allowed to send backward early media, or a source not allowed to receive forward early media, then it may remove the P-Early-Media header field or alter the direction parameter(s) of the P-Early-Media header field before forwarding the message, based on local policy.

The P-Early-Media header field with the "supported" parameter in an INVITE request indicates that the P-CSCF on the path recognizes the header field. The P-Early-Media header field includes one or more direction parameters where each has one of the values: "sendrecv",

"sendonly", "recvonly", or "inactive", following the convention used for SDP stream directionality. Each parameter applies, in order, to the media lines in the corresponding SDP messages establishing session media. The parameter value "sendrecv" indicates a request for authorization of early media associated with the corresponding media line, both from the UAS towards the UAC and from the UAC towards the UAS. The value "sendonly" indicates request for authorization of early media from the sender to the receiver and not in the other direction. The value "recvonly" indicates a request for authorization of early media from the receiver, and not in the other direction. The value "inactive" indicates either a request that no early media associated with the corresponding media line be authorized, or a request for revocation of authorization of previously authorized early media. Each parameter applies, in order, to the media lines in the corresponding SDP lines. Unrecognized parameters are discarded and non-direction parameters are ignored. If there are more direction parameters than media lines, the excess are silently discarded. If there are fewer direction parameters than media lines, the value of the last direction parameter applies to all remaining media lines. The P-Early-Media header field in any message within a dialog towards the sender of the INVITE request can also include the non-direction parameter "gated" to indicate that a network entity on the path towards the UAS is already gating the early media, according to the direction parameter(s).

The P-Early-Media Header and the Rx Interface

As defined in 3GPP TS 24.229, IP multimedia call control protocol based on Session Initiation Protocol (SIP) and Session Description Protocol (SDP); Stage 3 both the P-CSCF and IBCF may add, remove, or modify, the P-Early-Media header field within forwarded SIP requests and responses according to procedures in RFC 5009.

The P-CSCF can use the P-Early-Media header field for the gate control procedures, as described in 3GPP TS 29.214. In the current implementation, if you set the configuration option **early-media-allow** to **none**, the SBC sends the Flow-Status AVP (511) in any AAR request set to disable until there is a final response.

Although you can configure the SBC to provide PEM header information within the Flow-Status AVP (511) to provide early media status over the Rx interface, there are two conditions that must be in place before it can populate this AVP with PEM header flags.

The SBC does not include PEM header feature status in the Rx Flow-Status AVP unless:

1. You enable the **get-flow-status-from-sdp** option in the **sip-config**.

   ```
   ORACLEACMEPACKET#(media-manager) options +get-flow-status-from-sdp
   ```

2. There has been an SDP exchange. Note that provisional responses without SDP, which occur prior any SDP exchange, do not generate update data within the Rx flow-status AVP even if they include PEM status.

Functional Design

Acceptance of and authorization for early media is accomplished with two new ACLI parameters -- **p-early-media-header** and **p-early-media-direction**, which are added to SIP interface configuration in Version S-CZ7.2.0 and later releases.

The **p-early-media-header** parameter will enable the feature when the value is set to either “add” or “modify”. The **p-early-media-header** and **p-early-media-direction** should be configured on egress interface of the incoming message. The values for parameter **p-early-media-direction** are “sendrecv, sendonly, recvonly, inactive”. It is a list and each configured value corresponds to the m-line in the SDP. If the number of configured values is more than the number of m-lines in the SDP, the excess configured values are ignored. If the number of configured value is less than the number of m-lines in the SDP, the last configured value is used for all the m-lines.

The following illustrations show the ingress and egress sip-interface configuration.

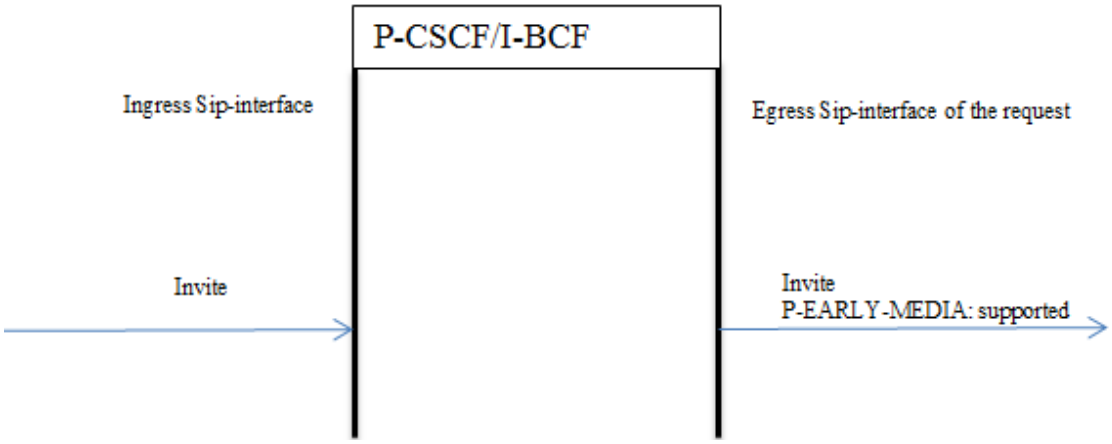


Figure 5-2 180 RINGING Specifying p-early-media Support

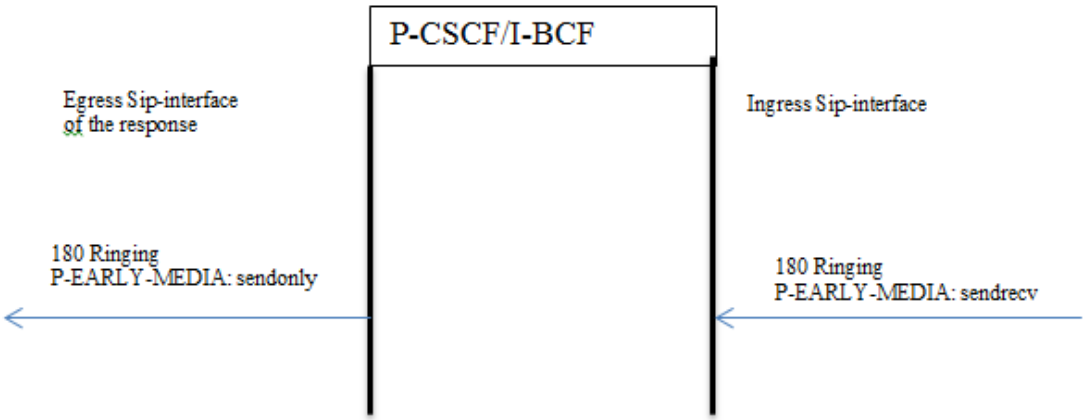


P-Early-Media headers in Re-Invites are ignored. If the SDP contains Content-Disposition: early-session the P-Early-Media header is ignored.

Endpoint is considered trusted or untrusted based on the configuration on the ingress sip-interface of the P-CSCF. Sip-interface has the configuration parameter “trust-mode”. If the “trust-mode” is set to “none” then nobody is trusted in sip-interface. By default the value is “all”. Possible values are <all, agents-only, realm-prefix, registered, none>.

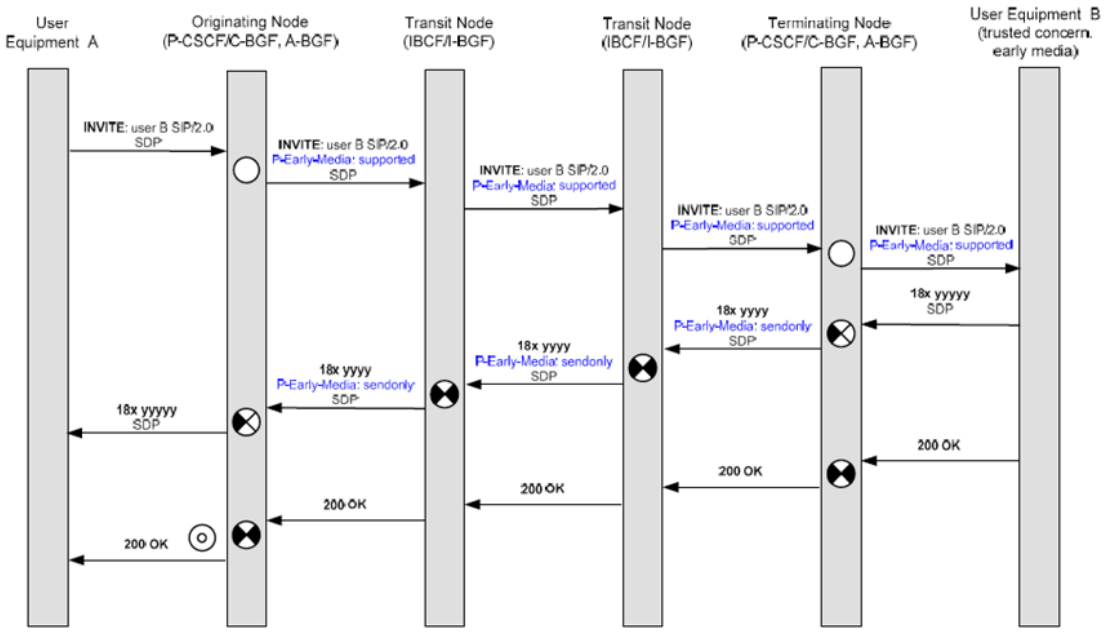
For multiple dialogs due to forking, P-CSCF will identify the media associated with a dialog, and then setup early media flow for the selected media. The configuration elements restricted-latching in realm-config, and latching in media-router should be enabled.

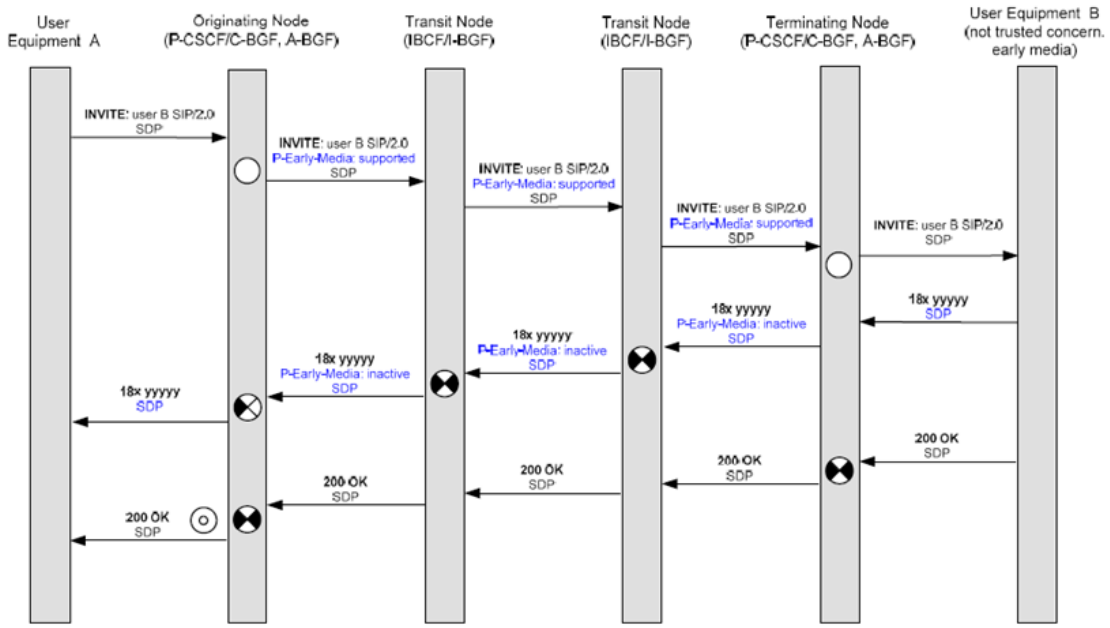
The following 3 tables detail early media implementation details.

P-Early-Media Trusted to Trusted

This table illustrates the P-CSCF case when messages are received from trusted endpoints and forwarded to trusted endpoints.

Message Parameters configured on egress interface	Request (Invite, UPDATE, PRACK) w/o header	Request (Invite, UPDATE, PRACK) with header with one or more direction parameters where each has one of the values: "sendrecv", "sendonly", "recvonly", or"inactive"	Response (18x, 200OK(UPDATE/ PRACK)) w/o header	Response (18x, 200OK(UPDATE/ PRACK) with header with one or more direction parameters where each has one of the values: "sendrecv", "sendonly", "recvonly", or"inactive"
p-early-media-header-"add" p-early-media-direction -"sendonly"	Add header with "supported" value. Setup flows based on SDP value	Add "supported" value if not present. Setup the flows based on the value in the SDP value.	Setup flows based on local config PEM value. Add the PEM header based on local config value. Status Flow AVP in AAR message updated.	Setup the flows based on the value in the incoming PEM header.
p-early-media-header-"modify" p-early-media-direction -"sendonly"	Add header with "supported" value. Setup flows based on SDP value	Add "supported" value if not present. Setup the flows based on the SDP value	Setup flows based on local config PEM value. Add the PEM header based on local config value. Status Flow AVP in AAR message updated.	Setup flows based on local config PEM value. Modify the PEM header based on local config value. Status Flow AVP in AAR message updated.
p-early-media-header-"add" No p-early-media-direction	Add header with "supported" value. Setup flows based on SDP value	Add "supported" value if not present. Setup the flows based on the SDP.	Setup flows based on local config PEM value. Add the PEM header based on default value. Status Flow AVP in AAR message updated.	Setup flows based on local config PEM value. Modify the PEM header based on default value. Status Flow AVP in AAR message updated.
p-early-media-header-"modify" No p-early-media-direction	Add header with "supported" value. Setup flows based on SDP value.	Add header with "supported" value if not present. Setup the flows based on the SDP.	config PEM value. Add the PEM header based on default value. Status Flow AVP in AAR message updated.	Setup flows based on local config PEM value. Modify the PEM header based on default value. Status Flow AVP in AAR message updated.





P-Early-Media Untrusted to Trusted

This table illustrates the P-CSCF case when messages are received from untrusted endpoints and forwarded to trusted endpoints.

Message Parameters configured on egress interface	Request (Invite, UPDATE, PRACK) w/o header	Request (Invite, UPDATE, PRACK) with header with one or more direction parameters where each has one of the values: "sendrecv", "sendonly", "recvonly", or"inactive"	Response (18x, 200OK(UPDATE/ PRACK)) w/o header	Response (18x, 200OK(UPDATE/ PRACK) with header with one or more direction parameters where each has one of the values: "sendrecv", "sendonly", "recvonly", or"inactive"
p-early-media-header-"add" p-early-media-direction -"sendonly"	Add header with "supported" value. Setup flows based on SDP value	Discard the header. Add the header with supported value. Setup flows based on SDP value.	Setup flows based on local config PEM value. Add the PEM header based on local config value. Status Flow AVP in AAR message updated.	Discard the header. Setup flows based on local config PEM value. Add the PEM header based on local config value. Status Flow AVP in AAR message updated.
p-early-media-header-"modify" p-early-media-direction -"sendonly"	Add header with "supported" value. Setup flows based on SDP value	Discard the header. Add the header with supported value. Setup flows based on SDP value.	Setup flows based on local config PEM value. Add the PEM header based on local config value. Status Flow AVP in AAR message updated.	based on local config PEM value. Add the PEM header based on local config value. Status Flow AVP in AAR message updated.
p-early-media-header-"add" No p-early-media-direction	Add header with "supported" value. Setup flows based on SDP value.	Discard the header. Setup flows based on SDP value.	Setup flows based on local config PEM value. Add the PEM header based on default value. Status Flow AVP in AAR message updated.	Discard the header. Setup flows based on local config PEM value. Add the PEM header based on default value. Status Flow AVP in AAR message updated.
p-early-media-header-"modify" No p-early-media-direction	Add header with "supported" value. Setup flows based on SDP value	Discard the header. Setup flows based on SDP value.	Setup flows based on local config PEM value. Add the PEM header based on default value. Status Flow AVP in AAR message updated.	Discard the header. Setup flows based on local config PEM value. Add the PEM header based on default value. Status Flow AVP in AAR message updated.

P-Early-Media Trusted to Untrusted

This table illustrates the P-CSCF case when messages are received from trusted endpoints and forwarded to untrusted endpoints.

Message Parameters configured on egress interface	Request (Invite, UPDATE, PRACK) w/o header	Request (Invite, UPDATE, PRACK) with header with one or more direction parameters where each has one of the values: "sendrecv", "sendonly", "recvonly", or"inactive"	Response (18x, 200OK(UPDATE/ PRACK)) w/o header.	Response (18x, 200OK(UPDATE/ PRACK) with header with one or more direction parameters where each has one of the values: "sendrecv", "sendonly", "recvonly", or"inactive"
p-early-media-header-"add" p-early-media-direction -"sendonly"	Setup flows based on SDP value.	Discard the header. Setup flows based on SDP value.	Setup flows based on SDP value.	Discard the header. Setup flows based on local config PEM value. Status Flow AVP in AAR message updated.
p-early-media-header-"modify" p-early-media-direction -"sendonly"	Setup flows based on SDP value.	Discard the header. Setup flows based on SDP value.	Setup flows based on SDP value.	Discard the header. Setup flows based on local config PEM value. Status Flow AVP in AAR message updated.
p-early-media-header-"add" No p-early-media-direction	Setup flows based on SDP value.	Discard the header. Setup flows based on SDP value.	Setup flows based on SDP value.	Discard the header. Setup flows based on default PEM value. Status Flow AVP in AAR message updated.
p-early-media-header-"modify" No p-early-media-direction	Setup flows based on SDP value.	Discard the header. Setup flows based on SDP value.	Setup flows based on SDP value.	Discard the header. Setup flows based on default PEM value. Status Flow AVP in AAR message updated.

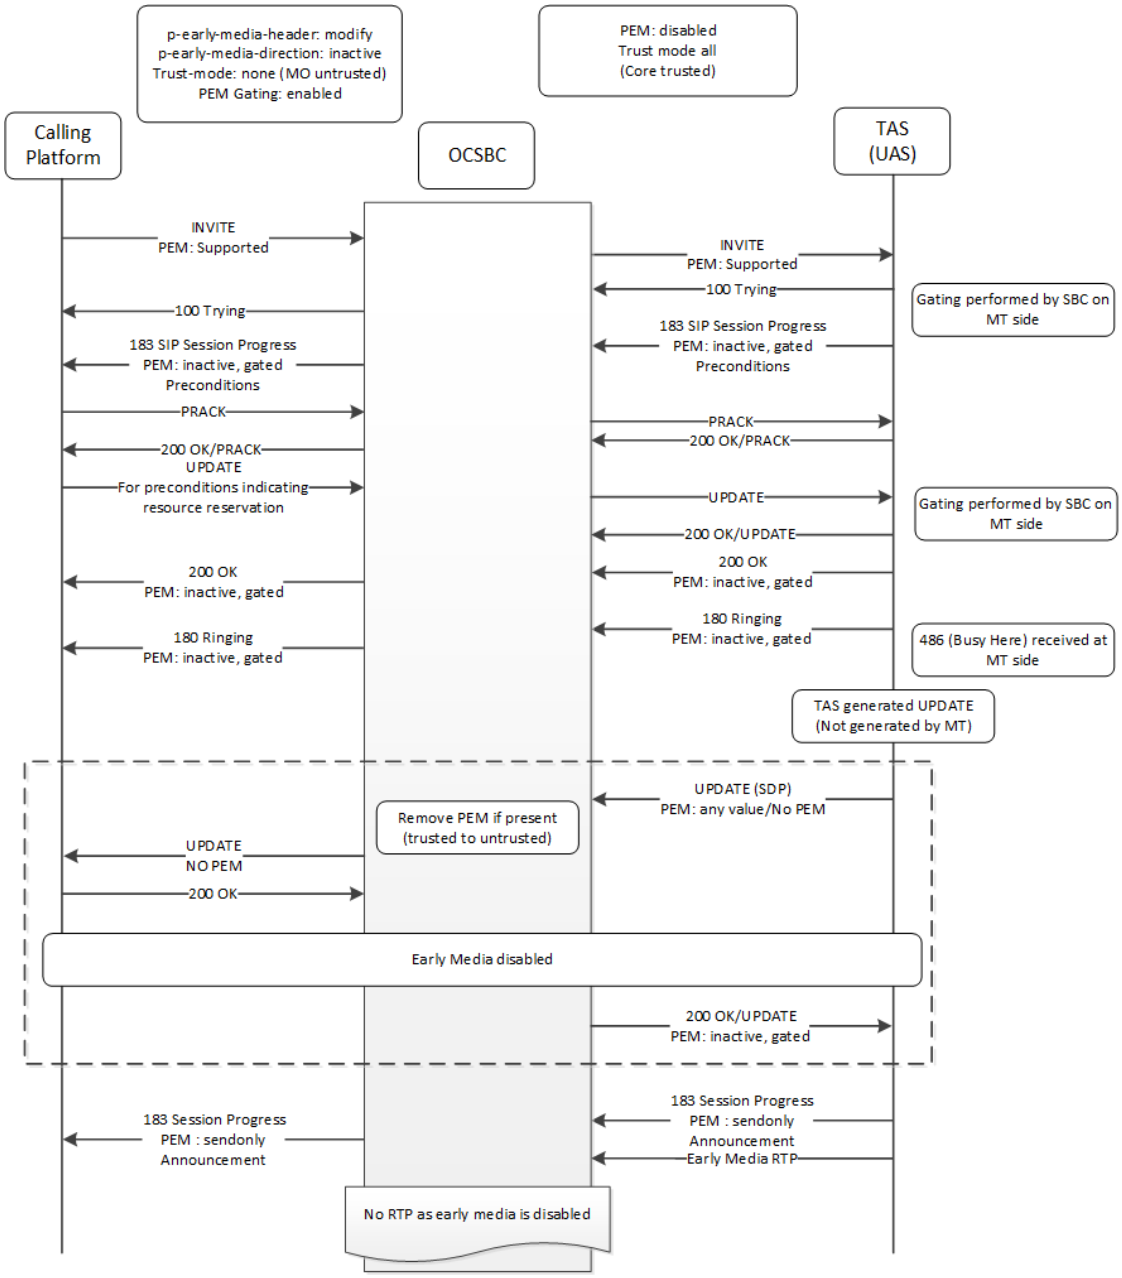
Bypassing Early Media Gating

You can configure the SBC to bypass gating and forward early media to untrusted domains. This feature resolves early media problems for situations including PEM gating when an UPDATE goes from the trusted side towards the untrusted side and the system prevents an early media announcement to play through the subsequent 18x. In this case, the default SBC behavior would be to gate the early media. To configure this feature, you enable the **pass-pem-in-update** option on the ingress **sip-interface**.

The SBC supports the SIP P-Early-Media (PEM) header and function used within SIP INVITE, PRACK, and UPDATE requests and responses to authorize the use of early media. Standard and default SBC behavior includes preventing early media signaling from entering networks that are not authorized or are not trusted. In some deployments, however, administrators may want early media forwarded even if the network is not trusted.

The SBC uses two key **sip-interface** parameters to control early media, including **p-early-media-header** and **p-early-media-direction**. Both of these parameters are effectively disabled by default, which gates early media from operating across the interface. In addition, you can set the **trust-mode** according to your setup (none, all, agents and so on), which establishes multiple security behaviors on the interface, including gating early media from a trusted source.

The call flow below presents an example of the issues this feature resolves. In this flow, the SBC closes the gate on early media when it receives the 200 OK to the UPDATE from the mobile originating (MO) side, depicted within the dashed box. This is default SBC behavior, resulting in PEM being inactive on the access side, and, in this call flow, prevents the presentation of early media on the MO leg.



An example of a problem case solved by this features includes the SBC receiving an UPDATE with a PEM header arriving from the trusted mobile terminating (MT) leg/core side. Without this feature, the SBC follows its default behavior, which includes not forwarding the PEM header towards the untrusted access side:

- If you set the **p-early-media-header** access **sip-interface** to **modify** and the **p-early-media-direction** is inactive, the 200 OK response to the update from the MO effectively closes the gate.

- The SBC closes the gate when receiving the 200 OK to the UPDATE from the MO side, which is by design (PEM inactive on access), thereby gating early media on the MO leg. In this case, the access is always untrusted, and the core is always trusted.

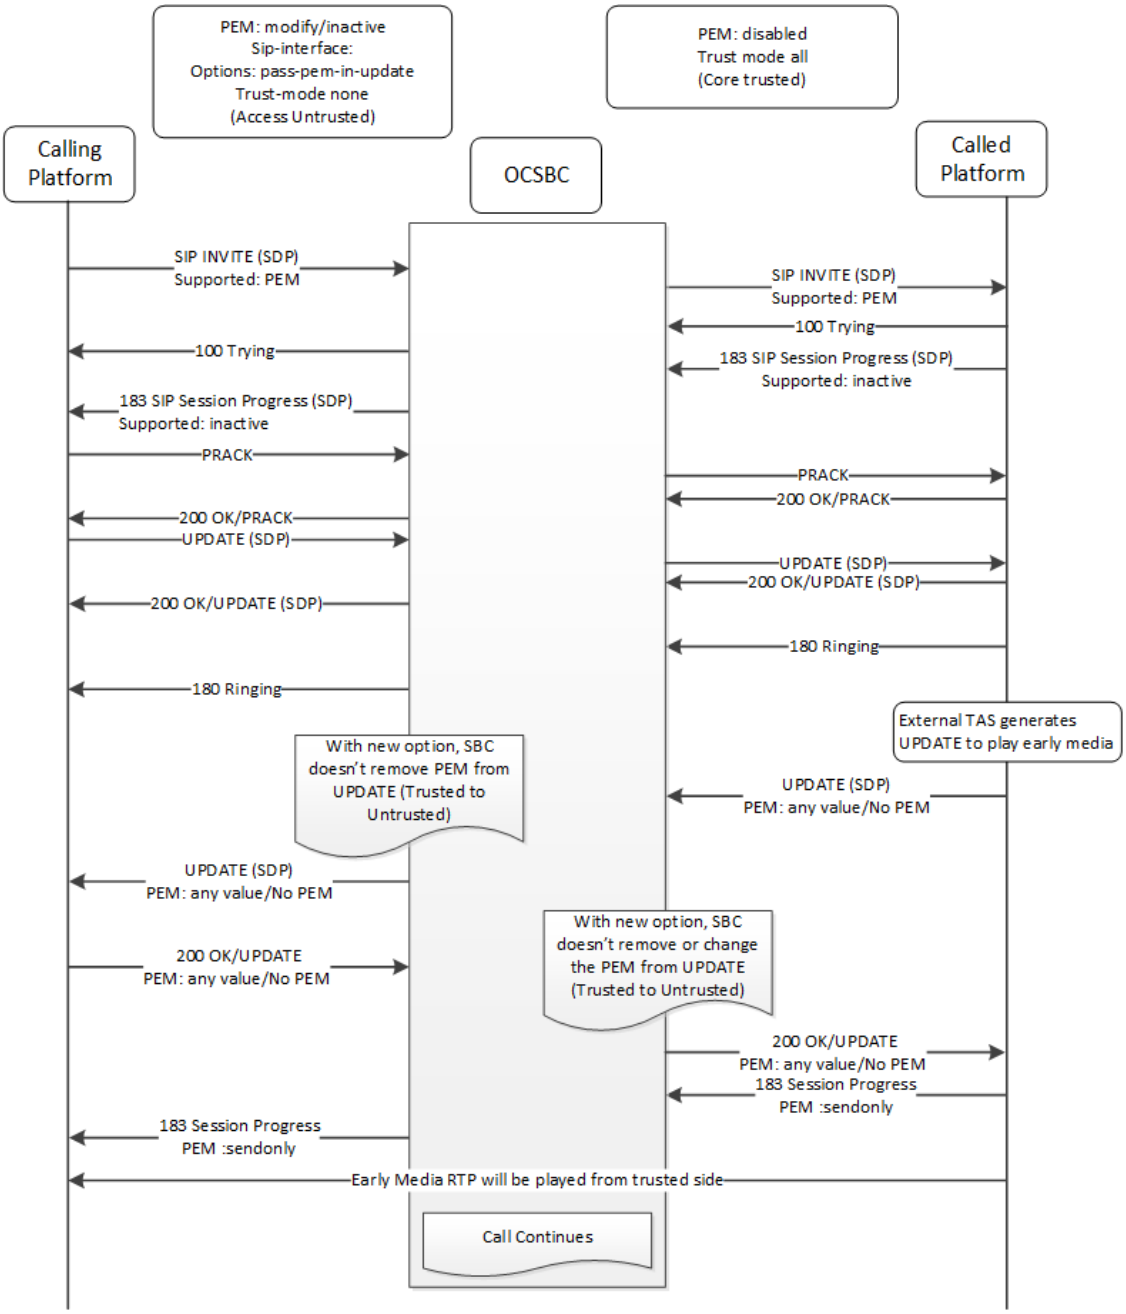
When you configure the **pass-pem-in-update** option, the SBC forwards the PEM header as received, ignoring other PEM header configuration. The applicable messages that can trigger this feature include the SBC:

- Receiving an UPDATE request from the trusted side and forwarding it towards the untrusted side.
- Receiving a 200 OK/UPDATE from the untrusted side and forwarding it towards the trusted side.

```
ORACLE(sip-interface)# +options pass-pem-in-update
```

The image below depicts the SBC supporting PEM across trusted and untrusted networks in both directions. You have configured the **trust-mode** to **none**, the **p-early-media-header** to **modify**, and the **p-early-media-header** to **inactive** on the access **sip-interface**. You have also set the **p-early-media-header** to **disabled** and the **trust-mode** to **all** on the egress **sip-interface**. Both of these configurations prevent early media across those interfaces.

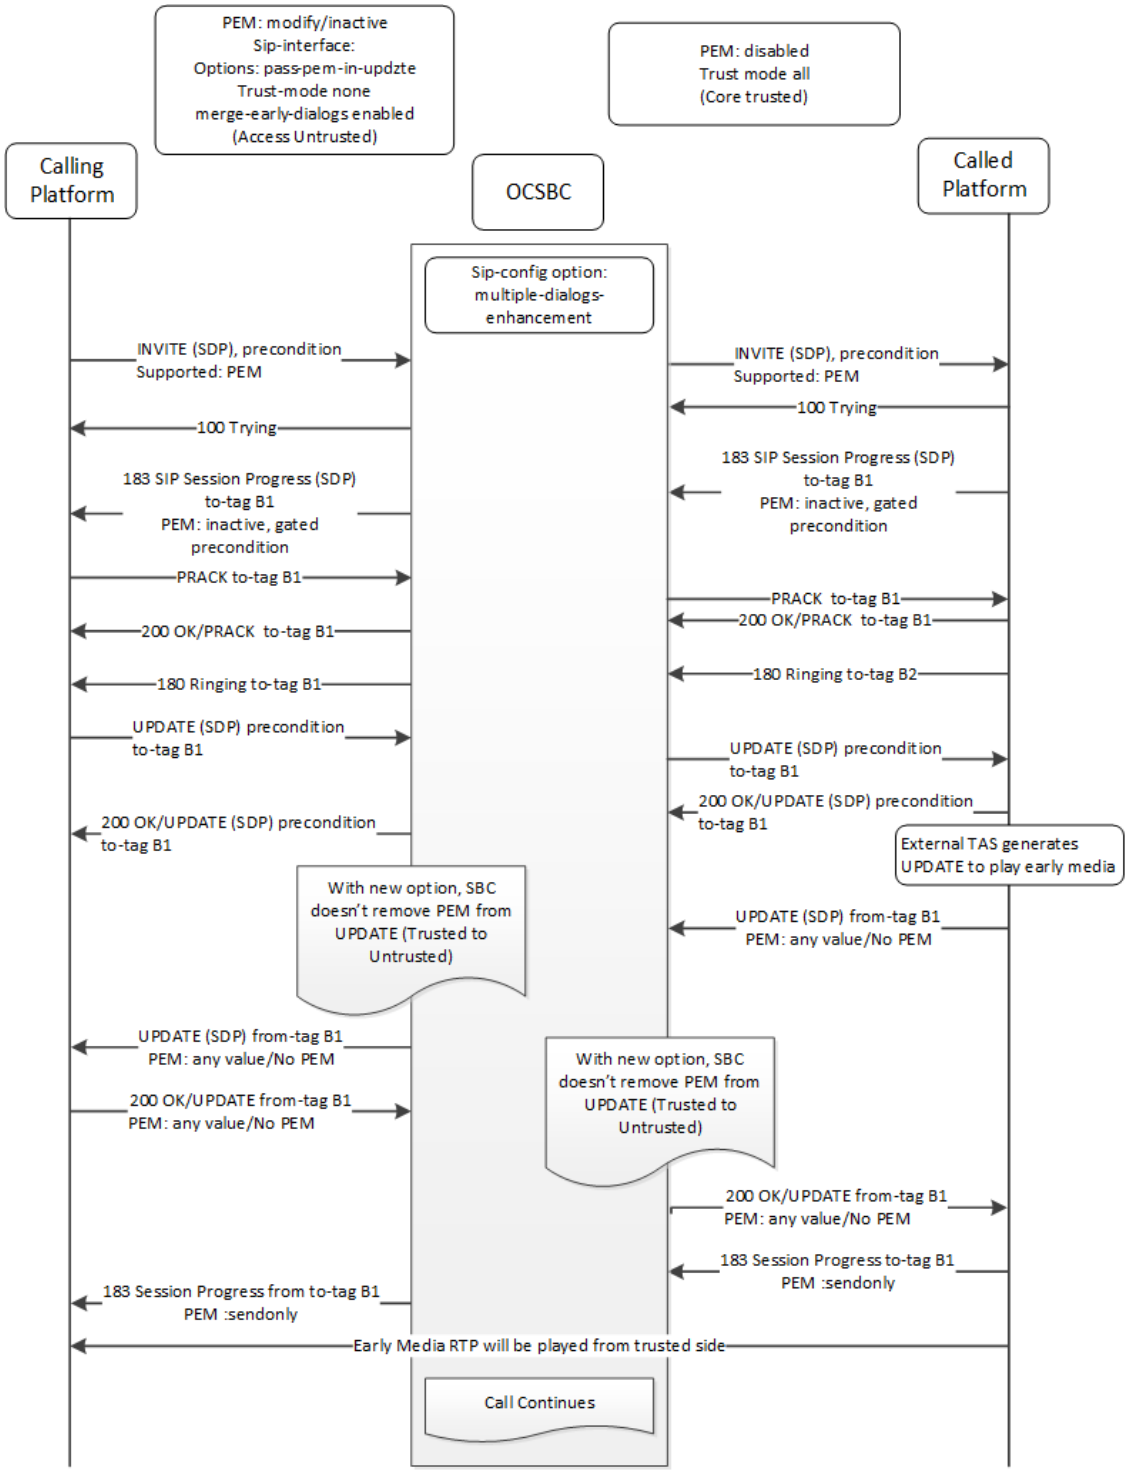
But you have also enabled the **pass-pem-in-update** option on the ingress **sip-interface**, which would be applied to the UPDATE coming from the core (access interface egress), based on the egress **sip-interface** configuration. This configuration supersedes the other configurations, allowing the SBC to accept early media, effectively bypassing what would be the standard SBC behavior of rejecting it.



This feature is compatible with the multiple early dialogs feature within the context of dialog merging, and many-to-many dialogs. You establish these configurations with the **merge-early-dialogs** configuration and the **multiple-dialogs-enhancement** option respectively. Applicable cases wherein the SBC receives an UPDATE from the trusted side allows early media include:

- multiple-early-dialogs in many-to-many mode cases:
  - UN-TRUSTED (ingress side) to TRUSTED (egress side)
  - UN-TRUSTED (egress side) to TRUSTED (ingress side)
- multiple-early-dialogs in merge mode cases, with the ingress configured as the merge realm:
  - UN-TRUSTED (ingress side) to TRUSTED (egress side)
  - TRUSTED (ingress side) to UN-TRUSTED (egress side)

> **Note:**
>
> This is supported in E2E precondition cases because the SBC responds to an UPDATE message from the calling party locally in the context of the merge.



P-Early-Media ACLI Configuration

Use the following procedure to configure P-Early-Media SIP header support.

1. Access the **sip-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

2. Select the **sip-interface** object to edit.

```
ORACLE(sip-interface)# select
<RealmID>:
1: realm01 172.172.30.31:5060

selection: 1
ORACLE(sip-interface)#
```

3. Use the **p-early-media-header** parameter to enable P-Early-Media SIP header support. This parameter is disabled by default.
   - **disabled**—(the default value) disables support
   - **add**—enables support and allows the Oracle Communications Session Border Controller to add the P-Early-Media header to SIP messages.
   - **modify**—enables support and allows the Oracle Communications Session Border Controller to modify or strip the P-Early-Media header in SIP messages.
   - **support**—adds additional PEM support, including enforcing PEM from trusted sources, preventing system modification of PEM direction, not adding PEM if absent from SIP replies, and adding PEM if it is not advertised in the initial INVITE.

```
ACMEPACKET(sip-interface)# p-early-media-header add
ACMEPACKET(sip-interface)#
```

4. Use the **p-early-media-direction** parameter to specify the supported directionalities.
   - **sendrecv**—send and accept early media
   - **sendonly**—send early media
   - **recvonly**—receive early media
   - **inactive**—reject/cancel early media

```
ACMEPACKET(sip-interface)# p-early-media-direction sendrecv,sendrecv
ACMEPACKET(sip-interface)#
```

5. Type **done** to save your configuration.

SIP Early Media Suppression

This section explains how to configure SIP early media suppression, which lets you determine who can send early media and in what direction. Early media are the RTP/RTCP packets sent from the called party to the caller, or vice versa, before a session is fully established (before a

200 OK is received). When the Oracle Communications Session Border Controller receives an INVITE message with SDP, it can forward media packets to the calling endpoint as soon as it forwards the INVITE to the next hop. It can also forward media packets received from the calling endpoint to the called endpoint as soon as the Oracle Communications Session Border Controller receives SDP in a SIP response to the INVITE, usually a provisional message. This allows for any early media to be played, such as remote ringback or announcement.

Early media can be unidirectional or bidirectional, and can be generated by the caller, the callee, or both.

With early media suppression, you can block early media until the call is established. You can define which outbound realms or next hop session agents are allowed to send or receive early media. early media suppression only applies to RTP packets. RTCP packets received by Oracle Communications Session Border Controller are still forwarded to their destination in both directions, unless an endpoint is behind a NAT and the media manager has not been enabled for RTCP forwarding.

> **Note:**
>
> To use early media suppression, you cannot configure media release of any kind: same-realm, same-network, or multiple-system media release.

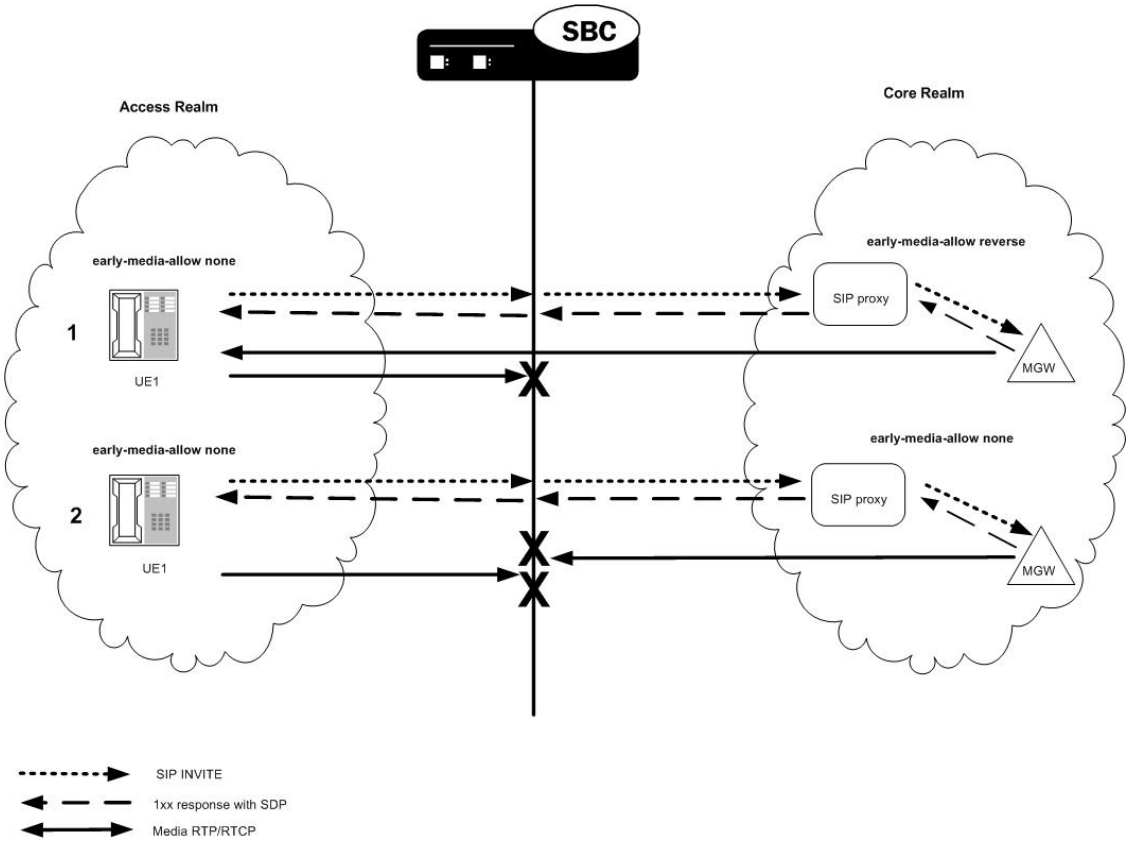
With the SIP-based addressing, early media suppression is based on the outbound SIP interface realms and the value of their early-media-allow parameter. When the Oracle Communications Session Border Controller forwards a SIP Invite out a SIP interface, the outbound realm is chosen based on the SIP layer information, such as the session agent for the next-hop or the address prefix of the next-hop SIP device. The matching realm's early-media-allow parameter value then applies to either allow all, block all, or block one-way early media until a 200 ok is received. At that point bidirectional media is allowed. The decision is based on SIP-layer addressing of next-hops.

You configure a rule for a realm or a session agent to use early media suppression. An early media suppression rule specifies whether you want to prevent early media in any direction, allow early media going to the calling endpoint in the reverse direction, or allow early media in both directions. The forward direction is when the packets flow from the caller to the called party. The reverse direction is when the packets flow from the called party to the caller.

The early media suppression rule is applied to a session. When the Oracle Communications Session Border Controller initiates a new session, it first checks whether the next hop is a session agent and if so, whether an early media suppression rule has been configured it. If an early media suppression rule is found, the Oracle Communications Session Border Controller enforces it. If the next hop is not a session agent or no early media suppression rule is configured, the Oracle Communications Session Border Controller checks whether an early media suppression rule has been configured for the outbound realm. If it finds one, it enforces it.

Example

The following illustration shows two examples of early media suppression.



1. Caller UE1 makes a call to the PSTN media gateway (MGW). The INVITE traverses from UE1 to the Oracle Communications Session Border Controller through the softswitch to the MGW. The Oracle Communications Session Border Controller allows early media from the core to reach UE1.
2. The PSTN MGW makes a call to UE1. The INVITE traverses to the Oracle Communications Session Border Controller and to UE1. The Oracle Communications Session Border Controller blocks all early media to and from UE1 until a 200 OK is received.

Early Media Suppression Support

The Oracle Communications Session Border Controller supports suppressing early media in the following directions no matter which side makes the SDP offer, until it receives 200 OK for an INVITE:

- Forward direction based on the outbound realm or next-hop session agent
- Forward and reverse directions based on the outbound realm or next-hop session agent.

The Oracle Communications Session Border Controller allows all media when a 200 OK response is received for the INVITE, regardless of whether the 200 OK response contains SDP.

Call Signaling

The Oracle Communications Session Border Controller media manager performs early media suppression according to an early media suppression rule. No change has been made to call signaling. For SIP, the Oracle Communications Session Border Controller still forwards SDP

received in an INVITE request or response after performing a NAT to the media connection address. After which, the Oracle Communications Session Border Controller is ready to receive media packets from the endpoints. If an early media suppression rule has been configured, the Oracle Communications Session Border Controller drops the packets going in the direction being specified by the rule.

For a H.323 to SIP call, early media suppression rule does not change how the Oracle Communications Session Border Controller performs H.225/Q.931 call signaling and starts the H.245 procedure (if required) to establish logical channels for early media on the H.323 leg of the call.

Suppression Duration

When early media suppression is enabled in a session, the block lasts until the session is established. For a SIP to SIP call or an H.323 to SIP call, a session is established when the system receives a 200 OK response to the INVITE. A 200 OK response to the INVITE terminates early media suppression, even when it does not contain a SDP. (A 200 OK response to a PRACK or an UPDATE request does not terminate early media suppression.) After a session is established, the Oracle Communications Session Border Controller can receive a change in media session (for example, a re-INVITE with a new SDP) without an early media suppression rule blocking the media.

About the Early Media Suppression Rule

An early media suppression rule is configured in the form of a permission. It specifies whether early media is allowed in both directions, the reverse direction only or not at all. Reverse direction media is media sent in the upstream direction towards the calling endpoint.

Session Agent Rule

The next-hop session agent's early media suppression rule is applied regardless of whether the media packet's source or destination address is the same as the session agent's address. For example, if the session's next hop session agent is 10.10.10.5 but the SDP in a 183 response specifies 10.10.10.6 as its connection address.

Rule Resolution

When the call's next hop is a session agent and both the outbound realm of the call and the session agent have an early media suppression rule, the session agent's early media suppression rule takes precedence. If the session agent's early media suppression rule has not been configured, the outbound realm's early media suppression rule is used, if configured.

Selective Early Media Suppression

Normally, the Oracle Communications Session Border Controller performs early media blocking based on destination realm. Calls to such realms are prohibited from sending and receiving RTP until a SIP 200 OK response is received, and you can set the direction of the blocked media.

While decisions to block early media are customarily based on SIP-layer addressing, there are cases when the Oracle Communications Session Border Controller can reject early media based on the SDP address in the SDP answer for a 1XX or 2XX response. By comparing the SDP address with the realm prefix or additional prefix address, it can block early media for matching realms. For these cases, you define global or signaling realms—ones that are not tied to SIP interfaces, but which establish additional address prefixes and rules for blocking early media.

This way, the Oracle Communications Session Border Controller blocks all early media for SIP interface realms, but can accept it for global realms that reference media or PSTN gateways. This configuration allows early media for calls destined for the PSTN, and blocks it for user-to-user and PSTN-to-user calls.

Selective early media suppression addresses the fact that some service providers need to allow early media for certain user-to-user and PSTN-to-user calls to support, for example, custom ringback tones. The enhancements also address the fact that Oracle Communications Session Border Controllers can themselves lose the ability to decide whether or not early media should be blocked when confronted with hairpinned call flows, or with traffic that traverses multiple Oracle Communications Session Border Controllers.

To address this need, you can configure realm groups. Realm groups are sets of source and destination realms that allow early media to flow in the direction you configure. For example, you can set up realm groups to allow media from PSTN realms to user realms so that users can listen to PSTN announcements, but prohibit early media from user realms to PSTN realms.

> **Note:**
>
> The source and destination realms you add to your lists need to be a global signaling realm matching the caller's SDP address prefix or a SIP realm.

Configuring the Realm

To configure the realm:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm
   ORACLE(realm)#
   ```

4. If configuring an existing realm, enter the select command to select the realm.
5. **early-media-allow**—Enter the early media suppression rule for the realm. The valid values are:
   - **none**—No early media is allowed in either direction
   - **both**—Early media is allowed in both directions
   - **reverse**—Early media received by Oracle Communications Session Border Controller in the reverse direction is allowed

     There is no default value. If you leave this parameter blank, early media is allowed in either direction. You can use the following command to clear this parameter:

     ```
     early-media-allow ()
     ```

6. Save and activate your configuration.

   For example:

```
realm-config
        identifier                      access1
        addr-prefix                     192.168.1.0/24
        network-interfaces
                                        media:0
        mm-in-realm                     enabled
        mm-in-network                   enabled
        msm-release                     disabled
        qos-enable                      disabled
        max-bandwidth                   0
        max-latency                     0
        max-jitter                      0
        max-packet-loss                 0
        observ-window-size              0
        parent-realm
        dns-realm
        media-policy
        in-translationid
        out-translationid

Configuring Session Agents

If you do not configure early media suppression for a session agent, the early media suppression for the outbound realm is used, if configured.

To configure session agents:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the system-level configuration elements.

```
ORACLE(configure)# session-router
```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

4. If configuring an existing session agent, enter the select command to select the session agent.

5. **early-media-allow**—Enter the early media suppression rule for the session agent. The valid values are:

   - **none**—No early media is allowed in either direction
   - **both**—Early media is allowed in both directions
   - **reverse**—Early media received by Oracle Communications Session Border Controller in the reverse direction is allowed

     There is no default value. If you leave this parameter blank, early media is allowed in either direction. You can use the following command to clear this parameter:

     ```
     early-media-allow ()
     ```

6. Save and activate your configuration.

   For example:

```
session-agent
        hostname                        cust1
        ip-address                      192.168.1.24
        port                            5060
        state                           enabled
        app-protocol                    SIP
        app-type
        transport-method                UDP
        realm-id                        access1
        description
        carriers
        constraints                     disabled
        max-sessions                    0
        max-outbound-sessions           0
        max-burst-rate                  0
        max-sustain-rate                0
        time-to-resume                  0
        ttr-no-response                 0
        in-service-period               0
        burst-rate-window               0
        sustain-rate-window             0
        req-uri-carrier-mode            None
        proxy-mode
        redirect-action
        loose-routing                   enabled
        send-media-session              enabled
        response-map
        ping-method
        ping-interval                   0
        media-profiles
        in-translationid
        out-translationid
        trust-me                        disabled
        early-media-allow               reverse
        last-modified-date              2006-05-06 13:26:34
```

Configuring Realm Groups

To configure a realm group for selective early media suppression:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-group** and press Enter.

```
ORACLE(media-manager)# realm-group
ORACLE(realm-group)#
```

4. **name**—Enter the name of the realm group.
5. **source-realm**—Enter the list of one or more global/SIP realms that you want to designate as source realms for the purpose of blocking early media; this is the realm identifier value for the realms you want on the list. Values in this list refer to calling SDP realms; this parameter has no default. To enter more than one realm in the list, list all items separated by a comma and enclose the entire entry in quotation marks:

```
ORACLE(realm-group)# source-realm Private, Public
```

   To add a realm to the list, use the plus sign (+) in front of each new entry.

```
ORACLE(realm-group)# source-realm +Private
```

   You can also remove single items in the list by using the minus sign (-) directly in front of the realm identifier.

```
ORACLE(realm-group)# source-realm -Private
```

6. **destination-realm**—Enter the list of one or more global/SIP realms that you want to designate as destination realms for the purpose of blocking early media; this is the realm identifier value for the realms you want on the list. Values in this list refer to called SDP realms; this parameter has no default. To enter more than one realm in the list, list all items separated by a comma and enclose the entire entry in quotation marks:
7. ORACLE(realm-group)# **source-realm Private, Public**

   To add a realm to the list, use the plus sign (+) in front of each new entry.

```
ORACLE(realm-group)# destination-realm +Private
```

   You can also remove single items in the list by using the minus sign (-) directly in front of the realm identifier.

```
ORACLE(realm-group)# destination-realm -Private
```

8. **early-media-allow-direction**—Set the direction for which early media is allowed for this realm group. Valid values are:
   - none—Turns off the feature for this realm group by blocking early media

- reverse—Allows early media to flow from called to caller
- both (default)—Allows early media to flow to/from called and caller

9. Save and activate your configuration.

SDP-Response Early Media Suppression

This section explains how to configure SDP-response early media suppression, which can be used when the Oracle Communications Session Border Controller is deployed after a softswitch or proxy in the signaling path. In this deployment, user endpoints and gateways communicate directly with the softswitch or proxy, which in turn sends call signaling to the Oracle Communications Session Border Controller. The call signaling gets sent back to the same or different softswitch or proxy. Because the Oracle Communications Session Border Controller does not communicate with the endpoints or gateways that are the media terminators, early media suppression for this deployment must use SDP-based addressing rather than the SIP-based addressing (described in the SIP Early Media Suppression section in this technical notice).

Using this feature lets you configure specific IP addresses for which early media should not be suppressed, based on SDP addressing. The Oracle Communications Session Border Controller checks the SDP addresses in SIP responses against these IP address or address ranges to determine on which media gateway a call terminates.

SIP-Based Addressing

With the SIP-based addressing described in the SIP Early Media Suppression section, early media suppression is based on the outbound SIP interface realms and the value of their early-media-allow parameter. When the Oracle Communications Session Border Controller forwards a SIP Invite out a SIP interface, the outbound realm is chosen based on the SIP layer information, such as the session agent for the next-hop or the address prefix of the next-hop SIP device. The matching realm's early-media-allow parameter value then applies to either allow all, block all, or block one-way early media until a 200 ok is received. At that point bidirectional media is allowed. The decision is based on SIP-layer addressing of next-hops.

SDP-Based Addressing

SDP-response early media suppression follows the same sequence described for SIP-based addressing with one exception. A provisional response with SDP media can make the Oracle Communications Session Border Controller select a new early-media-allow rule from another realm, based on the addressing inside the responding SDP.

When the SDP-response early media suppression feature is enabled, the Oracle Communications Session Border Controller searches the outbound SIP interface's realms for a matching address prefix with the connection address in the responding SDP. If it finds a match, it uses the early-media-allow parameter value of that realm until the 200 OK message is received, then bidirectional media is allowed regardless. If the Oracle Communications Session Border Controller does not find a match, it searches all of the global realms for one. If it finds a match, the Oracle Communications Session Border Controller uses that realm's early-media-allow parameter value. If it does not find a match in the global realm(s), the Oracle Communications Session Border Controller continues to use the previous early-media-allow parameter value.

Global Realms

Global realms are realms that are not parents or children of any other realms, do not have defined SIP interfaces and ports (or any signaling interface or stack), and are configured to use

the network interface lo0:0. They are special realms, applicable system-wide, and are currently only used for this feature. The only global realm configuration parameters applicable to early media suppression are:

- addr-prefix
- additional-prefixes
- early-media-allow
- network-interface (which must be set to lo0:0)

Additional Prefixes

You can specific additional prefixes in addition to that of the addr-prefix parameter you configure for a realm. For example, you can configure a global realm with additional address prefixes to specify the IP addresses (or ranges of addresses) of the media gateways that are allowed to send and receive early media. This overrides the SIP interface realm's early media blocking settings.

You can also enter additional prefixes in non-global realms. These additional prefixes function the same as would multiple values in the addr-prefix parameter (which only takes one value), except addresses in additional-prefixes are not used for SIP NATs.

Using the SDP-Response Early Media Suppression Rule

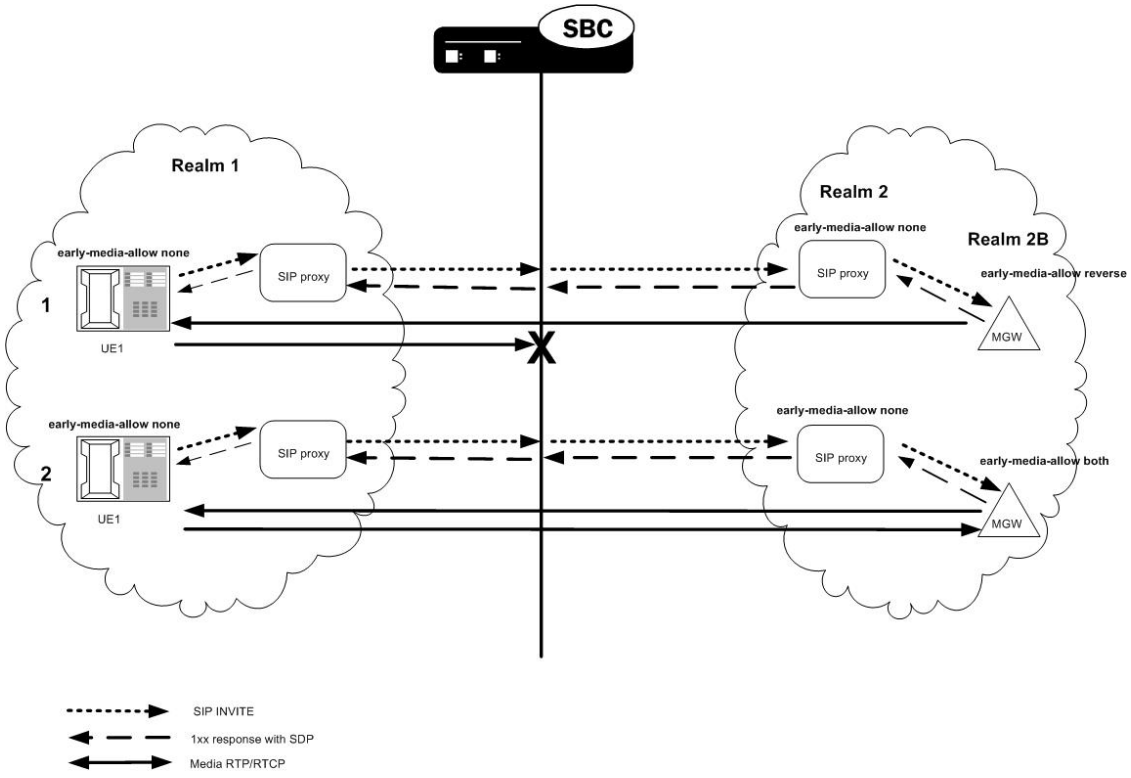
To use SDP-response early media suppression, you must add the early-media-sdp-realms option to the SIP interface configuration that interfaces with the next-hop device, such as the supported softswitch.

When the Oracle Communications Session Border Controller receives a provisional response that includes SDP from the called endpoint, and the early-media-sdp-realms option is active in the outgoing SIP interface of the call, it first searches the realms that apply to the outgoing SIP interface. If it does not find a realm, the Oracle Communications Session Border Controller searches the global realms. If the search yields a new realm that is not the SIP interface realm, its early media suppression rule (if any) replaces the existing one. Only the early media suppression rule of the new realm is applied to the call. Other realm properties from the outbound realm remain applicable to the call. If no new realm is found, the early media policy of the outgoing SIP interface realm is applied.

TheOracle Communications Session Border Controller allows media when the SDP media connect address in a response matches one of a configured list of IP address ranges defined in a realm and the realm has early media allowed. You need to configure specific a IP address or address range to specify which media gateways should not be suppressed based on SDP media addresses. The IP addresses are checked against the SDP being received. The decision for suppression is based on whether the matching realm allows early media. The early media will be suppressed if the matching realm does not allow early media or if there is no match and the outbound SIP interface ream does not allow early media.

Example

The following illustration shows two examples of SDP-response early media suppression.



Configuring SDP-Response Early Media Suppression

To configure SDP-response early media suppression:

1. Add the early-media-sdp-realms option to the SIP interface that interfaces with the softswitch.
2. Configure the SIP interface realm with an early media suppression rule that blocks all early media.
3. Configure either or both of the following:
   - One or more of the SIP realm's child realms, each with an early media suppression rule that allows all or reverse direction early media and a list of additional prefixes that specifies the IP addresses of the media gateways, or a range of IP addresses that includes the media gateways. Early media is allowed from these gateways only for calls that signals through this SIP interface.
   - One or more realms that has the network interface equal to lo0:0, an early media suppression rule that allows all or reverse direction early media and a list of additional prefixes that specifies the IP addresses of the media gateways, or a range of IP addresses that includes the media gateways. Early media is allowed from these gateways regardless of interface.

Configuring the SIP Interface

To configure a SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the system-level configuration elements.

```
ORACLE(configure)# session-router
```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

From this point, you can configure SIP interface parameters. To view all sip-interface parameters, enter a **?** at the system prompt.

4. If configuring an existing interface, enter the select command to select the interface.
5. **options**—Enter early-media-sdp-realms as the option. If adding to an existing list of options, use a preceding plus (+) sign.

```
options +early-media-sdp-realms
```

6. Continue to the next section to configure the outbound realm.

For example:

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)# options + early-media-sdp-realms
ORACLE(sip-interface)# done
sip-interface
        state                           enabled
        realm-id                        access1
        sip-port
                address                         192.168.1.30
                port                            5060
                transport-protocol              UDP
                allow-anonymous                 all
        carriers
        proxy-mode                      Proxy
        redirect-action
        contact-mode                    maddr
        nat-traversal                   none
        nat-interval                    30
        registration-caching            disabled
        min-reg-expire                  300
        registration-interval           3600
        route-to-registrar              disabled
        teluri-scheme                   disabled
        uri-fqdn-domain
        options                         early-media-sdp-realms
        trust-mode                      all
        last-modified-date              2006-05-10 18:27:31
```

Configuring a Realm

To configure a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)#
   ```

4. If configuring an existing realm, enter the select command to select the realm.
5. **early-media-allow**—Enter the early media suppression rule for the realm. The valid values are:
   - **both**—Early media is allowed in both directions
   - **reverse**—Early media received by Oracle Communications Session Border Controller in the reverse direction is allowed
   - **none**—Early media is blocked
6. **additional-prefixes**—Enter a single or a comma-delimited list of IP address prefixes to use in addition to the value of the **addr-prefix** parameter.

   ```
   <IPv4> [/<number of bits>]
   ```

   <IPv4> is a valid IPv4 address and <number of bits> is the number of bits to use to match an IP address with the address prefix. Not specifying <number of bits> implies that all 32 bits are used for matching.

   Enclose the list between quotes if there is any space between a comma and the next address prefix.

   You can add and remove address prefixes to and from the list:

   - add-additional-prefixes adds one or more additional prefixes

     ```
     add-additional-prefixes 192.168.201.69
     ```

   - remove-additional-prefixes removes one or more additional prefixes

     ```
     remove-additional-prefixes 192.168.201.69
     ```

     If using multiple address prefixes, enter a comma-delimited list.
7. Save and activate your configuration.

   For example:

   ```
   ORACLE# configure terminal
   ORACLE(configure)# media-manager
   ORACLE(media-manager)# realm-config
   ORACLE(realm-config)# additional-prefixes 192.168.200.0/24,192.168.201.68
   ORACLE(realm-config)# done
   ```

```
realm-config
        identifier                      early-media
        addr-prefix                     0.0.0.0
        network-interfaces
                                        media2:0
        mm-in-realm                     disabled
        mm-in-network                   enabled
        msm-release                     disabled
        qos-enable                      disabled
        max-bandwidth                   0
        max-latency                     0
        max-jitter                      0
        max-packet-loss                 0
        observ-window-size              0
        parent-realm
        dns-realm
        media-policy
        in-translationid
        out-translationid
        in-manipulationid
        out-manipulationid
        class-profile
        average-rate-limit              0
        access-control-trust-level      none
        invalid-signal-threshold        0
        maximum-signal-threshold        0
        untrusted-signal-threshold      0
        deny-period                     30
        symmetric-latching              disabled
        pai-strip                       disabled
        trunk-context
        early-media-allow               reverse
        additional-prefixes             192.168.200.0/24
192.168.201.69
        last-modified-date              2006-05-11 06:47:31
```

Early Media Support for Multiple Early Dialog Scenarios

By default, the SBC supports the P-Early-Media (PEM) header for authorizing early media, and multiple early dialogs with PEM headers. With additional configuration, it can expand on early media support functions related to multiple early dialogs and PEM header management that target specific environments or deployments, such as SIP/SIPI interworking and access VoLTE deployments.

Specific configurable early media support functions include:

- Hiding the multiple early dialogs by merging them into a single dialog when deployed in a SIP/SIPI environment. With some legacy equipment (MGCs, PBXs), this becomes necessary because SIP-I does not support multiple early dialog
- Resolution and collation of many-to-many dialog scenarios
- Mapping a SIP UPDATE towards the right early dialog when deployed within an access VoLTE environment
- Appropriate media latching when presented with multiple latching choices

Configuration of these enhanced multiple early dialog support, including PEM header, dialog merging, and many-to-many dialog support includes:

- Set the **sip-config** option **multiple-dialogs-enhancement**. By default this option is not configured.
- In the **realm-config**, enable the **merge-early-dialogs** parameter on the caller side to merge early media dialogs.
- In addition, you can set the **p-early-media-header** configuration in **sip-interface** to **support** to trigger behavior that supports merged early dialogs.

All of this configuration supports real-time configuration, not requiring a reboot.

> **Note:**
>
> The SBC uses its interaction with the PCRF, via the SIP-Forking-Indication AVP, to reserve the highest QoS requested for that media component by any forked responses. This does not require configuration.

Related Feature Dependencies

The complexity of these enhancements and their related functions can conflict, supercede or depend on other aspects of your SBC configuration. Configuration dependencies include:

- The **realm-config** must have:
  - **hide-egress-media-update** enabled to maintain RTP consistency
  - A **codec-policy** set (xcoding enabled)
- The **sip-config** must have the **multiple-dialogs-enhancement** option enabled.
- If the **media-manager** has latching enabled, **sdp-restrict** is disabled.
- You must not set the **dont-save-early-dialog-sdp** option.

Recall that the SBC requires the **100-rel-interworking** option set on the ingress **sip-interface** to support PRACK interworking, which is needed for early dialog support.

> **Note:**
>
> Legacy SDP management (SCz7.2.0 and below) uses the last SDP seen as the source for SDP. You can enable this legacy behavior by setting the **dont-save-early-dialog-sdp** option in the **sip-config**. Do not use this unless directed by Oracle.

```
ORACLE(sip-config)# options +dont-save-early-dialog-sdp
```

Merge Function within Early Dialog Support

Dialog merge functionality allows the SBC to manage media, handle potential transcoding change requirements, and accommodate complex PRACK and UPDATE scenarios for merged (single caller, multiple callee) call flows. You configure this support in conjunction with other configuration depending on your deployment. This merge requires that any forking proxy send only one final response to the SBC, either a 200 OK or an error response. You configure the

merge-early-dialogs parameter on the caller realm to support the merging of multiple early dialogs into a single dialog.

The SBC aggregates all early dialogs on the calling party side using the same early dialog, identified via the presence of the same To-Tag identifier, consistent CSeq, RSeq, SDP session and so forth. If there are provisional responses containing SDP, the associated provisional responses towards the ingress leg contain the same unique SDP, as created by the SBC.

The final response sent by the SBC also belongs to the same dialog (same To-Tag identifier). If a former provisional response sent contained SDP, the final response contains the exact same SDP. If PRACK is activated for this dialog, however, the response would not contain SDP.

There is no need to drop messages coming from the calling party side, although the first early dialog received from the calling side determines the codec used for the call. The SBC also performs transcoding and PRACK interworking on a per call leg basis. Furthermore, the SBC does not increment the SDP version on the merged leg unless there is a renegotiation on that leg.

Operational behavior of this merging includes:

- The SBC maintains consistency of RTP parameters regardless of whether or not there is transcoding. These parameters include Seq Number, Timestamp, SSRC and so forth. This support includes on-the-fly transcoding setup as new early dialogs are received.
- There is only one dialog on the caller side even if there are multiple early dialogs on the called side.
- The SBC forwards every provisional message received to the caller with a single to-tag.
- The SBC sends an ACK for 200OK/INVITE to the correct dialog, which is the dialog with the to-tag in the 200OK/INVITE message.
- The SBC sends a BYE message to the correct dialog, which is the dialog with the to-tag in the 200OK/INVITE message.
- The SBC maintains the same SDP Version Number in all messages to the caller.

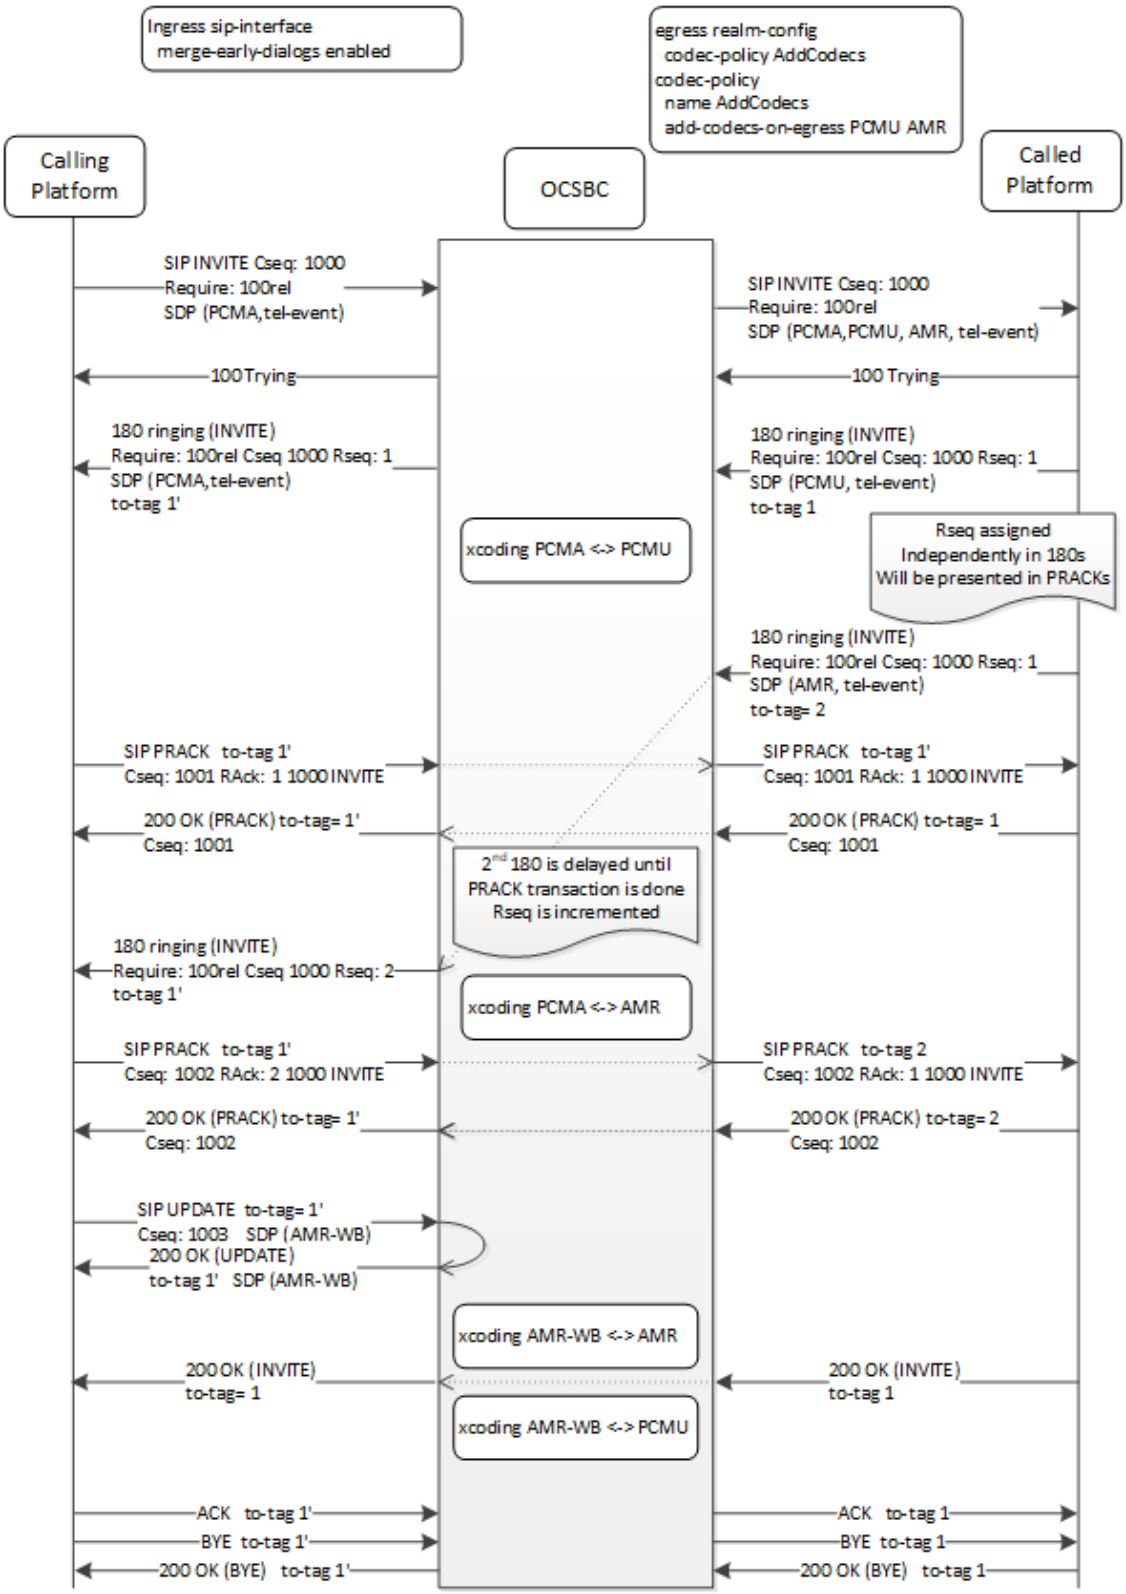
Consider the following configuration rules:

- You should configure HMU to maintain RTP consistency.
- When enabled, dialog-transparency disables this merging.
- You should configure transcoding resources and at least one codec policy on the ingress and/or egress side. This could be as simple as a codec policy configured to allow all.

This merge function does not support:

- Offerless call
- Preconditions interworking
- SRVCC
- multiple audio or video m-line
- p-early-media-header with 'add' and 'modify' options

The call flow below presents an example of the SBC supporting a merge scenario with an UPDATE message received from the calling party. The SBC hairpins a 200OK in response to the UPDATEs locally towards the merged (single) dialog side.



The call flow below presents an example of the SBC supporting a merge scenario with an UPDATE message received from the called party. The SBC forwards the UPDATEs and associated 200OKs maintaining the same To-Tag for the calling platform.

Many-to-Many Support within Early Dialog Support

The SBC provides early dialog support for many-to-many dialog scenarios, which are defined by working with multiple early dialogs established by and for both the callee and the caller. The SBC establishes a one-to-one correspondence between to-tag identifiers for the dialogs it sends and receives. This support applies to both reliable and unreliable dialogs (with or without PRACK). It also provides this support for both transcoding and non-transcoding call flows.

While processing responses within different dialogs, the SBC matches the dialogs of corresponding offers and answers and updates the flows to maintain SDP selection for the subsequent session. The ensuing behavior depends on whether the call is reliable, meaning it includes PRACKs, or unreliable:

- If the flow is reliable, the SBC does not restore the SDP for the final response in the same dialog, resulting in no SDP in the outgoing final response. If the final response, such as a 200 OK, arrives within a dialog that is different and doesn't include SDP, the SBC participates in changing the dialog switching and a media update.
- If the flow is unreliable and a final response arrives within the same dialog and without SDP, the SBC restores the SDP from the matching dialog, updates the media flows and then sends the final response with SDP inserted.

The SBC maintains the SDP version consistent across dialogs on both sides throughout the call.

Many-to-many cases require that you disable the **merge-early-dialogs** config. Also, the UAC must maintain same IP and port in the SDP c line across all dialogs.

This many-to-many configuration does not support the following:

- Offerless calls with **add-sdp-invite**
- Preconditions interworking
- PRACK IWF
- multiple audio or video m-line
- **p-early-media-header** with **support** option

The call flow below presents the SBC supporting a Multiple Early dialog scenario, wherein both the called and calling plarforms are initiating dialogs using reliable exchanges.

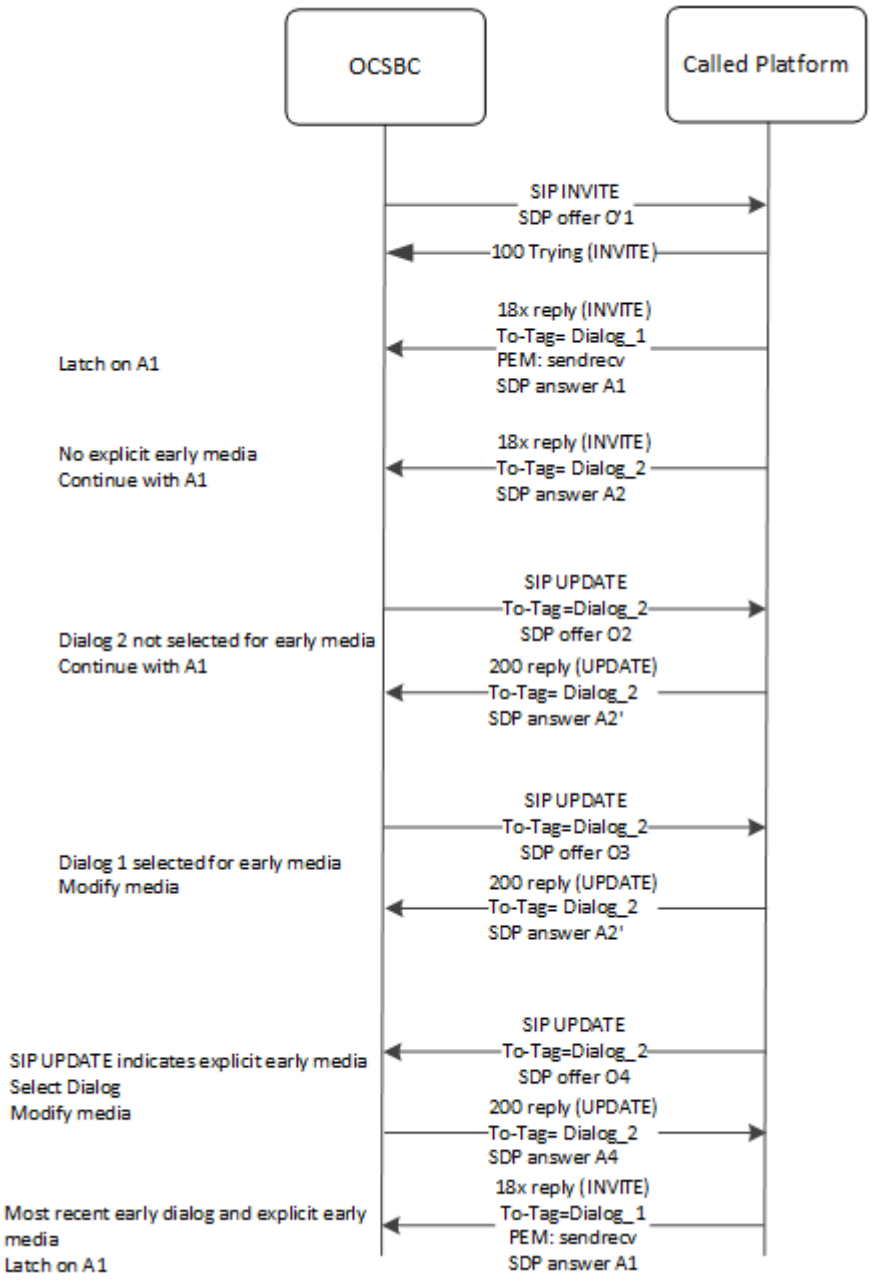
PEM Header Support for Early Dialogs

PEM support on the SBC is fully documented in the section P-Early-Media SIP Header Support. Note that PEM header support is disabled by default, which causes the SBC to ignore all PEM headers and not enforce directionality. Within the context of multiple dialogs, an additional behavior supports early multiple dialog merging.

When you set the **sip-interface**, **p-early-media-header** parameter to **support**, you enable PEM processing in replies without interfering with the signaling, thereby supporting multiple early dialog merge. This attribute value causes the SBC to perform the following:

- The SBC enforces received PEM from trusted sources if they are not restricted by some other condition.
- The SBC does not modify PEM direction; the SBC ignores the direction attribute on the applicable **sip-interface**.
- If a PEM header is absent from a SIP reply, the SBC does not add it.
- If PEM support is not advertised in the initial SIP INVITE, the SBC adds it.
- The SBC forwards PEM in SIP replies to any calling party (trusted or untrusted) that advertises PEM support.

Regarding the early dialog media selection process, the SBC is expected to retain only the last received early media with P-Early-Media set to sendonly or sendrecv. This support extends to call flows that include many-to-many dialog presentation, within which both the UAC and UAS initiate multiple dialogs, using UPDATES for example to trigger a media change. The call flow below presents an example of the applicable behavior.



Configuring Multiple Early Dialog Support

You enable the parameters below to enable specific components of multiple early dialog support. Refer to Related Feature Dependencies to ensure you consider complementary and conflicting configuration properly for your deployment.

Use the following procedure to configure default multiple early dialog support.

1. Navigate the **sip-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-config
```

2. Apply the **multiple-dialogs-enhancement** option.

```
ORACLE(sip-config)#options +multiple-dialogs-enhancement
```

3. Use **done**, **exit** to save the configuration.
4. Navigate to the **realm-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# media-manager
ORACLE(session-router)# realm-config
```

Select the desired **realm-config** or create a new one.

5. Enable the **merge-early-dialogs** parameter.

```
ORACLE(realm-config)#merge-early-dialogs enable
```

6. Use **done**, **exit** to save the configuration.
7. Navigate to the **sip-interface** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-interface
```

Select the desired **sip-interface** or create a new one.

8. Enable the **p-early-media-header** parameter.

```
ORACLE(sip-interface)#p-early-media-header enable
```

9. Use **done**, **exit** configuration mode, and perform a subsequent **verify-config** and **activate-config** to complete the configuration.

These configurations support real-time configuration, and therefore do not require a reboot.

Selecting SDP within Multi-Dialog Call Scenarios

By default, the Oracle Communications Session Border Controller saves SDP presented in a series of early dialogs using To tags to differentiate between dialogs. If the session continues with a 200OK that does not include SDP, the Oracle Communications Session Border Controller refers to the To tag to identify the dialog from which the Oracle Communications Session Border Controller selects the SDP for the media flow. This complies with 3GPP TS 24.628, TS 24.182 and RFC 5009 behavior for sessions supporting early media.

Consider a SIP dialog with early media that proceeds by establishing call scenarios in which the final 200 OK does not include any SDP. This messaging may include multiple 183 (Session Progress) messages with SDP that differ from each other and include different To tags, establishing multiple early dialogs. In these scenarios, the Oracle Communications Session Border Controller uses the saved SDP from the dialog that matches the dialog indicated in the 200 OK's To tag to anchor the media. If the 200 OK includes SDP, the Oracle Communications Session Border Controller uses that SDP to anchor the media.

> **Note:**
>
> The user can disable this behavior, for example, to use the functional behavior in Oracle Communications Session Border Controller version S-CZ7.2.0 and below, which is to use the last SDP seen as the source for SDP. Deployments that rely on this behavior must revert to it using the **sip-config**'s **dont-save-early-dialog-sdp** option parameter.

```
ORACLE(sip-config)# options +dont-save-early-dialog-sdp
```

SDP Compliance Enforcement

You can configure the SBC to enforce SDP compliance on incoming messages and reject non-compliant messages and change the non-compliant SDP in ensuing messages. By default, the SBC forwards response message even if the Content-Length is greater than the SDP size and the SDP does not have mandatory parameters. You enable the **sip-strict-compliance** option when the SBC is operating in environments where it is expected to monitor and validate these aspects of SDP.

When you enable the **sip-strict-compliance** option in the **sip-config**, the SBC:

- Ignores/drops any response message if the SDP Content-Length header value is greater than the SDP size. The system also increments the "Invalid Responses" statistic.
- Forwards any response message without any SDP if the message does not include mandatory SDP parameters. Mandatory parameters include:
  - version
  - origin
  - session-name
  - connection
  - timer

  The SBC provides an "SDP Stripped Responses" statistic in the sip-errors HDR group to track SDP stripped responses system-wide. Enable this HDR group to obtain statistics on SDP responses the SBC has removed because the original message violated the mandatory SDP parameter requirements.

SDP Compliance Enforcement Configuration

To enforce SDP compliance for SIP sessions:

1. In Superuser mode, type configure terminal and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

If you are adding support for this feature to a preexisting configuration, you must select (using the ACLI **select** command) the single instance **sip-config** element.

4. **options**—Set the options parameter by typing options, a Space, and then the option name **sip-strict-compliance**. Then press Enter.

```
ORACLE(sip-config)# options +sip-strict-compliance
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

SIP Duplicate SDP Suppression

Using the **strip-dup-sdp** option in the SIP configuration, you can enable your Oracle Communications Session Border Controller to suppress a duplicate SDP answer in the reliable responses (1xx and 2xx) in an INVITE transaction.

During INVITE transactions in certain networks, SDP answers in reliable provisional responses (1xx) can cause interoperability issues. This issue occurs when the UAS includes the SDP answer in subsequent 1xx responses or in the final 2xx response, and the UAC views that inclusion as a protocol violation. The UAC does so based on the fact that the SDP answer was reliably delivered to it in a 1xx response, and so it views additional SDP information as unnecessary in and ensuing reliable 1xx or 200 OK responses.

RFCs 3216 and 3262 do not specifically call out the UAS's including SDP information in this way as a protocol violation. Still, the system allows you set enable the **strip-dup-sdp** option as a means of preventing the UAC from terminating sessions. With this option enabled, the Oracle Communications Session Border Controller removes the SDP answer in subsequent reliable provisional or final 200 OK responses if it is identical to the SDP answer previously received.

SIP Duplicate SDP Suppression Configuration

To enable duplicate SDP suppression for SIP sessions:

1. In Superuser mode, type configure terminal and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **options**—Set the options parameter by typing options, a Space, and then the option name **strip-dup-sdp**. Then press Enter.

```
ORACLE(sip-config)# options +strip-dup-sdp
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

SIP SDP Address Correlation

SIP SDP address correlation ensures that when the Oracle Communications Session Border Controller receives a request containing SDP, the L3 source address of the request is compared against the address in the c-line of the SDP. When the addresses match, the session proceeds as it normally would. If there is a mismatch, the call is rejected with the default 488 status code. You can also configure the code you want to use instead of 488.

This functionality works only with non-HNT users. The value c=0.0.0.0 is an exception and is always processed.

SIP SDP Address Correlation Configuration Address Checking

The **sdp-address-check**, in the **enforcement-profile** element can be set to enable the SDP address correlation.

To enable SDP address checking:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **enforcement-profile** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# enforcement-profile
ORACLE(enforcement-profile)#
```

4. Use the ACLI **select** command so that you can work with the enforcement profile configuration to which you want to add this parameter.

```
ORACLE(enforcement-profile) select
```

5. **sdp-address-check**—Enable or disable SDP address checking on the Oracle Communications Session Border Controller. The default for this parameter is **disabled**.

```
ORACLE(enforcement-profile)# sdp-address-check enabled
```

6. Save and activate your configuration.

   If a mismatch occurs and you want to reject the call with a status code other than 488, you set the code you want to use in the local response code map entries.

SIP SDP Address Correlation Configuration Mismatch Status Code

To apply a new status code to a SDP address correlation mismatch:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **local-response-map** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# local-response-map
ORACLE(local-response-map)#
```

4. Type **entries** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(local-response-map)# entries
ORACLE(local-response-map-entry)#
```

   From here, you can view the entire menu for the local response map entries configuration by typing a **?**.

5. **local-error**—Enter sdp-address-mismatch for which to apply the new status code.
6. **sip-status**—Set the SIP response code to use.
7. **sip-reason**—Set the SIP reason string you want to use for this mapping.

```
ACMEPACKET(local-response-map-entry)# local-error sdp-addressmismatch
ACMEPACKET(local-response-map-entry)# sip-status 403
ACMEPACKET(local-response-map-entry)# sip-reason sdp address mismatch
```

8. Save and activate your configuration.

SIP SDP Address Correlation Configuration Enforcement Profile

To apply an enforcement profile to a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. **enforcement-profile**—Enter the name of the enforcement profile you want to apply to this realm.

```
ORACLE(realm-config)# enforcement-profile profile1
```

5. Save and activate your configuration.

SDP Insertion for (Re)INVITEs

If your network contains some SIP endpoints that do not send SDP in ReINVITEs but also contains others that refuse INVITEs without SDP, this feature can facilitate communication between the two types. The Oracle Communications Session Border Controller can insert SDP into outgoing INVITE messages when the corresponding, incoming INVITE does not contain SDP.

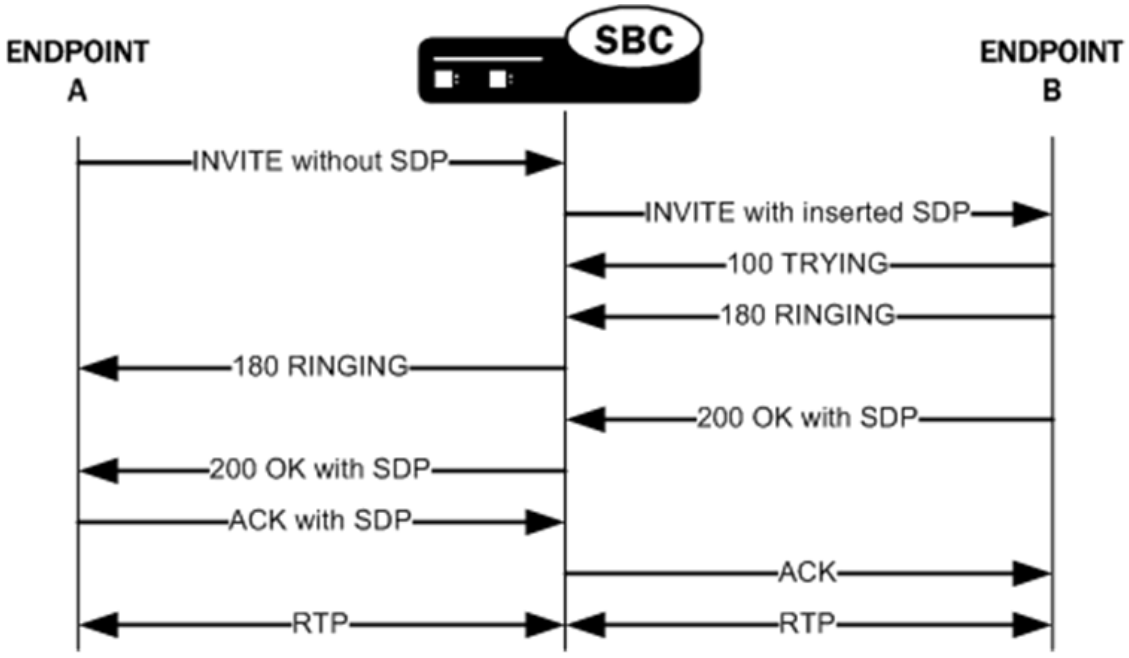
You can also use this feature when the network devices used in H.323-SIP interworking do not include SDP in the INVITEs sent to SIP endpoints. In this case, the Oracle Communications Session Border Controller can insert SDP in the outgoing INVITE messages it forwards to the next hop.

This feature works for both INVITEs and ReINVITEs.

This section explains how the SDP insertion feature works for INVITEs and ReINVITEs. The examples used this section are both pure SIP calls. Even when you want to use this feature for IWF calls, though, you configure it for the SIP side.

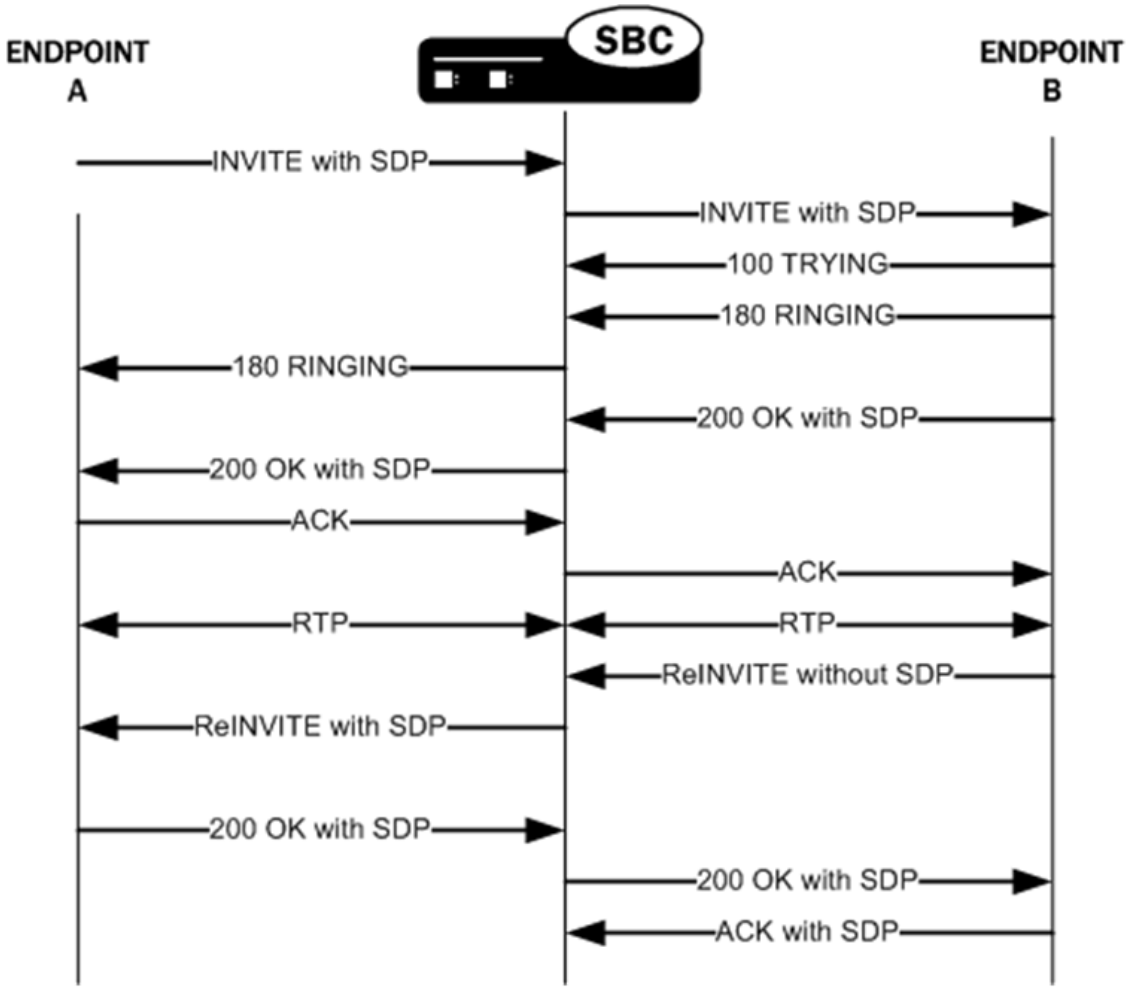
SDP Insertion for SIP INVITES

With the parameters mentioned above appropriately configured, the Oracle Communications Session Border Controller inserts SDP into an outgoing INVITE when the corresponding incoming INVITE has none. Because no SDP information is available for the session, the Oracle Communications Session Border Controller uses a media profile from a list of them you configure and then apply for SDP insertion.



SDP Insertion for SIP ReINVITEs

The section explains SDP insertion for ReINVITEs, using a case where SIP session has been established with an initial INVITE containing SDP. In the diagram below, you can see the initial INVITE results in a negotiated media stream. But after the media stream is established, Endpoint B sends a ReINVITE without SDP to the Oracle Communications Session Border Controller. In this case, the Oracle Communications Session Border Controller inserts the negotiated media information from the initial INVITE as the ReINVITE's SDP offer. For subsequent ReINVITEs with no SDP, the Oracle Communications Session Border Controller inserts the negotiated media information from the last successful negotiation as the ReINVITE's SDP offer. It then sends this ReINVITE with inserted SDP to the next hop signaling entity.



SDP Insertion Configuration

This section shows you how to configure SDP insertion for the calls cases described above.

Configuring SDP Insertion for SIP INVITEs

To work properly, SDP insertion for SIP invites requires you to set a valid media profile configuration.

To enable SDP insertion for INVITEs:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-config)#
```

4. **add-sdp-invite**—Change this parameter from disabled (default), and set it to **invite**. To include an SDP in both the INVITE and ReINVITE, change this parameter to **both**.
5. **add-sdp-profile**—Enter a list of one or more media profile configurations you want to use when the system inserts SDP into incoming INVITEs that have no SDP. The media profile contains media information the Oracle Communications Session Border Controller inserts in outgoing INVITE.

   This parameter is empty by default.
6. Save and activate your configuration.

Configuring SDP Insertion for SIP ReINVITEs

In this scenario, the Oracle Communications Session Border Controller uses the media information negotiated early in the session to insert after it receives an incoming ReINVITE without SDP. The Oracle Communications Session Border Controller then sends the ReINVITE with inserted SDP to the next hop signaling entity. You do not need the media profiles setting for ReINVITEs.

To enable SDP insertion for ReINVITEs:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-config)#
```

4. **add-sdp-invite**—Change this parameter from disabled (default), and set it to **reinvite**. To include an SDP in both the INVITE and ReINVITE, change this parameter to **both**.
5. Save and activate your configuration.

SDP Version Change without SDP Body Change

When an SRTP call is made through the Oracle Communications Session Border Controller and a UE sends a reINVITE, there may be no change in the SDP contents. When the other UE responds, some devices will increment the o= line's session version, despite no SDP change. Normally the change in SDP version indicates that the SDP has changed, which would otherwise require the Oracle Communications Session Border Controller to modify the media flow set-up. In order to leave the media flows unchanged when session version changes but the rest of the SDP does not, an option is configured in the **media-manager-config**.

If the Oracle Communications Session Border Controller attempts to modify these media flows when unnecessary, calls could be dropped by the system disrupting media packet sequence number synchronization.

The **ignore-reinv-session-ver** option is set to handle this situation. When configured, the Oracle Communications Session Border Controller compares the current SDP received from a UE against the previously-received SDP from the same UE. If the SDP in the newer and older messages is the same, the Oracle Communications Session Border Controller ignores any changes to the session-version and will not modify the media flow portion of the call.

> **Note:**
>
> When the SDP change is only a reordering of SDP lines without any other change, the option has no effect.

SDP Version Change Configuration

To configure media over TCP:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the media-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ORACLE(media-manager)#
   ```

3. Type **media-manager** and press Enter to begin configuring media over TCP.

   ```
   ORACLE(media-manager)# media-manager
   ORACLE(media-manager-config)#
   ```

4. **options** — Set the options parameter by typing **options**, a Space, the option name **ignore-reinv-session-ver** with a “plus” sign in front of it, and then press Enter.

   ```
   ORACLE(media-manager-config)# options +ignore-reinv-session-ver
   ```

   If you type the option without the “plus” sign, you will overwrite any previously configured options. In order to append the new options to the realm configuration’s options list, you must prepend the new option with a “plus” sign as shown in the previous example.

   Save and activate your configuration.

Enhanced SIP Port Mapping

This section explains how to configure SIP port mapping feature to support:

- Anonymous requests from endpoints
- Cases where endpoints dynamically change transport protocols between UDP and TCP

Anonymous Requests

If a SIP endpoint sends an INVITE message with a From header that is anonymous, the Oracle Communications Session Border Controller can find the registration cache entry by using the Contact and Via headers. In cases such as instant messaging (IM), where there is no Contact header, the Oracle Communications Session Border Controller can use the Via header.

The Oracle Communications Session Border Controller's checks whether the reg-via-key option is configured for the access-side SIP interface where a REGISTER is received. If the option is enabled, the Oracle Communications Session Border Controller makes the via-key by adding the IP address from the Via header to the firewall address (if there is a firewall present between the Oracle Communications Session Border Controller and the endpoint).

When an INVITE arrives at a SIP interface where this option is enabled, the Oracle Communications Session Border Controller determines whether the From header is anonymous or not. If it is anonymous, then the Oracle Communications Session Border Controlleruses the Via-key to find the registration entry.

Anonymous SIP Requests Configuration

To enable support for anonymous SIP requests:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. Type **options +reg-via-key** and press Enter.

   ```
   ORACLE(sip-interface)# options +reg-via-key
   ```

   If you type **options reg-via-key** without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

5. Save and activate your configuration.

SIP Registration Via Proxy

The Oracle Communications Session Border Controller supports a number of features that require it to cache registration information for UAs (endpoints) registering and receiving requests through it. For those features to operate correctly, the Oracle Communications Session Border Controller must act as the outbound proxy through which these endpoints register.

In order to support deployments where a proxy sits between the Oracle Communications Session Border Controller and the endpoints, the Oracle Communications Session Border Controller must consider the bottom Via header it receives from endpoints when constructing and matching cache registration entries. And when you use SIP port mapping, the system must use the bottom Via header as a way to determine the endpoint uniquely so that it can have a unique mapping port when the SIP interface is configured with the reg-via-key=all option.

Using the reg-via-proxy option, you can enable your Oracle Communications Session Border Controller to support endpoints that register using an intervening proxy. You can set this option either for a realm or for a SIP interface. If you use it for a SIP interface, add to the SIP interface pointing toward the proxy and endpoints—the access side.

Considerations for Reg-Via-Key and Port Mapping

When you set the **reg-via-proxy** option, the Oracle Communications Session Border Controller includes the bottom Via header from received requests in the registration cache Via Key. The system also uses it for determining whether or not the request matches a registration cache entry. Each unique bottom Via received a unique mapping port when you turn SIP port mapping on and set the SIP interface with the **reg-via-key=all** option.

Request Routing

So that requests addressed to the corresponding registered contact are routed to the proxy, the Oracle Communications Session Border Controller includes the intervening proxy (i.e., the top Via) in the routing information for the registration cache when you set **reg-via-proxy**. To carry out this routing scheme, the system adds a Path header (if none is present) to the REGISTER. But it removes the Path header prior to sending the REGISTER to the registrar.

Note that when the received REGISTER contains a Path header, the Oracle Communications Session Border Controller uses it for routing requests toward the endpoint and includes it in the forwarded REGISTER request—as is the case when you do not enable SIP registration via proxy.

SIP Registration Via Proxy Configuration

To configure SIP registration via proxy:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

4. Type **options +reg-via-proxy** and press Enter.

```
ORACLE(sip-interface)# options +reg-via-proxy
```

If you type options reg-via-proxy without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

5. Save and activate your configuration.

Dynamic Transport Protocol Change

The Oracle Communications Session Border Controller also uses the IP address and port in the Contact and Via headers. This is useful for cases when endpoints dynamically change transport protocols (TCP/UDP), and the port number used for sending an INVITE might not be the same one used to send a Register message.

If you do not enable this feature, when an endpoint registered with the Oracle Communications Session Border Controller used UDP for its transport protocol, a call fails if that endpoint subsequently initiates the call using TCP. The Oracle Communications Session Border Controller checks for the Layer 3 IP address and port, and it rejects the call if the port is changed.

With the new option reg-no-port-match added to the SIP interface configuration, the Oracle Communications Session Border Controller will not check the Layer 3 port in the INVITE and REGISTER messages.

Dynamic Transport Protocol Change Configuration

To enable dynamic transport protocol change:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

4. Type **options +reg-no-port-match** and press Enter.

```
ORACLE(sip-interface)# options +reg-no-port-match
```

If you type options reg-no-port-match without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

5. Save and activate your configuration.

SIP Privacy Extensions

This section explains how you can configure privacy services to be applied only when the source is trusted and the destination is considered untrusted. (Prior to this release, the Oracle Communications Session Border Controller always applied the privacy services, unless the source and the destination were both trusted.)

The Oracle Communications Session Border Controller considers all user endpoints and nodes outside the core as untrusted.

The Oracle Communications Session Border Controller acts as the boundary device between the trusted platform and the untrusted Internet, to implement privacy requirements. When it receives a message, the Oracle Communications Session Border Controller checks whether the source is trusted. It evaluates the level of privacy requested in a Privacy header, if present.

Depending on whether the source is trusted or untrusted, the Oracle Communications Session Border Controller can do different things when passing the message to the outgoing side. It also checks whether the destination is trusted.

Privacy Types Supported

The Oracle Communications Session Border Controller supports the following Privacy types:

- user: user-level privacy function provided. Any non-essential informational headers are removed, including the Subject, Call-Info, Organization, User-Agent, Reply-To, and In-Reply-To. Possibly the original value of the From header is changed to anonymous.
- header: headers that cannot be set arbitrarily by the user (Contact/Via) are modified. No unnecessary headers that might reveal personal information about the originator of the request are added. (The values modified must be recoverable when further messages in the dialog need to be routed to the originator.)
- id: third-party asserted identity kept private with respect to SIP entities outside the trust domain with which the user authenticated.

The following SIP headers can directly or indirectly reveal identity information about the originator of a message: From, Contact, Reply-To, Via, Call-Info, User-Agent, Organization, Server, Subject, Call-ID, In-Reply-To and Warning.

user

The Oracle Communications Session Border Controller supports the Privacy type user. It can remove non-essential information headers that reveal user information by:

- Setting the SIP From header and display information to anonymous
- Removing the Privacy header
- Removing Proxy-Require option tag = privacy (if present)
- Removing the following headers:
  Subject

  Call-Info

  Organization

  User-Agent

  Reply-To

In-Reply-To

header

The Oracle Communications Session Border Controller also supports the Privacy type header. It modifies SIP headers that might reveal the user identity by:

- Stripping the Via header
- Replacing the Contact header
- Stripping Record-Route
- Removing the Privacy header
- Removing Proxy-Require option tag = privacy (if present)

In general, the B2BUA behavior of the Oracle Communications Session Border Controller by default provides header privacy for all sessions.

id

The Oracle Communications Session Border Controller also supports the Privacy type id. It keeps the Network Asserted Identity private from SIP entities outside the trusted domain by:

- Stripping only P-Asserted-Identity
- Removing the Privacy header and Proxy-Require option-tag = privacy
- Setting the From header to anonymous (for the backward compatibility)

Examples

The following examples show the actions the Oracle Communications Session Border Controller performs depending on the source and target of the calls.

Calls from Untrusted Source to Trusted Target

When calls are from an untrusted source to a trusted target and PPI is included in the INVITE sent to IP border elements, the Oracle Communications Session Border Controller maps the PPI information to PAI in the outgoing INVITE to the trusted side (even if the Privacy header is set to id or to none). The Privacy and From headers get passed on unchanged.

IP border elements must pass PAI (if received in the ingress INVITE) and the From and Privacy headers to the egress side just as they were received on the ingress side.

The Oracle Communications Session Border Controller maps the PPI to PAI by default, if the outgoing side is trusted. To change this behavior, you need to configure the disable-ppi-to-pai option.

Calls from Trusted to Untrusted

When calls are from a trusted source to an untrusted target, and the Privacy header is set to id, the Oracle Communications Session Border Controller strips PAI, makes the From header anonymous, and strips the Privacy header.

If the Privacy header is set to none, the Oracle Communications Session Border Controller does not change the From header and passes on the Privacy header, if there is one.

Calls from Trusted to Trusted

When calls are going from trusted source to trusted target acting as a peer network border element and PPI is included, the Oracle Communications Session Border Controller maps PPI to PAI. The Privacy header remains the same as signaled and the Oracle Communications Session Border Controller passes the From header and the PAI without changes.

Configuring SIP Privacy Extensions

Prior to this release the session agent's trust mode provided this functionality. Now you configure SIP interface's trust-mode as none, which means nothing is trusted for this SIP interface.

You also configure the disable-ppi-to-pai parameter disable the changing of the P-Preferred header to the P-Asserted-Identity header, if the outgoing side is trusted.

Trust Mode

To configure the trust mode:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ORACLE(sip-interface)#
   ```

   From this point, you can configure SIP interface parameters. To view all sip-interface parameters, enter a **?** at the system prompt.

4. If configuring an existing interface, enter the select command to select the interface.
5. **trust-mode**—Select the trust mode for this SIP interface. The default value is **all**. The valid values are:
   - **all**—Trust all previous and next hops except untrusted session agents
   - **agents-only**—Trust only trusted session agents
   - **realm-prefix**—Trusted only trusted session agents or address matching realm prefix
   - **registered**—Trust only trusted session agents or registered endpoints
   - **none**—Trust nothing
6. Save and activate your configuration.

The following example shows the trust-mode set to none. The remaining SIP interface options are omitted for brevity.

```
sip-interface
        state                           enabled
        realm-id                        access1
        sip-port
                address                         192.168.1.30
                port                            5060
                transport-protocol              UDP
                allow-anonymous                 all
        carriers
        proxy-mode                      Proxy
        redirect-action
        contact-mode                    maddr
        nat-traversal                   none
        nat-interval                    30
        registration-caching            disabled
        min-reg-expire                  300
        registration-interval           3600
        route-to-registrar              disabled
        teluri-scheme                   disabled
        uri-fqdn-domain
        options
        trust-mode                      none
```

Disabling the PPI to PAI Change

To disable the changing of PPI to PAI:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   From this point, you can configure SIP configuration parameters. To view all sip-config parameters, enter a **?** at the system prompt.

4. If configuring an existing SIP configuration, enter the select command to select it.
5. **options**—Enter **disable-ppi-to-pai**. If adding to an existing list of options, use a preceding plus (+) sign.

   ```
   options +disable-ppi-to-pai
   ```

6. Save and activate your configuration.

SIP Registration Cache Limiting

Using SIP registration cache limiting for SIP endpoint access deployments, you can restrict the size of the SIP registration cache for the global SIP configuration.

You can implement this feature if you have been seeing issues where, either due to network failure scenarios or incorrect sizing of system capabilities, the Oracle Communications Session Border Controller and/or the SIP registrar cannot support the number of registering endpoints. Although the Oracle Communications Session Border Controller protects itself and the registrar against SIP REGISTER floods, conditions can still occur where too many legitimate endpoints attempt to register with the registrar via the Oracle Communications Session Border Controller.

By enabling SIP registration cache limiting, you restrict the number of legitimate endpoints that can register. The Oracle Communications Session Border Controller rejects any endpoints beyond the limit you set. If you do not want to use this feature, simply leave the reg-cache-limit parameter set to its default of 0, meaning there is no limit to the entries in the SIP registration cache.

When you limit the number of registered endpoints allowed in the Oracle Communications Session Border Controller's registration cache, the Oracle Communications Session Border Controller analyzes each registration before starting to process it. First, the Oracle Communications Session Border Controller checks the contact header to determine if it is already in the list of contacts for the user. If it finds the contact in its cache list, the Oracle Communications Session Border Controller treats the registration as a refresh; it treats any other headers as new. Note that the Oracle Communications Session Border Controller checks the message prior to making any changes to the cache because it must either accept or reject the message as a whole.

The Oracle Communications Session Border Controller adds the number of new contacts to the number already present in the cache, and rejects any registration with a contact that would cause it to exceed its limit. Rejection causes the Oracle Communications Session Border Controller to send a response communicating that its registration cache is full. The default response is the 503 Registration DB-Full message, but you can use the SIP response mapping feature to use another message if required.

You can set an option in the global SIP configuration that defines the value in the Retry-After header. The Oracle Communications Session Border Controller sends this header as part of its rejection response when the registration cache is full. Another option sets the percentage of the registration cache size which, if exceeded, causes the Oracle Communications Session Border Controller to send an alarm.

About Registration Cache Additions Modifications and Removals

When it receives a REGISTER message with new contact information for a user, the Oracle Communications Session Border Controller considers it an addition to the cache and augments the number of registration cache entries. Then the Oracle Communications Session Border Controller forwards the message to the registrar, and—when and only when the registrar returns both the original and new contacts in the 200 OK—the registration cache count stays the same. However, if the registrar returns only the new contact (making this a case of modification), then the Oracle Communications Session Border Controller removes the old contact information and subtracts accordingly from the number of registration cache entries.

Thus the Oracle Communications Session Border Controller does not know whether a REGISTER might result in an addition or a modification until it receives a response from the registrar. For this reason, the Oracle Communications Session Border Controller first assumes

it is to make an addition, and then updates the registration cache and count when it has the necessary information from the registrar.

The registration cache count does not reflect removals during the rejection check because the Oracle Communications Session Border Controller ignores registration messages or expires headers with their expires values set to zero when it counts new entries. The fact that removals take place after additions and modifications means that messages which remove one contact while adding another might be rejected. That is, the addition might exceed the registration cache limit before any removal can take place to make room for it.

Registration Cache Alarm Threshold

A percentage of the registration cache limit, the registration cache alarm threshold is a configurable value you can set to trigger an alarm when the registration cache is reaching its limit. When exceeded, this threshold triggers the generation of an alarm and SNMP trap. When registrations fall back beneath the threshold, the Oracle Communications Session Border Controller clears the alarm and sends a clear trap.

This alarm is Major in severity, and its text reads as follows:

```
Number of contacts <registration count> has exceeded the registration cache
threshold <threshold %> of <registration cache limit value>.
```

Notes on Surrogate Registration

The Oracle Communications Session Border Controller does not, under any circumstances, reject surrogate registrations on the basis of the registration cache limit. However, surrogate registrations generate contacts, and so they do add to the global registration count. In the case where the surrogate registrations add to the registration count to the extent the count exceeds the limit you configure, you will have more registrations in the cache than the configured limit.

Monitoring Information

You can monitor how many entries are in the SIP registration cache using the ACLI **show registration** command and referring to the Local Contacts statistics.

SIP Registration Cache Limiting Configuration

This section shows you how to configure the registration cache limit, and how to set the options controlling retry times and thresholds for alarm purposes.

To configure SIP registration cache limiting:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

If you are adding this feature to an existing configuration, you need to select the configuration (using the ACLI **select** command) before making your changes.

4. **registration-cache-limit**—Set the registration cache limit, or the maximum number of SIP registrations that you want to keep in the registration cache. The minimum and default value for this parameter is 0, and you can set it to a maximum value of 999999999. Leaving this parameter set to 0 means there is no limit on the registration cache (and therefore leaves this feature disabled).

5. **options**—Set the options parameter by typing options, a Space, the option name **reg-cache-lim-retry-after=X** (where X is the value added to the Retry-After header) with a plus sign in front of it. This option defaults to 1800, and you can enter values from 0 to 999999999.

   You can configure the alarm threshold option the same way, substituting the option name **reg-cache-alarm-thresh=X** (where X is the percentage of registration cache limit that triggers an alarm). This option defaults to 95, and you can enter value from 0 to 100.

```
ORACLE(sip-config)# options +reg-cache-lim-retry-after=2500
ORACLE(sip-config)# options +reg-cache-alarm-thresh=90
```

   If you type options and then the option value for either of these entries without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

6. Save and activate your configuration.

SIP Registration Overload Protection

You can configure your Oracle Communications Session Border Controller for SIP Registration overload protection, which augments the Oracle Communications Session Border Controller's protection methods. Working with the Oracle Communications Session Border Controller's access control and registration caching functions, this new feature guards against benign avalanche restarts. The avalanche is caused by events where many endpoints lose power or connectivity at once, are restored to service, and then flood the Oracle Communications Session Border Controller as they attempt to register again.

Normally, the Oracle Communications Session Border Controller handles SIP registration by creating a temporary registration cache for the endpoint's address of record (AoR) and forwards the REGISTER request to the registrar. To challenge the endpoint's registration, the registrar sends back either a 401 Unauthorized or 407 Proxy Authorization Required response. When it receives the 401 or 407, the Oracle Communications Session Border Controller saves the challenge context in anticipation of receiving a second REGISTER with the endpoint's authentication credentials. The Oracle Communications Session Border Controller forwards the second REGISTER (with authentication credentials) to the registrar, and then the registrar confirms registration with a 200 OK. Both REGISTER requests are subject to the system's access control rules, set either for the ingress realm or the ingress session agent. The Oracle Communications Session Border Controller also honors the maximum registration sustain rate constraint for session agents; this applies when the incoming REGISTER is from a session agent and the outgoing REGISTER is sent to a session agent.

When you enable SIP Registration overload protection, the Oracle Communications Session Border Controller temporarily promotes the endpoint to the trusted level when it receives the 401 or 407 response (to the first REGISTER) from the registrar. This ensures that the second REGISTER (containing authentication credentials) can reach the Oracle Communications Session Border Controller. Temporary promotion lasts only for the amount of time remaining before the REGISTER server transaction expires plus the time allotted in the transaction expiration parameter in the SIP configuration. Before the temporary promotion expires, there is enough time for any necessary retransmissions of the first REGISTER and for the second REGISTER to take place. The following situations might also occur:

- If the Oracle Communications Session Border Controller receives a 401 or 407 to the second REGISTER request, it resets its access control level for the endpoint's address to the default level; it then treats additional REGISTER requests from the same context at the default access control level.
- If the Oracle Communications Session Border Controller receives a 200 OK response to the REGISTER message, it extends the promotion time to the expiration period for the registration cache.

If the Oracle Communications Session Border Controller is able to find the temporary registration cache and the saved challenge context when the second REGISTER arrives, it forwards the REGISTER without checking the maximum registration sustain rate constraint for ingress and egress session agents—thereby ensuring that the REGISTER with authentication credentials is sent to the registrar. So when you use this feature, you should set the maximum registration sustain rate constraint of the session agent (representing the registrar) at half the registrar's maximum registration sustain rate. Additional REGISTER requests with the same challenge context are subject to the maximum registration sustain rate constraint.

SIP Registration Overload Protection Configuration

When you configure this feature, be sure to set the **reg-overload-protect** option in your global SIP configuration:

To enable SIP Registration overload protection on your Oracle Communications Session Border Controller:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name preceded by a plus sign (+) (**reg-overload-protect**), and then press Enter.

   ```
   ORACLE(sip-config)# options +reg-overload-protect
   ```

If you type either of these options without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

> **Note:**
>
> Note that the sip-config option "cache-challenges" (enabled by default) must not have been disabled for SIP Registration Overload Protection to work properly. If you have disabled cache-challenges, re-evaluate the reason you disabled it. If registration overload protection supersedes your reason for disabling cache-challenges, re-enable the option as shown below.

```
ACMEPACKET(sip-config)# options +cache-challenges=yes
```

Note that the configuration syntax above is equivalent to the following, which uses the "-" character to remove the option.

```
ACMEPACKET(sip-config)# options -cache-challenges
```

5. Save and activate your configuration.

SIP Registration Overload Protection for IMS-AKA

The SIP Registration Overload Protection (SROP) feature supports registrations via IMS-AKA. From the endpoint's perspective, overload protection for IMS-AKA endpoints is the same as for other endpoints. From the Oracle Communications Session Border Controller's perspective, however, overload protection functions differently with IMS-AKA, using ACLs to manage connectivity with the endpoint. De-registration support remains the same, either explicitly by UE signaling or by registration timeout. The ingress realm must be set to low or medium trust level.

SROP, with or without IMS-AKA, requires that the user enable both **reg-overload-protect** and **cache-challenges** in the sip-config.

For IMS-AKA SROP, the system creates one ACL entry for the path between the endpoint’s secure client port and the SBC's secure server port. This ACL allows both TCP as well as UDP signaling traffic for the path between the endpoint’s secure server port and the SBC's secure client port. The system temporarily promotes these ACLs to trusted when it receives the registrar's challenge (401 or 407) to an IMS-AKA endpoint's REGISTER request. The promotion period is temporary.

After receiving the 200 OK, the system updates the flow session timer with the registration expire timer and the registration timers. In addition, it updates the ACL entry with the new timer value. This value is the sum of the registration expire timer plus the remaining registration cache linger value.

The temporary ACL promotion is equal to the remaining expiration time of the REGISTER server transaction plus the value of the transaction-expire parameter of the sip-interface/sip-config. If the registration does not finish within this temporary promotion, the system allows the ACL session to expire and removes the entries.

> **Note:**
>
> The Oracle Communications Session Border Controller does not replicate this ACL's security associations to a standby system.

If signaling before the registration is complete shows the endpoints have changed their secure ports, the system deletes the ACLs initially set up for the registration. There are two ways for the system to delete these entries:

- The user can set the **remove-old-secured-acl-entries** option on the ingress sip-interface. This option causes the system to delete the entry as soon as it detects the secure ports are changed.
- If the option above is not set, the system deletes the entries when the session-timer expires.

> **Note:**
>
> The system adds the **Reset UE Ipp** keyword with the IP and port of the UE as an ACL entry to the log.sipd file each time it creates these ACLs.

SIP Instance ID in Registration Cache

As defined in RFC 5626, Managing Client-Initiated Connections in the Session Initiation Protocol (SIP), the `+sip.instance` uniquely identifies a specific user agent instance. The instance-id does not change even when the User Agent is rebooted or power cycled. Using the instance-id from the `+sip-instance` parameter allows the SBC to locate a registered contact even when the IP address of the UA has changed.

The +sip.instance is a Contact header field parameter that contains a globally unique identifier, generally a Universally Unique Identifier (UUID) Uniform Resource Name (URN) that identifies a specific user agent client.

As defined in RFC 5626, Managing Client-Initiated Connections in the Session Initiation Protocol (SIP), the parameter contains an "instance-id" that uniquely identifies a specific user Agent instance. The instance-id does not change even when the User Agent is rebooted or power cycled (see Section 3.1 of RFC 5626). Using the instance-id from the +sip-instance parameter allows the SBC to locate a registered contact even when the IP address of the UA has changed.

An example REGISTER message containing a `+sip-instance` parameter and assigned value is shown below.

```
REGISTER sip:example.com SIP/2.0
Via: SIP/2.0/TCP 192.0.2.2;branch=z9hG4bK-bad0ce-11-1036
Max-Forwards: 70
From: Bob <sip:bob@example.com>;tag=d879h76
To: Bob <sip:bob@example.com>
Call-ID: 8921348ju72je840.204
CSeq: 1 REGISTER
Supported: path, outbound
Contact: <sip:line1@192.0.2.2;transport=tcp>; reg-id=1;
```

```
;+sip.instance="<urn:uuid:00000000-0000-1000-8000-000A95A0E128>"
Content-Length: 0
```

The user agent calculates a `+sip.instance` generally using a time-stamp, a unique string -- such as a MAC address, and/or a randomly generated number. After calculating the value, the user agent saves it to persistent storage, thus ensuring that the value is unchanged by subsequent power cycles.

SIP Instance ID and the Registration Cache

Every assignment of a new IP address to a mobile user agent client results in a new REGISTER request. The receipt of the REGISTER request, in turn, generates an additional entry in the registration cache. The implementation can be simplified by including the +sip.instance value in the criteria used to match incoming REGISTER requests with existing sessions maintained in the registration cache. When a match is found, the SBC re-uses the existing registration cache rather than adding a new one.

If such a +sip.instance match is found and the contact address has changed, the SBC determines if digest authentication has been used in previous associated REGISTER requests. If so, the SBCs forwards the REGISTER request to the registrar for authentication of the new location.

SIP Instance ID Configuration

Because this configuration is dynamically performed at the **sip-config** level, it applies to all SIP interfaces and takes effect immediately

1. Access the **sip-config** configuration element.

   ```
   ORACLE# configure terminal
   ORACLE(configure)# session-router
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

2. Select the **sip-interface** object to edit.

   ```
   ORACLE(sip-interface)# select
   <RealmID>:
   1: realm01 172.172.30.31:5060

   selection: 1
   ORACLE(sip-interface)#
   ```

3. **match-sip-instance**—Set this parameter to enabled to use the +sip-instance-id when matching incoming calls with the registration cache. Valid values are:

   - **disabled**—(the default) disables the use of the +sip-instance-id when matching incoming calls with the registration cache
   - **enabled**—enables the use of the +sip-instance-id when matching incoming calls with the registration cache

   ```
   ACMEPACKET(sip-config)# match-sip-instance enabled
   ACMEPACKET(sip-config)#
   ```

4. Type **done** to save your configuration.

SIP Request Method Throttling

You can configure throttling mechanisms for SIP INVITEs and REGISTERs using session agent constraints. However, you might want to throttle other types of SIP methods, and for those methods you should use the rate constraints configuration available both in the session constraints (which you then apply to a SIP interface or a realm) and the session agent configurations.

Oracle recommends you use session agent constraints for session-rate INVITE throttling and registration-rate for REGISTER throttling.

For SIP access deployments, you can configure rate constraints for individual method types along with a set of burst and sustain rates. These constraints can help to avoid overloading the core network. In addition, they restrain the load non-INVITE messages use, thus reserving capacity for INVITE-based sessions and Registrations

When you configure SIP request method throttling, you must exercise care because it is possible to reject in-dialog requests. Therefore, Oracle recommends you do NOT configure constraints—although the configuration allows you to and will not produce error messages or warnings if you set them—for the following SIP method types:

- ACK
- PRACK
- BYE
- INFO
- REFER

However, the Oracle Communications Session Border Controller is likely to throttle NOTIFY requests despite their being part of a Subscribe dialog.

Therefore, the methods you will most likely configure for throttling are:

- NOTIFY
- OPTIONS
- MESSAGE
- PUBLISH
- REGISTER

The Oracle Communications Session Border Controller counts Re-INVITEs and challenged responses against the throttle limit, but does not check to determine if the constraints have been exceeded for either.

You can configure separate constraints—inbound and outbound values for burst and sustain rates—for each different method type you configure. Although you should use session agent constraints (and not rate constraints) for INVITEs, if you also set up rate constraints for INVITEs, then the smallest configured value takes precedence.

About Counters and Statistics

Each rate constraint you configure for a SIP method tracks its own counters. For example, if you configure a rate constraint for the PUBLISH method, the burst and sustain rates you set for it apply only to the PUBLISH method and not to any other methods for which you might set up

rate constraints. You can, however, set the burst rate window in the session constraints configuration that will apply to all methods configured as rate constraints.

The Oracle Communications Session Border Controller captures statistics for SIP methods throttled by rate constraints for SIP interfaces and session agents; it does not capture these statistics for the global SIP configuration.

SIP Request Method Throttling Configuration

This section shows you how to set up rate constraints for session constraints (which are then applied to SIP interfaces) and session agents.

To use this feature, you must enable the **extra-method-stats** parameter in the global SIP configuration.

To set the extra-method-stats parameter in the global SIP configuration:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
If you are adding this feature to an existing configuration, you need to
select the configuration (using the ACLI select command) before making
your changes.
```

4. **extra-method-stats**—Set this parameter to **enabled**.
5. Save and activate your configuration.

Rate Constraints for SIP Interfaces

To apply rate constraints to SIP interfaces, you need to configure rate constraints in the session constraints configuration and then apply the session constraints to the SIP interface where you want them used.

Note that you need to set up the parent **session-constraint** configuration to save any rate constraints you configure.

To configure rate constraints:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-constraints** and press Enter.

```
ORACLE(session-router)# session-constraints
ORACLE(session-constraints)#
```

If you are adding rate constraints to an existing configuration, then you will need to select the configuration you want to edit.

4. Type **rate-constraints** and press Enter.

```
ORACLE(session-constraints)# rate-constraints
ORACLE(rate-constraints)#
```

5. **method**—Enter the SIP method name for the method you want to throttle. Although the parameter accepts other values, your entries should come only from the from the following list for the feature to function properly:
   - NOTIFY
   - OPTIONS
   - MESSAGE
   - PUBLISH
   - REGISTER
6. **max-inbound-burst-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the inbound burst rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
7. **max-outbound-burst-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the outbound burst rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
8. **max-inbound-sustain-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the inbound sustain rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
9. **max-outbound-sustain-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the outbound sustain rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
10. Save your changes and apply this session constraint and its rate constraint(s) to SIP interfaces.

Applying Session and Rate Constraints to a SIP Interface

You need the name of the session constraints configuration to apply the restrictions you set up to a SIP interface.

To apply session and rate constraints to a SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

   If you are adding this feature to an existing configuration, then you will need to select the configuration you want to edit.

4. **constraint-name**—Enter the name of the session constraint configuration where you have set up rate constraints to apply them to this SIP interface. This parameter has no default, and must be the valid name of a session constraint configuration.
5. Save and activate your configuration.

Configuring Rate Constraints for Session Agents

You can also use this feature for individual SIP session agents.

To configure rate constraints for a SIP session agent:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-agent** and press Enter.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

   If you are adding rate constraints to an existing configuration, then you will need to select the configuration you want to edit.

4. Type **rate-constraints** and press Enter.

```
ORACLE(session-agent)# rate-constraints
ORACLE(rate-constraints)#
```

5. **method**—Enter the SIP method name for the method you want to throttle. Your entries should come only from the following list:

- NOTIFY
- OPTIONS
- MESSAGE
- PUBLISH
- REGISTER

6. **max-inbound-burst-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the inbound burst rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
7. **max-outbound-burst-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the outbound burst rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
8. **max-inbound-sustain-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the inbound sustain rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
9. **max-outbound-sustain-rate**—For the SIP method you set in the methods parameter, enter the number to restrict the outbound sustain rate on the SIP interface where you apply these constraints. The default and minimum value is 0, and the maximum is 999999999.
10. Save and activate your configuration.

Suppressing Re-INVITEs for Call Hold/Resume Dialogs

You can configure the SBC to suppress Re-INVITEs for Call Hold/Resume dialogs and REPLACES dialogs to reduce excess signaling traffic. From the perspective of the SBC, a re-INVITE on one side of a session does not necessarily need to be forwarded to other side. When the SBC receives a Re-INVITE that triggers, for example, a call hold, it can suppress that message from being sent out the egress and handle the transaction locally, between itself and the endstation that sent the re-INVITE.

Within an existing session, SIP allows for re-INVITEs when a station requests a change to dialog parameters, session parameters, or both. To configure this feature, you enable the **suppress-hold-resume-reinvite** on the applicable **realm-config**. The applicable realm depends on your design. You enable **suppress-hold-resume-reinvite** on:

- The ingress realm to suppress hold/resume INVITEs that come from the egress
- The egress realm to suppress hold/resume INVITEs that come from the ingress

In addition, if you enable **suppress-hold-resume-reinvite** on both the ingress and egress realms, the system does not suppress hold/resume re-INVITEs.

When enabled, the SBC targets Re-INVITEs for this suppression feature when it receives a Re-INVITE within specific call flow scenarios:

- Call Hold re-INVITE—The SBC recognizes a hold re-INVITE when it receives an INVITE that is within the existing dialog and includes the SDP media attribute set to inactive or sendonly, or when it receives an INVITE with a connection IP set to 0.0.0.0.
  When it receives a call hold Re-INVITE the SBC:
  - Plays music on hold, assuming you have configured the tone to be played by the SBC during hold.

> **Note:**
>
> This feature does not require MOH.

  - Suppresses this INVITE
  - Responds locally to the station that sent the hold with a 200 OK

  The SBC does not suppress these re-INVITEs when it finds the SDP media attribute set to recvonly. Furthermore, the SBC continues to forward any subsequent re-INVITEs, disabling this re-INVITE suppression feature, after forwarding a recvonly INVITE until the call returns to sendrecv mode. Having returned to sendrecv, the SBC begins to enforce its re-INVITE suppression feature again.

- Call Resume re-INVITE—The SBC recognizes a resume re-INVITE when it receives an INVITE after a call hold re-INVITE that is within the existing dialog. In addition, this re-INVITE must include an SDP media attribute set to sendrecv and the connection IP set to the original IP.
  When it receives a resume Re-INVITE the SBC:
  - Stops MOH
  - Suppresses this INVITE
  - Responds locally to the station that sent the resume with a 200 OK
  - Resumes media support
- re-INVITE with codec change—This scenario can occur when an end-station simply changes codecs. In addition, each of the scenarios above may include a codec change whether or not the ensuing signaling results in transcoding.
- re-INVITE with Replaces header—The SBC suppresses a Re-INVITE that includes the REPLACES header. This scenario is a hold/resume scenario that includes moving the dialog to a different end station.
  When receiving an INVITE with a replaces header, the SBC:
  1. Suppresses this re-INVITE from forwarding out the egress
  2. Replies to the sender with a 200 OK
  3. Supports the new media
  4. Sends a BYE to the original station
- Offerless Re-INVITE—When you configure this feature, the SBC does not forward an offerless re-INVITEs out the egress interface.

Related Configuration

Related configuration considerations include:

- For deployments that need to support dialog replacement, this feature requires that you apply a **sip-profile** with the **replace-dialogs** parameter enabled to the **sip-interface**.
- This feature takes precedence over the **suppress-reinvite** option available on a **sip-interface**.
- If you configure a **session-timer-profile** on an applicable **sip-interface**, the system generates Re-INVITEs or UPDATEs based on **force-reinvite** parameter.
- This feature does not work in conjunction with TrFO configurations.

Consider the following functional limitations when deploying this feature:

- This feature does not work within REFER scenarios.
- This feature does not perform INVITE suppression on re-INVITEs and replace INVITEs when they contain multiple m-lines.
- If a call is on hold with music on hold playing, an HA switchover causes the MOH to stop.

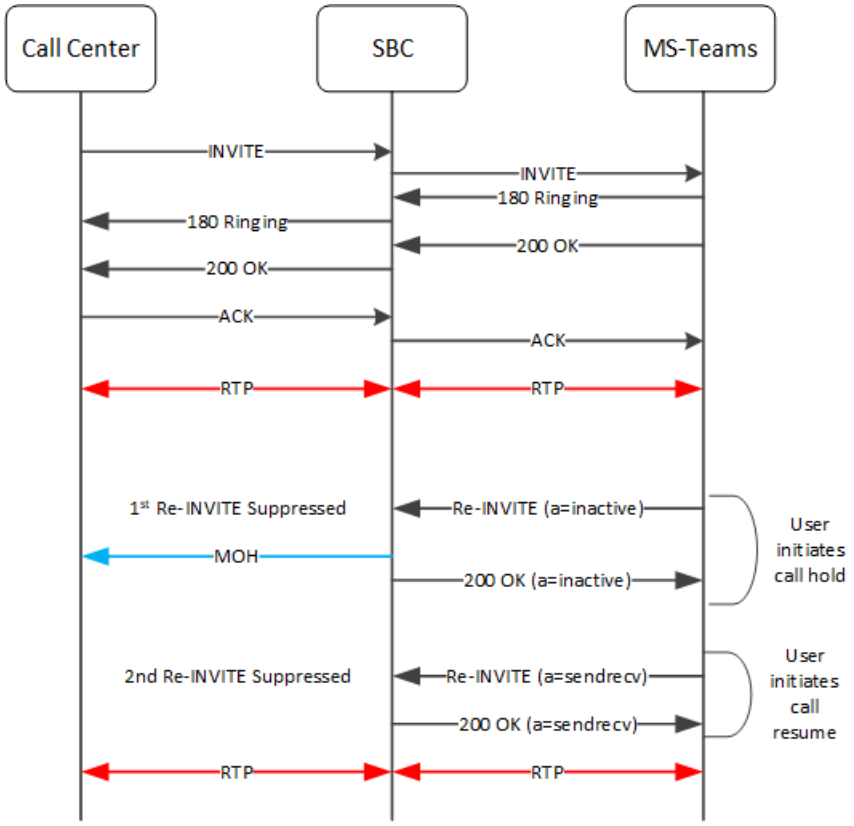
Call Flows for INVITE Suppression

This section provides categories of call flows within which the SBC suppresses INVITEs from transmission out the egress realm to reduce traffic in that realm. The call flows present an MS-Teams environment that initiates and receives calls to a call center and supports a set of applicable operations.

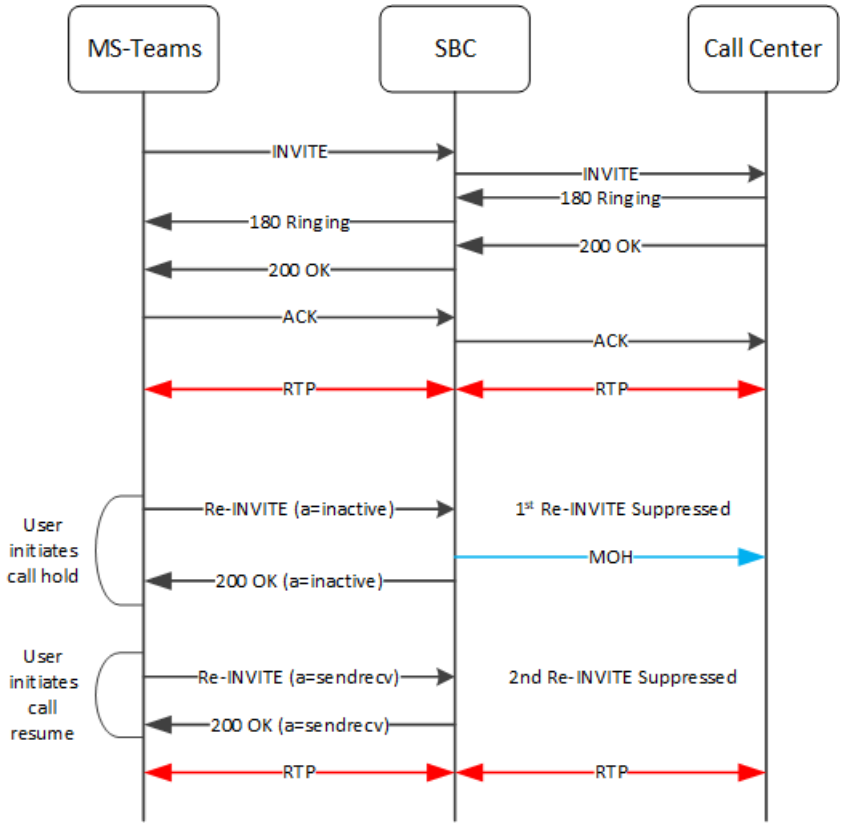
This section displays signaling detail on hold, transcoding, replaces and offerless INVITE operations within which the SBC suppresses INVITEs.

Hold and Resume Call Flows

In this first call flow, the SBC supports a call from the call center to the MS-Teams deployment within which the Teams station temporarily puts a call on hold. The SBC suppresses extraneous INVITEs that occur when the call goes on hold and resumes. In both cases, the SBC responds locally to the MS-Teams station to maintain transaction integrity. In addition, this flow shows that you have configured and properly triggered music on hold to the call center while waiting for the RTP to resume.



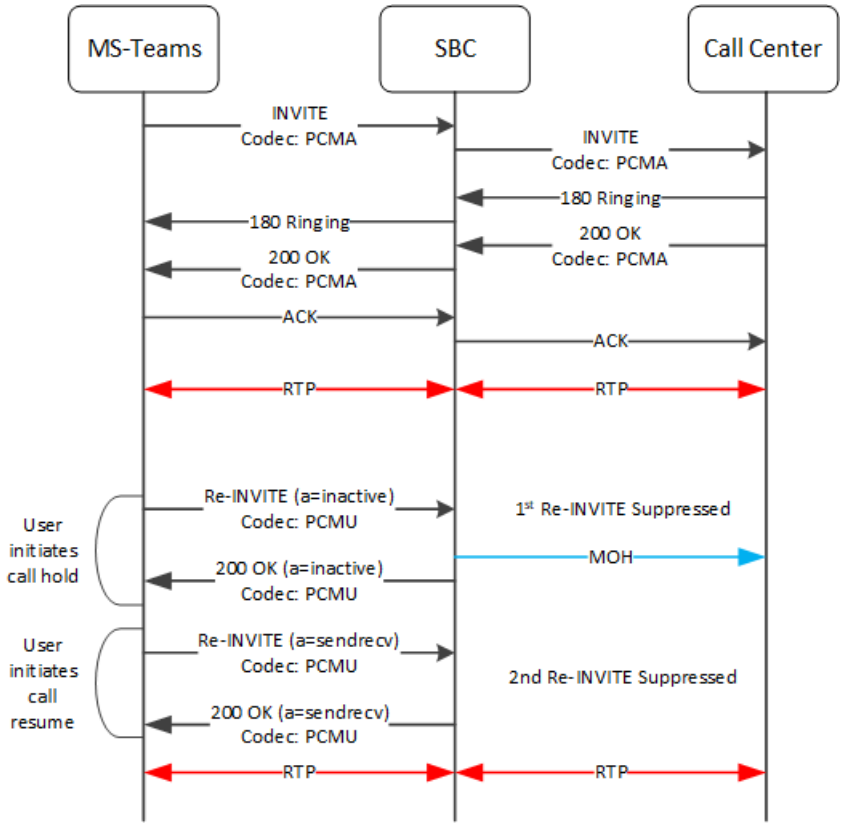
This call flow performs the same function as the first flow with the exception that the call starts on the MS-Teams side. The flow demonstrates the SBC supporting the suppression function on behalf of the caller instead to the callee.



Transcoding

This call flow depicts the SBC performing re-INVITE suppression when an MS-Teams station that has started a call initiates a codec change. The initial call had been proceeding using PCMA on both sides of the call. With the request of a codec change, the SBC changes codec support between itself and the MS-Teams station from PCMA to PCMU. The calling station includes a call hold signal while the codec change takes place, and the SBC issues music on hold during the change.

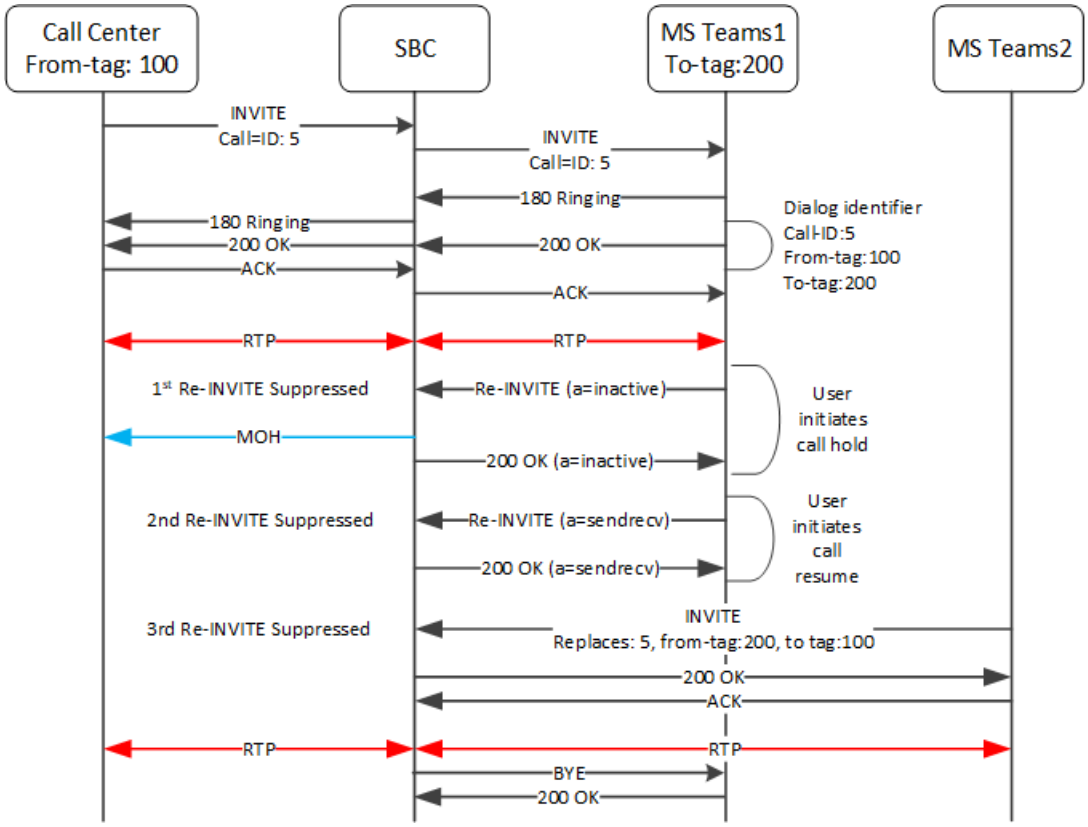
This codec change is not needed on the call center side, so the SBC suppresses the re-INVITE and issues music on hold during the codec change. When the SBC receives a resume re-INVITE, it stops the music on hold and transcodes from PCMU to PCMA transparently to the call center.



REPLACES Call Flow

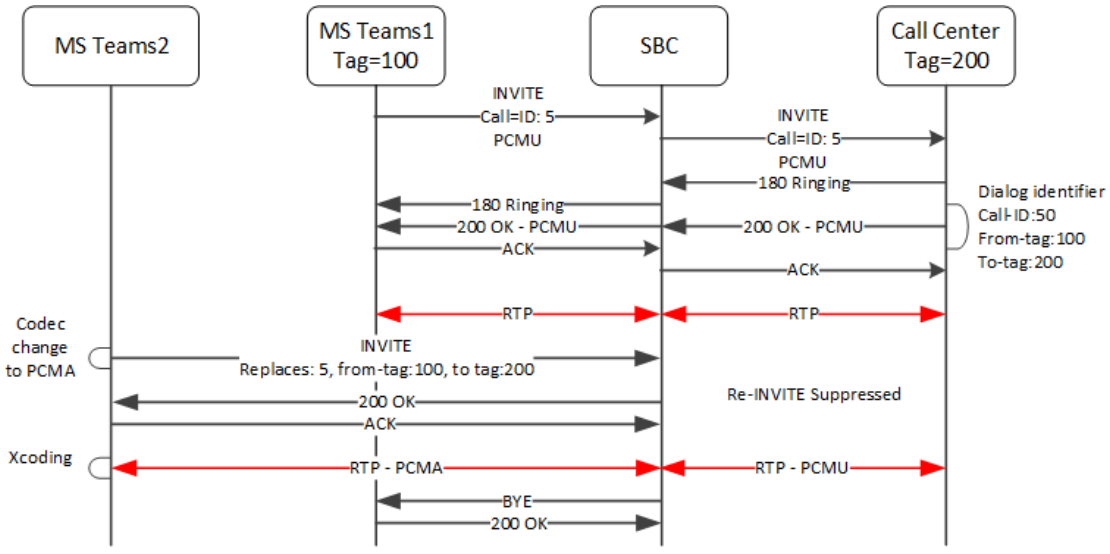
This first replaces flow depicts a call initiated from a call center to an MS Teams endstation. The SBC supports this call setup using its original dialog identifier. The scenario then includes the original MS Teams station replacing the dialog to transfer the call to a second MS Teams station. During the replaces process, the SBC suppresses the INVITEs from the call center, including the hold, resume and replaces INVITEs. The SBC accepts the new dialog to the seconds MS Teams station, and sends a BYE to the first.

After the replaces process, both legs of the SBC maintain different call-id's for the same call.



This next replaces flow depicts a call initiated from a call center to an MS Teams endstation, and includes a codec change resulting in the SBC performing transcoding. In this flow the call center initiates a similar call to the first MS Teams station using PCMU.

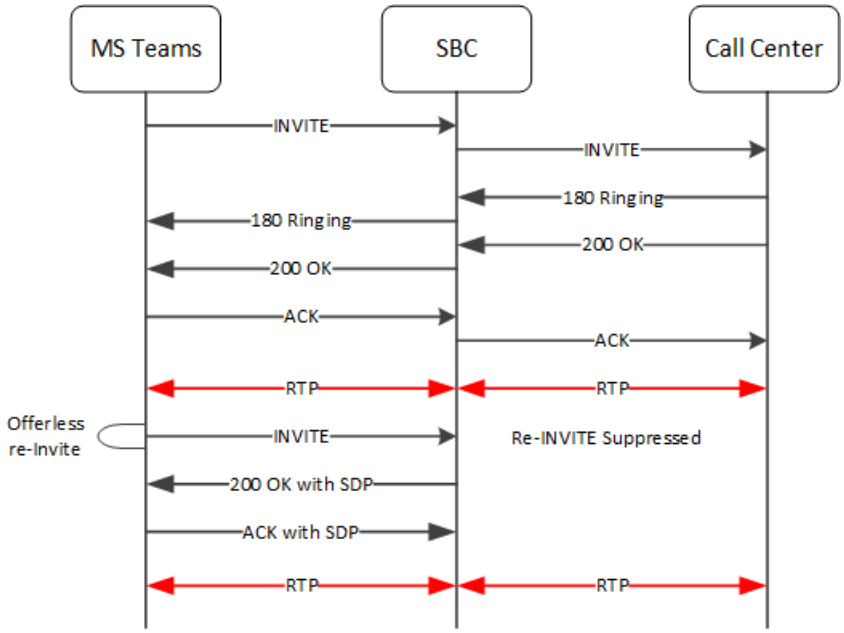
Within the context of the replaces process, however, the second MS Teams station includes a different change. The SBC suppresses this re-INVITE from the call center, accepts the media flow in PCMA. The result is a new media flow using transcoding.



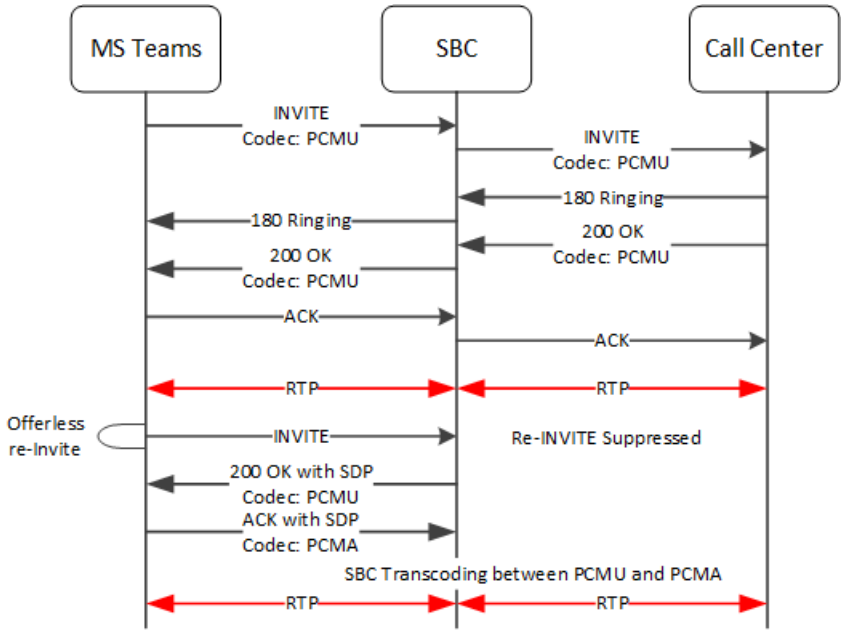
Offerless Re-INVITE Call Flows

In this call flow, an MS Teams station initiates a successful call to a call center. Subsequently, the MS Teams station issues a re-INVITE that does not include SDP. The SBC suppresses this

re-INVITE and responds to the MS Teams station with a 200 OK that includes SDP. MS Teams responds with an ACK and the RTP resumes.



This second offerless INVITE example is similar to the first, with the exception that the final ACK presents a different codec. The SBC responds to this situation by transcoding the PCMA RTP presented by the MS Teams station to PCMU, which was previously used by both legs of the call.



Interaction Between Session Timers and re-INVITE Suppression

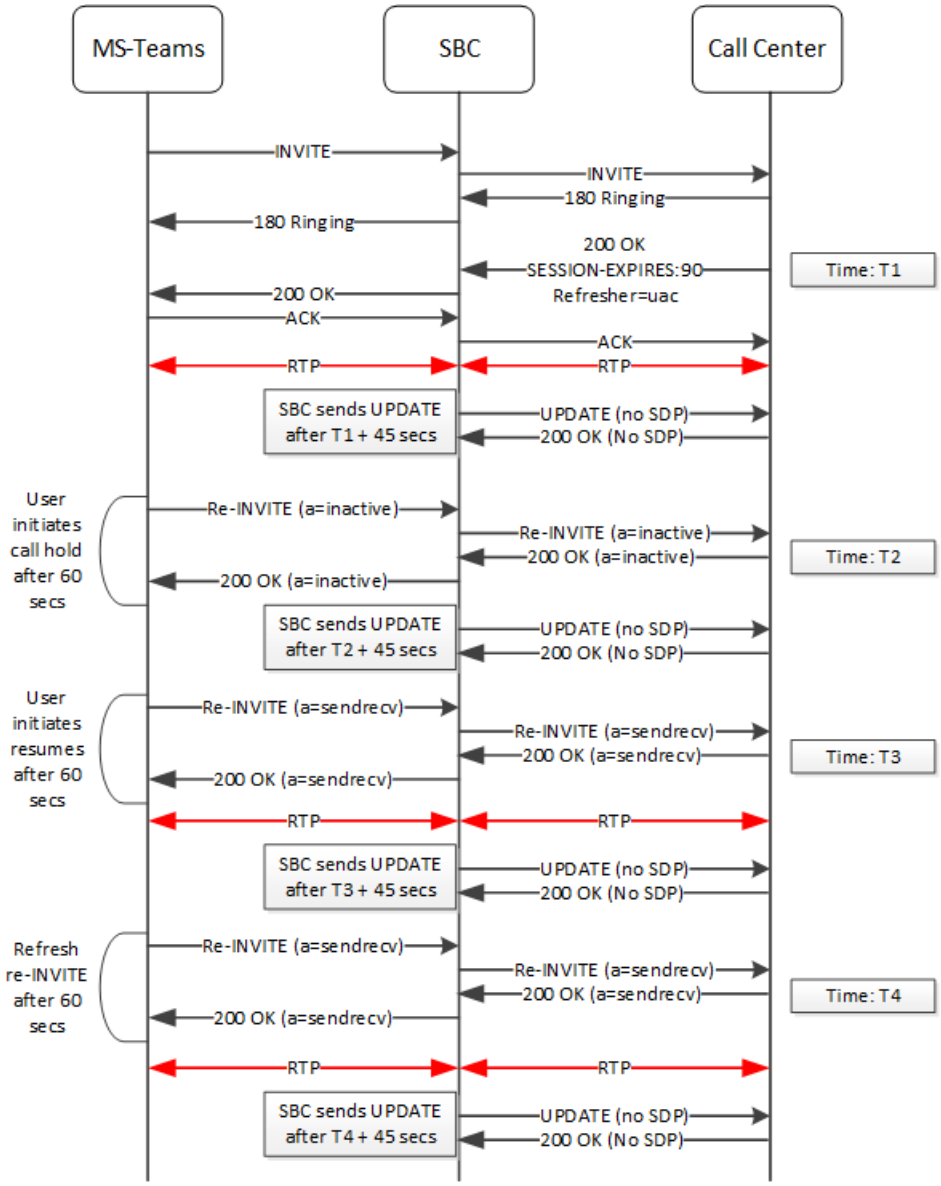
When configured, the SBC performs session timer and re-INVITE suppression operations simultaneously.

This re-INVITE suppression excludes refresh re-INVITEs. Within the context of standard SIP operation, neither an endstation nor the SBC may necessarily be aware of a session ending, for example, without a BYE. SIP operation may use session timer mechanisms within refresh

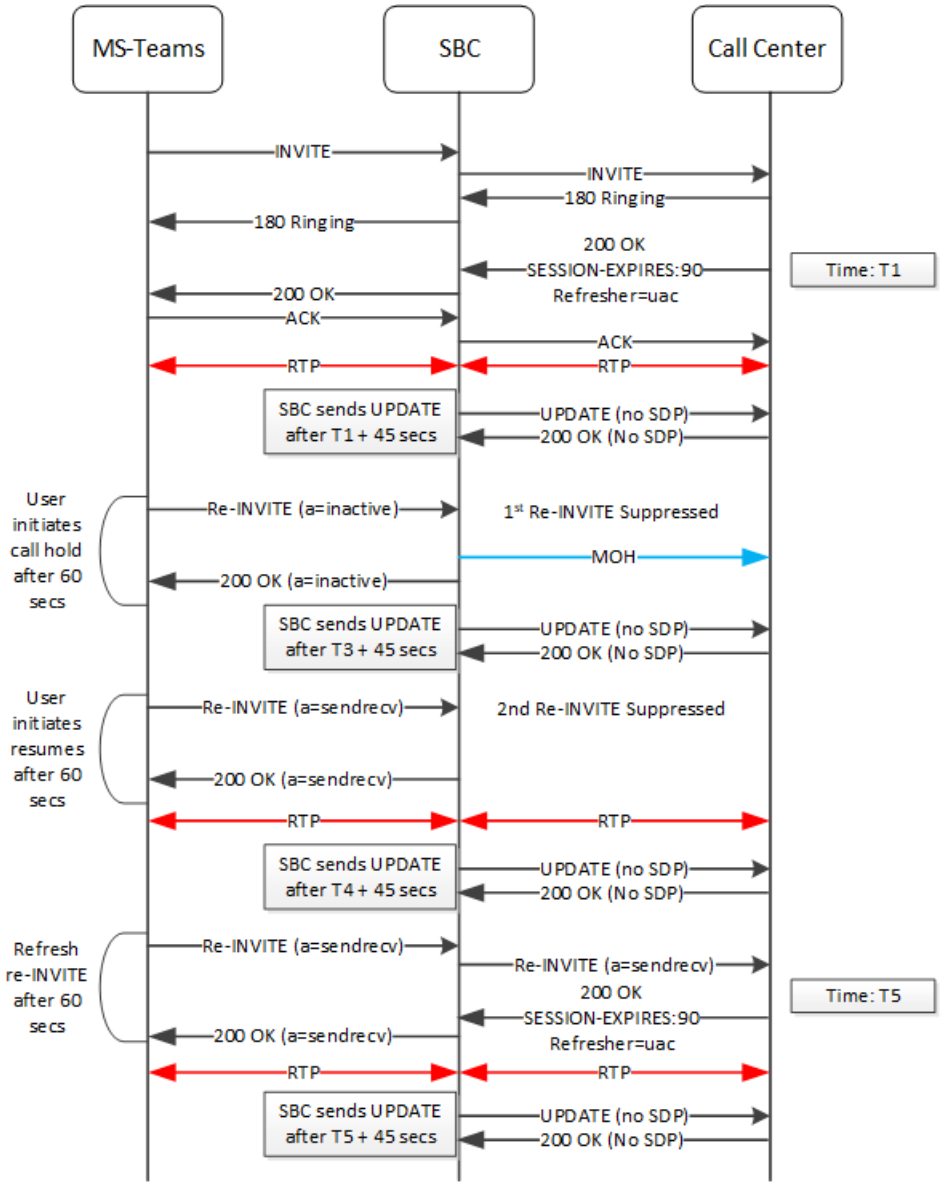
re-INVITEs and UPDATEs to convey expiration or minimal session timing information, which can confirm that a session is still active.

The SBC distinguishes between a re-INVITE that, for example, triggers a call hold and one that performs a refresh re-INVITE triggered by the presence of the Session-Expires parameter. The Session-Expires parameter conveys the lifetime of the session. The Min-SE parameter conveys the minimum allowed value for the session timer. The SBC forwards the latter to support session timing mechanisms unless you have also configured the **session-timer-profile** on the applicable **sip-interface**. This profile allows the SBC to end the session by itself.

The call flow below presents the SBC performing the functions of the **session-timer-profile** below. This profile has its **force-reinvite** parameter set to its default, enabled.



The call flow below presents the SBC performing the functions of the **session-timer-profile** and the the **suppress-hold-resume-reinvite** on the ingress **realm-config** below.



SIP Delayed Media Update

The Oracle Communications Session Border Controller supports SIP delayed media update. When enabled, this feature keeps the Oracle Communications Session Border Controller from updating its media flow information for flows established after an offer-answer exchange. The Oracle Communications Session Border Controller does not update the flow information until a new offer and answer arrive for a specific set of media flows.

The (subsequent) offer does not have to be for the same session; rather, it can appear as a new SIP INVITE that uses the same SDP.

Delayed Media Update Disabled

When this feature is disabled (which is the default behavior), the Oracle Communications Session Border Controller updates media flow entries in its CAM based on signaled SDP when it processes the SDP. If it processes an SDP offer, Oracle Communications Session Border

Controller allocates steering port resources; the Oracle Communications Session Border Controller updates any missing elements for the flow when the answer is returned.

In cases when a secondary offer arrives (either a reINVITE, an UPDATE, or the original INVITE is hairpinned back through the Oracle Communications Session Border Controller), the Oracle Communications Session Border Controller updates the following media flow information at the time of the offer

- Destination IP address
- Destination port
- Realm for the media flows
- Media release settings

This behavior affects specific applications that are better served by the Oracle Communications Session Border Controller waiting to update media flow information until it receives the answer to the second offer.

Delayed Media Update Enabled

When you enable the SIP delayed media update feature, the Oracle Communications Session Border Controller:

- Delays changing the active media flow CAM entry for a new offer if a previous offer and answer have been received for the same media flows; it encodes new SDP information in an outgoing offer, but does not change the CAM entry until the answer is received
- Delays changing the active media flow CAM entry even when the new offer is for a new session
- Supports media release when performing delayed media update changes
- Offers per-realm configuration

This section describes how the delayed media update feature works for hairpinned call flows and for an SDP offer arriving for installed flows.

- Hairpinned call flows—In this type of call flow, the application server (AS) sends an INVITE back to the Oracle Communications Session Border Controller and that INVITE needs to be forwarded to another user (user B). When it receives the offer in this INVITE and delayed media update is disabled, the Oracle Communications Session Border Controller determines that the call is hairpinned and deletes the CAM entry for the flow for user A, who has sent the initial INVITE. The Oracle Communications Session Border Controller deletes the CAM entry for the flow from the AS to user A.
  With delayed media update enabled, the CAM entry for the flow from the AS to user A is not deleted. Instead, the Oracle Communications Session Border Controller waits until it has an answer from user B, and then performs the necessary updates and deletions.
- SDP offer for installed media flows—With delayed media update enabled, if it has received an offer and answer and a new offer arrives for the same flow, the Oracle Communications Session Border Controller delays updating the CAM entries until an answer is received for the new offer.

SIP Delayed Media Update Configuration

You enable this feature on a per-realm basis by setting one parameter.

To enable SIP delayed media update:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the signaling-related configurations.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm-config** and press Enter.

   ```
   ORACLE(media-manager)# realm-config
   ```

   If you are adding support for this feature to a pre-existing realm, then you must select (using the ACLI **select** command) the realm that you want to edit.

4. **delay-media-update**—Enable keeping the Oracle Communications Session Border Controller from updating its media flow information for flows established after an offer/answer exchange. The default is **disabled**. The valid values are:
   - enabled | disabled
5. Save and activate your configuration.

Expedited Call Leg Release for Preempted Hairpin Calls

When hairpinned calls are ended because of signaling failures (such as a SIP mid-dialog signaling timeout, or an H.323 TCP keepalive failure) on one call leg, the Oracle Communications Session Border Controller deletes both legs' media flows simultaneously by default. In addition, when the first hairpinned call leg is torn down, the second call leg is gracefully released immediately by the Oracle Communications Session Border Controller creating and sending an appropriate signaling message (e.g., BYE for a SIP call or ReleaseComplete for an H.323 call) to the endpoint.

You can override this behavior by configuring the **dont-terminate-assoc-legs** option in the media manager. When configured, the orphaned call leg in the hairpin scenario will be torn down after the **initial guard timer expires.** The disconnect times of the two call legs, as recorded by the accounting appliation, will be significantly different, due to the initial guard time for the second call leg.

Accounting Considerations

To indicate cases like this, where the second leg of the hairpinned call was preempted, Oracle Communications Session Border Controller includes the following combination of release/termination causes in the CDR:

```
VSA 49: Acct-Terminate-Cause = NAS_REQUEST
VSA 62: Acme-Disconnect-Cause = 8
```

Supporting Released Flows that are Subsequently Hairpinned back to the SBC

The Oracle Communications Session Border Controller (SBC) allows you to quickly re-establish media flows for released calls that may be hairpinned back the SBC by other network elements.

When the SBC releases a media flow, it also deletes information related to that flow by default. For a call that the environment subsequently hairpins back to the SBC, there is a delay in determining how to forward it. You can configure the SBC to retain IP/port information for all released calls to cause it to quickly process and forward these calls. To do this, you configure the **media-manager** with the **hairpin-released-flows** option.

```
ORACLE(media-manager)# options +hairpin-released-flows
```

This configuration makes the SBC store the IP/port information of the released media port sent out in the SDP. Should a proxy or media server send the media connection with that IP/port back to the SBC, the SBC recognizes the leg and performs the proper linking between the flows.

Recall that you determine whether the SBC releases or manages media using the **mm-in-realm**, **mm-in-network**, **mm-same-ip** and **mm-in-system** settings in the realm configuration.

SIPconnect

The Oracle Communications Session Border Controller supports the SIPconnect model, wherein PBXs register themselves so that service providers do not need to know IP addresses or locations in advance for static configurations. This is particularly helpful when the PBX is behind a NAT.

In the PBX registration process, the PBX creates a binding between one of its phone numbers as the address of record (AoR) and Contact-URI in the REGISTER message. The registrar knows that the single AoR actually represents many addresses, and so it registers them implicitly. However, the registrar does not return the implicit AoR number in P-Associated-URIs.

The SIPconnect feature resolves the following issues that arise from using this model:

- SIP INVITEs sent to the PBX from the Registrar through the Oracle Communications Session Border Controller have the Request-URI of registered contact. Because it typically ignores the To-URI, the PBX needs the Request-URI username portion to be the specific extension number being called.
  With the SIP connect feature enabled, the Oracle Communications Session Border Controller overwrites the Request-URI username with the To-URI username.
- SIP INVITEs from the PBX have the From AoR and Contact-URI usernames of specific phones rather than of the registered AoR and Contact-URI. For the Oracle Communications Session Border Controller, this means that it cannot use the **allow-anonymous** parameter value of register; there would be no registered user matches, and the Oracle Communications Session Border Controller would reject them (with a 403 Forbidden).
  With the SIP connect feature enabled, the Oracle Communications Session Border Controller performs allow-anonymous checking based on the registered Via address, which is the same for all requests for the same PBX.

Modifications to Registration Caching Behavior

With the SIP connect feature enabled, Oracle Communications Session Border Controller registration caching works the same way that it does with the feature disabled, with the following exceptions:

The Oracle Communications Session Border Controller determines whether the destination realm has the sip-connect-pbx-reg option configured, and then:

- If it is configured, the Oracle Communications Session Border Controller replaces the user part of the Request-URI with the user part of the To header. When the INVITE contains a P-Called-Party-ID header, the Oracle Communications Session Border Controlleruses the user part of the P-Called-Party-ID header (instead of the To header).
- If it is not configured, the Oracle Communications Session Border Controller determines if the destination address is for a session agent and whether that session agent has sip-connect-pbx-reg option configured. When it is configured, the Oracle Communications Session Border Controller performs the same replacements described in the bullet directly above. When it is not configured, the Oracle Communications Session Border Controller does not make any replacements.

When it receives an INVITE request, the Oracle Communications Session Border Controller checks the incoming realm for the sip-connect-pbx-reg option.

- If it is configured, the Oracle Communications Session Border ControllerC uses the INVITE's source address (instead of the AoR and Contact-URI) to search the registration cache for a matched registration entry.
- If it is not configured, the Oracle Communications Session Border Controller determines if the INVITE's source address is for a session agent and whether that session agent has sip-connect-pbx-reg option configured.
  When it is configured, the Oracle Communications Session Border Controller replaces the user part of the Request-URI with the user part of the To header. When the INVITE contains a P-Called-Party-ID header, the Oracle Communications Session Border Controlleruses the user part of the P-Called-Party-ID header (instead of the To header).

  When it is not configured, the Oracle Communications Session Border Controller does not make any replacements.

Configuring SIP Connect Support

You configure this feature by adding the sip-connect-pbx-reg option to the realm configuration. In addition, though this feature requires that your configuration also be set up as outlined in this section. The first two items are required, and Oracle recommends that you also implement the suggested additional configuration.

Required Configuration

- Registration caching is enabled.
- For the realm from which registrations come, the options list must include sip-connect-pbx-reg; this is new configuration introduced to support this feature. The presence of this option instructs the Oracle Communications Session Border Controller to skip matching the Contact header in the INVITE request with the registered Contact of the registration entry. The Oracle Communications Session Border Controller finds a registration using only the INVITE's source address.

Alternatively, you can configure the sip-connect-pbx-reg option in the options list for a session agent. When the realm where an INVITE comes from does not have this option set, the Oracle Communications Session Border Controller determines whether or not the INVITE came from a session agent. You might choose to configure session agents with this option if you do not want it applied to an entire realm. If the PBX is behind a NAT device, the session agent's IP address for the PBX (if statically configured) must be the IP address of the NAT device. And if DNS is use, the session agent's hostname must resolve to the NAT device's IP address.

Suggested Additional Configuration

- In the SIP ports configuration (accessed through the SIP interface configuration), the **allow-anonymous** parameter must be set to registered. This setting allows the Oracle Communications Session Border Controller to accept SIP requests from session agents and registered endpoints only, but to accept REGISTER requests from any endpoint.
- For the SIP interface that accepts registrations, the **options** parameter must be set to reg-via-key. This setting allows the Oracle Communications Session Border Controller to use the source address of an INVITE as the key to find a registration entry in the registration cache. When the INVITE's Contact header matches the registered Contact in the registration entry, the Oracle Communications Session Border Controller accepts the INVITE request.

SIP Connect Configuration

To set the SIP connect option for a realm configuration:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the signaling-related configurations.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **realm-config** and press Enter.

   ```
   ORACLE(media-manager)# realm-config
   ```

   If you are adding support for this feature to a pre-existing realm, then you must select (using the ACLI **select** command) the realm that you want to edit.

4. **options**—Set the options parameter by typing **options**, a Space, the option name **sip-connect-pbx-reg** with a plus sign in front of it, and then press Enter.

   ```
   ORACLE(realm-config)# options +sip-connect-pbx-reg
   ```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the realm configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

   To set the SIP connect option for a SIP session agent configuration:

6. In Superuser mode, type **configure terminal** and press Enter.

```
Oracle Communications Session Border Controller# configure terminal
```

7. Type **session-router** and press Enter to access the signaling-related configurations.

```
Oracle Communications Session Border Controller(configure)# session-router
```

8. Type **session-agent** and press Enter.

```
ORACLE(session-router)# session-agent
```

   If you are adding support for this feature to a pre-existing session agent, then you must select (using the ACLI **select** command) the session agent that you want to edit.

9. **options**—Set the options parameter by typing **options**, a Space, the option name **sip-connect-pbx-reg** with a plus sign in front of it, and then press Enter.

```
Oracle Communications Session Border Controller(session-agent)# options
+sip-connect-pbx-reg
```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the session agent's configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

10. Save and activate your configuration.

SIP Registration Event Package Support

Certain endpoints subscribe to the Registration Event Package, RFC 3680, which defines how SIP user agents can request and obtain notifications about registration events. Previously, the Oracle Communications Session Border Controller (SBC) passed the Subscribe and Notify messages of this package transparently, without modifying the XML bodies of either. However, in many cases the XML body can contain IP addresses, contact URIs, and expires times that the SBC needs to modify for proper operation. This new feature enables the SBC to modify correctly the XML body for the Registration Event Package.

In addition to resolving this type of issue, enabling registration event package support on your system provides the functions described below:

- The SBC performs NAT on all contacts in the reginfo, regardless of their state.
- The SBC performs NAT on the address of record (AoR) attribute of the Registration element when it matches an existing cache entry. When either the Contact-URI or the AoR does not match a cache entry and the host part of the URI is an IP address, the SBC will NAT the host part using the applicable SIP NAT configuration
- Contacts are found in the XML URI element for the contact. But if there is no URI element, then the SBC uses the Contact element information for the contact.
- If the expires attribute in the Contact element is a value other than zero, the SBC uses (inserts) the expires values from the registration cache.
- This feature also introduces delayed deletion from the registry cache. When a 200 OK comes back in response to a REGISTER message and the 200 OK does not include all previously registered contacts, the missing contacts are deleted. If the global SIP

configuration option contact_cache_linger=XX (where XX is the number of seconds to wait before deleting), then the contacts to be deleted remain for the specified number of seconds before they in fact are deleted.

The SBC provides statistics counters for the number of Reg-Event subscriptions it manages via the ACLI, SNMP and HDR.

Updating Expiration Values

This feature also supports updating the expiration values for the registration cache when a Contact element has the expires attribute. For this support, the following apply:

- If the value of the expires attribute is greater than the expiration value for the access-side registration cache entry, the Oracle Communications Session Border Controller replaces the XML expires attribute value with the cached one from the access side.
- If the value of the XML expires attribute is less than the core-side expiration value for the core-side registration cache entry, the Oracle Communications Session Border Controller updates the core-side expiration value with the value from the expires attribute. Further, the Oracle Communications Session Border Controller adjusts the access-side expiration value of the registration cache in these ways:
  - If the value of the XML expires attribute is less than the current access-side expiration value for the registration cache entry, the Oracle Communications Session Border Controller sets the access-side expiration value to be equal to the value in the expires attribute.
  - Otherwise, the Oracle Communications Session Border Controller leaves the expires value for the access-side expiration value for the registration cache entry unchanged. If this happens, the Oracle Communications Session Border Controller replaces the value of the XML expires attribute with the adjusted access-side expiration value.
- If the expires attribute from a Contact element is 0 (meaning that the core is removing the registration), the Oracle Communications Session Border Controller removes that Contact-URI from its registration cache. And if the registration cache entry has no remaining Contact-URIs, the Oracle Communications Session Border Controller deletes the registration cache entry altogether.

Contact Cache Linger Configuration

You enable this feature as part of the global SIP configuration, using that configuration's **options** parameter. You can optionally configure the number of seconds you want to keep a contact in the registration cache before it is deleted. This is the option:

- **contact-cache-linger=XX**—Number of seconds to wait before a contact is deleted from the cache (where XX is the number of seconds)
  To enable SIP Registration overload protection on your Oracle Communications Session Border Controller:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. **options**—Set the options parameter by typing **options**, a Space, the option name preceded by a plus sign (+) (**contact-cache-linger=XX**) where XX is the number of seconds to keep a contact in the cache before deleting it.

```
ORACLE(sip-config)# options +contact-cache-linger=5
```

If you type either of these options without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

5. Save and activate your configuration.

SIP Event Package for Registrations

This feature enables the Oracle Communications Session Border Controller, acting as a Proxy Call Session Control Function (P-CSCF) to initiate subscription to the SIP Event Package for Registrations.

Applicable Standards

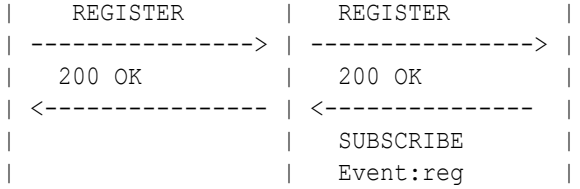
RFC 3265, *Session Initiation Protocol (SIP)-Specific Event Notification*, outlines a framework within which a SIP node, designated as the subscriber, can request automatic, asynchronous notification of certain events from a remote peer, designated as the notifier. RFC 3265 also defines an Event Package as a set of state information to be reported by a notifier to a subscriber, and mandates that such Event Packages be described in a specific RFC explicitly identifying the state information to be reported by the notifier and defining required syntax and semantics to support the subscription/notification exchange.

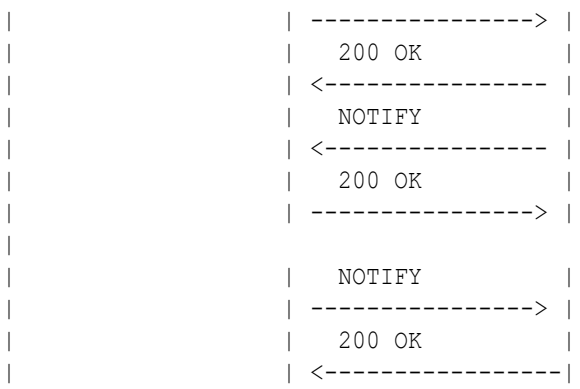
RFC 3680, *A Session Initiation Protocol (SIP) Event Package for Registrations*, fulfills this requirement by defining a method that enables SIP user agents to request a defined set of state information from a SIP Registrar.

Section 5.2.3 of the 3GPP (Third Generation Partnership Project) 24.229, *IP Multimedia Call Control Protocol Based on Session Initiation Protocol (SIP) and Session Description Protocol (SDP)*; Stage 3, mandates that a P-CSCF subscribe to the SIP Event Package for Registrations as defined in RFC 3680.

Call Flow

An example call flow between a SIP endpoint, the Oracle Communications Session Border Controller, acting as a P-CSCF, and a SIP Registrar (S-CSCF) illustrates the Subscription/ Notification process.





The first two messages (the REGISTER request and the 200 REGISTER response) accomplish the successful registration of the SIP endpoint.

```
REGISTER sip:example.com SIP/2.0
Via: SIP/2.0/UDP pc34.example.com;branch=z9hG4bKnaaff
From: sip:joe@example.com;tag=99a8s
To: sip:joe@example.com
Call-ID: 88askjda9@pc34.example.com
CSeq: 9976 REGISTER
Contact: sip:joe@pc34.example.com
```

Immediately after processing the initial 200 OK from the SIP Registrar, the Oracle Communications Session Border Controller sends a SUBSCRIBE Request to the S-CSCF.

```
SUBSCRIBE sip:joe@example.com SIP/2.0
Via: SIP/2.0/UDP app.example.com;branch=z9hG4bKnashds7
From: sip:sd.example.com;tag=123aa9
To: sip:joe@example.com
Call-ID: 9987@app.example.com
CSeq: 9887 SUBSCRIBE
Contact: sip:joe@pc34.example.com
P-Asserted-Identity: <sip:sd@example.com>
Event: reg
Max-Forwards: 70
Accept: application/reginfo+xml
```

The Request URI and To header contain the address-of-record (sip:joe@example.com) of the subscription subject. This value was previously contained in the From and To headers of the of the original REGISTER request. These fields are always identical in REGISTER requests, except in the case of third-party registration.

The From and P-Asserted-Identity headers contain the identity of the subscription requester.

The Contact header contains an IP address or FQDN at which the subscription subject can be reached. This field duplicates the value of the Contact header in the original REGISTER request. Multiple contacts can be registered for a single address-of-record.

The Event header contains the required value, reg, which identifies the requested Event Package subscription. reg specifies the SIP Event Package for Registrations.

The Accept header contains the required, default value, application/reginfo+xml, indicating syntactical support for Registration notifications and attached XML notification bodies.

Assuming the S-CSCF accepts the subscription, it responds with a 200 SUBSCRIBE response.

```
SIP/2.0 200 OK
Via: SIP/2.0/UDP app.example.com;branch=z9hG4bKnashds7
;received=192.0.2.1
From: sip:sd.example.com;tag=123aa9
To: sip:joe@example.com;tag=xyzygg
Call-ID: 9987@app.example.com
CSeq: 9987 SUBSCRIBE
Contact: sip: joe@pc34.example.com
Expires: 3600
```

The From header contains the identity of the subscription requester.

The To header contains the address-of-record of the subscription subject.

The Contact header contains an IP address or FQDN at which the subscription subject can be reached.

The Expires header contains the subscription duration in seconds. Upon receipt of a 2xx response to the SUBSCRIBE request, the Oracle Communications Session Border Controller stores the information for the established dialog and the expiration time. If continued subscription is required, the Oracle Communications Session Border Controller automatically refreshes the subscription to the SIP Event Package for Registrations, either 600 seconds before the expiration time if the initial subscription was for greater than 1200 seconds, or when half of the time has expired if the initial subscription was for 1200 seconds or less.

Following the 200 SUBSCRIBE response, the S-CSCF generates an initial notification, with Event Package state information contained in an XML body.

```
NOTIFY sip:app.example.com SIP/2.0
Via: SIP/2.0/UDP server19.example.com;branch=z9hG4bKnasaij
From: sip:app@example.com;tag=xyzygg
To: sip:sd.example.com;tag=123aa9
Call-ID: 9987@app.example.com
CSeq: 1289 NOTIFY
Contact: sip:server19.example.com
Event: reg
Max-Forwards: 70
Content-Type: application/reginfo+xml
Content-Length: ...

<?xml version="1.0"?>
<reginfo xmlns="urn:ietf:params:xml:ns:reginfo" version="1"
state="partial">
    <registration aor="sip:joe@example.com" id="a7" state="active">
        <contact id="76" state="init" event="registered"
        duration-registered="0">
            <uri>sip:joe@pc34.example.com</uri>
        </contact>
    </registration>
</reginfo>
```

Notification Bodies

Registration state changes are reported in XML attachments to NOTIFICATIONS generated by the S-CSCF. As shown above, the XML consists of one or more registration elements that report the state of a specific address-of-record. Attributes supported by the registration element are as follows:

aor contains the address-of-record

id identifies this specific registration

state reports the Registration state — init, active, or terminated

init — address-of-record not yet cached

active — address-of-record maintained in current cache

terminated — address-of-record removed from cache, not currently valid

registration elements, in turn, contain one or more child contact elements. Attributes supported by the contact element are as follows>

id identifies this specific contact

state reports the Contact state — active or terminated

event reports the event that generated the last state change — registered, created, refreshed, shortened, expired, deactivated, probation, unregistered, or rejected

duration-registered reports the length (in seconds) of the current registration

contact elements, contain a single child uri element that identifies the contact address of FQDN.

SIP Event Package for Registrations Configuration

Subscription to the SIP Event Package for Registrations is enabled at the SIP interface level.

1. Use the following command sequence to move to **sip-interface** Configuration Mode.

   ORACLE# **configure terminal**

   ORACLE(configure)# **session-router**

   ORACLE(session-router)# **sip-interface**

   ORACLE(sip-interface)#

2. Use the **subscribe-reg-event** parameter to subscribe to the SIP Event Package for Registrations.

   By default, subscription is disabled.

   ORACLE(sip-interface)# **subscribe-reg-event enabled**

   ORACLE(sip-interface)#

3. Use **done**, **exit**, and **verify-config** to complete enabling the Event Package subscription.

SIP Transport Selection

With this feature enabled, when the Oracle Communications Session Border Controller forwards a message larger than the value specified in the maximum UDP length parameter, it attempts to open on outgoing TCP connection to do so. This connection might fail for a number of reasons; for example, an endpoint might not support UDP, or it might be behind a firewall. The UDP fallback option addresses this condition. If it is configured in SIP interfaces associated with an outgoing message and a TCP session cannot be established, the Oracle Communications Session Border Controller falls back to UDP and transmits the message. When the option is not present, the Oracle Communications Session Border Controller's default behavior is to return the SIP status message 513 Message too Large.

SIP Transport Selection Configuration

You enable this feature per SIP interface by setting options that control the maximum UDP length and allow UDP fallback:

- max-udp-length=X (where X is the maximum length)—Sets the largest UDP packers that the Oracle Communications Session Border Controller will pass. Packets exceeding this length trigger the establishment of an outgoing TCP session to deliver the packet; this margin is defined in RFC 3261. The system default for the maximum UDP packet length is 1500.
  You can set the global SIP configuration's max-udp-length=X option for global use in your SIP configuration, or you can override it on a per-interface basis by configuring this option in a SIP interface configuration.
- udp-fallback—When a request needs to be sent out on the SIP interface for which you have configured this option, the Oracle Communications Session Border Controller first tries to send it over TCP. If the SIP endpoint does not support TCP, however, then the Oracle Communications Session Border Controller falls back to UDP and tries the request again.
  To enable SIP Transport Selection:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the **session-router** path.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# sip-interface
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **max-udp-length=X** (where X is the maximum UDP length you want to set), and then press Enter.

   ```
   ORACLE(sip-interface)# options +max-udp-length=900
   ```

If you type options max-udp-length=X, you will overwrite any previously configured options. In order to append the new option to the sip-interface's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. **options**—Set the options parameter by typing **options**, a Space, the option name **udp-fallback**, and then press Enter.

```
ORACLE(sip-interface)# options +udp-fallback
```

If you type options udp-fallback, you will overwrite any previously configured options. In order to append the new option to the sip-interface's options list, you must prepend the new option with a plus sign as shown in the previous example.

6. Save and activate your configuration.

uaCSTA NAT Support

The Oracle Communications Session Border Controller offers User Agent Computer Supported Telecommunications Application (uaCSTA) support, which allows for the network address translation (NAT) of a key XML element in SIP INFO messages to use a phone's real contact URI.

Overview

Certain customers who use a uaCSTA for third party call control have encountered difficulties with the XML in their SIP messages used to support business applications. In these cases, the XML—specifically the <deviceID> XML tag—carries encoded IP addresses that need to be changed as they traverse the Oracle Communications Session Border Controller.

The SIP business application allows users to click-to-dial another party using e-mail application clients. The user's click triggers the application server to send a uaCSTA SIP INFO message through the system to the UA/phone. These SIP INFO messages contain XML with the user's Contact-URI. But the server is only aware of the Oracle Communications Session Border Controller's NAT'd Contact-URI and not the user's, so the XML in the SIP INFO is carrying incorrect information.

The XML element, then, needs to be NAT'd to the phone's real Contact-URI. This is especially important because of the broad use of SIP INFO messages, which instruct a phone to:

- Answer a call
- Hold a call
- Retrieve a call

All of these functions are available via a clickable interface on the e-mail application.

The Oracle Communications Session Border Controller performs the NAT to the <deviceID> XML tag only if it is configured to perform registration caching.

When the Oracle Communications Session Border Controller receives a SIP message from the core side and the request has:

- A Content-Type of application/csta+xml
- A Content-Length greater than 0

it parses the message's message body into an XML document. Should parsing fail, then the Oracle Communications Session Border Controller will forward the SIP INFO request without modification to the XML message body. Otherwise, the Oracle Communications Session

Border Controller searches for the <deviceID> subelement within the XML document. If it finds the <deviceID> subelement, the Oracle Communications Session Border Controller searches through its registration cache for a registered Contact that matches the value of the <deviceID>. If it finds a match, the Oracle Communications Session Border Controller replaces the value of the <deviceID> with that of the corresponding registered Contact. If the value of the <deviceID> is a Contact that the Oracle Communications Session Border Controller generates for a registered UA, the corresponding contact from the look-up would be the Contact of the registered UA.

These functions performed, the Oracle Communications Session Border Controller then reformats the SIP INFO request with the modified XML message body before sending it to the next hop. If there is no match found, then the Oracle Communications Session Border Controller forwards the SIP INFO request without modifying the XML message body.

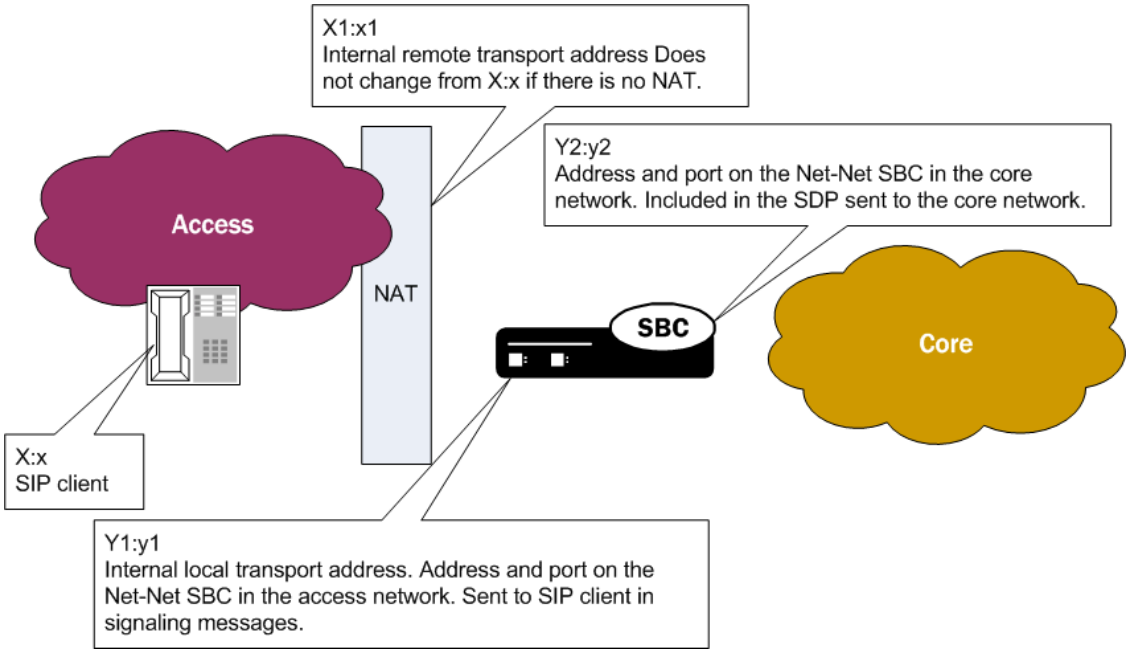
Other than ensuring your Oracle Communications Session Border Controller is configured to perform registration caching, you do not need take any further steps.

SIP Packet Cable Multi-Media

As a packet cable multi-media (PCMM) enhancement for SIP sessions key to next generation architectures, the Oracle Communications Session Border Controller can now include certain SDP attributes specifying media flow addresses in outgoing SIP messages. Previously, these address were hidden by the Oracle Communications Session Border Controller. Since SIP proxies and application servers in the core network, however, need to know these addresses to guarantee QoS for media flows in packet cable networks.

Certain options in the SIP interface configuration enable the Oracle Communications Session Border Controller to reveal address information on the core side.

When a SIP client in the access network sends and receives RTP media, the Oracle Communications Session Border Controller uses the SIP client's IP address and port (X:x) as its own internal remote transport address. The Oracle Communications Session Border Controller adds this information to outgoing SDP that it sends to the core side, and removes it from incoming SDP. If the SIP client sits behind a NAT, then the Oracle Communications Session Border Controller uses the IP address and port produced from the NAT (X1:x1) process for insertion and removal. The SIP client sends RTP to an IP address and port (Y1:y1) on the Oracle Communications Session Border Controller, referred to as the internal local transport address; this information is included in SDP (included in SIP messages) sent to the SIP client. Meanwhile, the Oracle Communications Session Border Controller also has an IP address and port (Y2:y2) in the core network. The far-end SIP UA sends RTP to this IP address and port, which are also included in SDP the Oracle Communications Session Border Controller sends to the core side.



To enforce QoS properly on the access side, the flow between the SIP client (or the SIP client's post-NAT IP address and port) and the internal local address must be revealed on the core side using SIP signaling messages.

Details

To enable this enhancement, you set three parameters in the SIP interface configuration:

- **sdp-internals**—Establishes that local and remote transport addresses need to be added.This option must be enabled on the access-side SIP interface, which is where the Oracle Communications Session Border Controller receives SDP.
- **sdp-local=<name>**—Sets a name for the internal local transport port address that the Oracle Communications Session Border Controller inserts into outgoing SDP. This option is configured on the core-side SIP interface. This address is removed from incoming SDP from the core side to prevent attributes from being sent back to the core in a hairpinned call.
- **sdp-remote=<name>**—Sets a name for the internal remote transport address that the Oracle Communications Session Border Controller inserts into outgoing SDP. This option is also configured on the core-side SIP interface. This address is also removed from incoming SDP from the core side to prevent attributes from being sent back to the core in a hairpinned call.

Further, the Oracle Communications Session Border Controller determines whether or not to insert the SDP attributes based on a call's ingress and egress signaling realms:

Address Information	Calling-Side SDP	Called-Side SDP
Internal local transport address	Added to SDP when: The ingress signaling realm's SIP interface has the sdp-internals option configured The egress signaling realm's SIP interface has a defined sdp-local option	Added to SDP when: The egress signaling realm's SIP interface has the sdp-internals option configured The ingress signaling realm's SIP interface has a defined sdp-local option
Internal remote transport address	Added to SDP when: The ingress signaling realm's SIP interface has the sdp-internals option configured The egress signaling realm's SIP interface has a defined sdp-remote option	Added to SDP when: The egress signaling realm's SIP interface has the sdp-internals option configured The ingress signaling realm's SIP interface has a defined sdp-remote option

Core-Side SDP Insertion Configuration

In a typical configuration intended to send SDP to the core side with the inserted attributes, the access SIP interfaces have the **sdp-internals** option enabled, and the core SIP interfaces have the **sdp-local** and **sdp-remote** values configured.

To set the access SIP interface for SDP insertion on the core side:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-interface)#
   ```

   If you are adding support for this feature to a pre-existing SIP configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **options**—Set the options parameter by typing **options**, a Space, the option name **sdp-internals** with a plus sign in front of it, and then press Enter.

   ```
   ORACLE(sip-interface)# options +sdp-internals
   ```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

To set the local and remote transport addresses for a core SIP interface:

6. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

7. Type **session-router** and press Enter to access the signaling-level configuration elements.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

8. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# sip-config
ORACLE(sip-interface)#
```

9. **options**—Set the options parameter by typing **options**, a Space, the option name preceded by a plus sign (+) (**sdp-local=<name>**, where the name is attribute name for the SDP), and then press Enter. Follow the same steps to add the **sdp-remote** option.

```
ORACLE(sip-interface)# options +sdp-local=Local_Turn
ORACLE(sip-interface)# options +sdp-remote=PCMM_USERADD
```

If you type either of these options without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

10. Save and activate your configuration.

SIP Method-Transaction Statistic Enhancements

In prior releases, the Oracle Communications Session Border Controller tracks SIP session agents, SIP interfaces and SIP realms on a global level. Only counters that are related to session rates and constraints are displayed.

You can now enable your Oracle Communications Session Border Controller to track transaction messages for specific SIP session agents, SIP realms, and SIP interfaces.

The following SIP methods are tracked for Recent, Total, and Period Max values:

- INVITE | ACK | BYE | REGISTER | CANCEL | PRACK | OPTIONS | INFO | SUBSCRIBE | NOTIFY | REFER | UPDATE | MESSAGE | PUBLISH | other (unknown)

With this new tracking enhancement, the **show sipd** command has been updated with a new method argument which allows you to query statistics for a particular method for a given SIP agent, SIP interface, or SIP realm.

SIP Method Tracking Enhancements Configuration

To enable or disable the expanded SIP Method statistics tracking:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
```

4. **extra-method-stats**—Enable this parameter if you want to use the expanded SIP Method tracking feature. The default is **disabled**. The valid values are:
   - enabled | disabled
5. Save and activate your configuration.

National Security and Emergency Preparedness for SIP

The Oracle Communications Session Border Controller (SBC) supports Emergency Telecommunications Service (ETS), which gives priority treatment of National Security and Emergency Preparedness (NSEP) communications for IP network infrastructures. ETS can increase the likelihood that calls, sessions, and other communications will be successfully completed when they are initiated by government-authorized users over the public network infrastructure. Legacy circuit-switched services such as Government Emergency Telecommunications Service (GETS) and Wireless Priority Service (WPS) also fall under the ETS rubric, and are now also supported on the SBC.

To provide this support, you can enable the SBC to act on SIP calls that contain an ETS dial number (DN) and/or the SIP Resource-Priority header that carries ETS resource values.

The SBC identifies ETS calls by using the system's network management controls (NMC) functionality. With NMC and Resource-Priority header (RPH) support enabled on your system, the SBC detects ETS calls and provides the appropriate treatment for them.

The SBC supports this feature by treating ETS calls based on the r-value parameter in the Resource-Priority header. The r-value is a key piece of information because it defines the resource priority that the call originator requests. The r-value parameter provides namespaces and priorities that the SBC can manipulate in outgoing traffic.

The system also allows you to specify a percentage of total session capacity that you reserve for NSEP sessions. When you do this, you extend upon the system's prioritization of NSEP sessions by ensuring transport of emergency sessions even when the system is overloaded with standard traffic. The system provides checks on what you can reserve and reports on its use of this reservation behavior.

An RPH profile is applied to an NMC rule to specify r-values, a media policy to use, and what type of call treatment to apply. Although this also applies to an NMC rule, the RPH policy provides information about which r-values to insert and which to override.

Matching by NMC and by RPH

When a Oracle Communications Session Border Controller has been enabled to act on RPH, it checks incoming requests for RPH, tries to parse that RPH, and then rejects requests in the circumstances listed below. For all of these rejections, the Oracle Communications Session Border Controller logs the error at the TRACE level.

- Request with multiple instances of the same namespace in the RPH—The Oracle Communications Session Border Controller sends out a 400 Bad Request response with

the Invalid RPH - Namespace repeated header showing that there are multiple instances of the same namespace in the RPH.

- Request with invalid resource priority for a namespace—The Oracle Communications Session Border Controller sends out a 400 Bad Request response with the Invalid RPH - Invalid rvalue: x showing that there is an invalid resource value (where x is the invalid value).
- Request with WPS namespace, but without ETS namespace—The Oracle Communications Session Border Controller sends out a 400 Bad Request response with the Invalid RPH - No ETS value header showing that there is no ETS namespace.

If the Oracle Communications Session Border Controller successfully parses the RPH, it identifies the ETS call by checking the Request-URI of the incoming request against destination identifiers that you configure in the NMC rules. If there is a match between the request's ETS DN and the destination value identifier in the NMC rules, the Oracle Communications Session Border Controller tags the call; note that NMC rules need to be configured with the **rph-feature** parameter set to enabled to identify an ETS call properly. If there is no match to an NMC rule, then the Oracle Communications Session Border Controller performs matching based on RPH by comparing resource values (r-values) in the RPH with values you set in the RPH profile configuration.

For an ETS call that matches by ETS DN and NMC rule, the system checks the NMC rule to determine if it has an RPH profile (with r-values) assigned to it. If so, the Oracle Communications Session Border Controller continues by comparing the RPH profile's r-values against those in the request's RPH. In cases where the RPH does not contain a recognized value r-value, the Oracle Communications Session Border Controller:

- Processes the call as it normally would (as a non-ETS call) without changing the RPH if the resource-priority option tag is not present in the Required header (for an INVITE only and not any other requests or response from which RPH would be deleted)
- Rejects the Request when the Require header has the resource-priority header; or, inserts an Accept-Resource-Priority header (ARPH) in the response if the **insert-arp-header** parameter option is enabled

However, the call goes through the Oracle Communications Session Border Controller as an ETS call when it is matched by ETS DN and the applicable NMC does not have an RPH profile assigned. According to the settings in the NMC rule, the Oracle Communications Session Border Controller either diverts or rejects such a call. And when the call matches by RPH rather than ETS DN, the Oracle Communications Session Border Controller applies the configured RPH profile from the relevant NMC rule.

It can be the case that non-ETS calls have RPH in their requests. Here, the Oracle Communications Session Border Controller call treatment is performed according to the settings in the matching RPH profile when there is no matching NMC rule. When you configure treatment as "reject," then the Oracle Communications Session Border Controller rejects the call with a 417 Unknown-Resource Priority status code. When you set the treatment to either "accept" or priority, the Oracle Communications Session Border Controller allows the call to proceed as a non-ETS call or as a priority call.

The ETS r-value can appear in ACK, BYE, INFO, PRACK, REFER and UPDATE requests. In cases when it does and the session with which the request is associated is a non-ETS call, the Oracle Communications Session Border Controller removes the RPH from the request before forwarding it and logs a TRACE-level error. The Oracle Communications Session Border Controller also removes RPH from responses before forwarding them and logs a TRACE-level error when responses contain RPH headers with ETS values for non-ETS sessions.

Call Treatment

This section describes how ETS calls are treated as they traverse the Oracle Communications Session Border Controller.

Call Treatment	Description
Routing	ETS calls are routed the same way as any other calls are, except when the applicable NMC rule's treatment type is divert, and rule defines the next hop. This route takes precedence over other normal routes.
Local NMC	ETS calls are exempt from the local NMC, including: session agent constraints, bandwidth constraints (e.g., per-realm bandwidth), per-user CAC, and CPU constraints. However, the call is subject to the ETS congestions control threshold. Licensing session constraints apply.
ETS Call Congestion Control	ETS calls are subject to congestion control constraints that you configure specifically for this type of traffic. In the global SIP configuration, you set up one option that defines a load limit (greater than that set for normal calls).
ETS CAC	Although the Oracle Communications Session Border Controller uses the call rate control value in the applicable NMC rule, you can also enforce call rate on a per-user basis for ETS calls.

When the Oracle Communications Session Border Controller receives a SIP INVITE with an RPH matching an NMC with an ETS DN, but whose r-values do not match the NMC's rph-profile, the Oracle Communications Session Border Controller behaves as follows:

- If the INVITE does not have the resource-priority option tag and:
  - If the matching NMS is set to PRIORITY, the call will be treated as an NSEP call. If there is an rph-profile matching the r-value (not necessarily the one in the NMC), the Oracle Communications Session Border Controller uses the media-policy from that rph-profile for the call. The rph-policy from the NMC (if present) also applies to the call.
  - If the matching NMC is not set to PRIORITY, the Oracle Communications Session Border Controller will treat the call as a normal one.

If the INVITE contains the resource-priority option tag, the Oracle Communications Session Border Controller will reject the call with the 417 Unknown Resource-Priority message.

Generating Egress RPH

For each ETS call, the Oracle Communications Session Border Controller generates RPH for the outgoing request. It forms this RPH according to the information in the NMC rule. The outgoing request types are INVITE, ACL, BYE, CANCEL, INFO, PRACK, REFER, and UPDATE.

Request RPH Status	Generated Egress RPH
Incoming request without RPH (matched by ETS DN)	Outgoing RPH value becomes the r-value set in the insert-r-value parameter in the RPH policy applied to the NMC rule.
Incoming request without RPH (matched by ETS DN)	If the insert-r-value parameter is empty in the RPH policy applied to the NMC rule or there is no RPH policy applied to the NMC rule, then the egress RPH will also not have RPH.
Incoming request has RPH	Egress RPH is the same as the ingress if the NMC rule has an RPH policy applied but the override-r-value for the policy is empty or if there is not RPH policy applied to the NMC rule. If the override-r-value for the policy is set, then the egress RPH is set to that value.

For example, given an incoming request with the resource priority ets.0, dsn.flash and an RPH policy with an override value of wps.1,ets.1, the egress request would be sent with a resource-priority of wps.1,ets.1,dsn.flash.

The Oracle Communications Session Border Controller also includes RPH in the following series of responses, even when the downstream SIP entity does not respond with an RPH: 1xx, 2xx, 3xx, 4xx, 5xx, and 6xx. The 401 Unauthorized response is an exception.

Media Treatment

If the RPH profile set in an NMC names a media policy, then the Oracle Communications Session Border Controller implements it for the ETS call. This media policy overrides any media policy set in the realm configuration.

The possible Differentiated Services Code Point (DSCP) values for an ETS call are:

- Audio—Applied to the respective media for an ETS call
- Video—Applied to the respective media for an ETS call
- SIP—Applied to the ETS calls' SIP signaling messages, only for the egress call leg for the ETS session

DSCP Marking for NSEP Traffic

You can configure the SBC to mark NSEP calls with DSCP codes on a realm-specific basis. To do this, you assign a **media-policy** that you configure for the realm's NSEP traffic using the **nsep-media-policy** parameter within the egress **realm-config**. When the system identifies this traffic, it handles the traffic according to that **media-policy**, which can include marking the traffic with DSCP values. If you have configure an **nsep-media-policy** on a realm, the system marks egress SIP messages that belong to NSEP sessions with the TOS bits set by that **nsep-media-policy**. The system applies this **nsep-media-policy** to all responses except self-generated responses. The SBC applies precedence to this policy configuration, referring to other traffic policy configuration if this parameter is empty. Applicable media traffic for this configuration includes ETS and WPS. You can configure this policy using the ACLI, REST, and OCSDM.

The **nsep-media-policy** configuration provides you with the flexibility to mark NSEP calls going out different realms with different DSCP values. The system uses the same **network-management-control** and **rph-profile** configurations to identify NSEP traffic, requiring you to configure these objects normally. In addition. the **network-management-control** may or may not use an **rph-policy** in addition to the **rph-profile**. The use of an **rph-policy** is dependent on your needs for special r-value handling on this realm's NSEP traffic.

Having identified the traffic, however, the system next checks to see if there is **nsep-media-policy** configuration on the egress realm. If so, the system uses the **media-policy** configured under the **nsep-media-policy** parameter to determine how to handle the traffic.

When the **nsep-media-policy** is empty, the SBC refers to the **media-policy** of the **RPH-profile** that matches the RPH-header in the incoming SIP message to handle the traffic.

1. Refers to the media-policy associated with RPH-profile that matched the RPH header present in incoming SIP message to handle the NSEP traffic.
2. If there is no **RPH-profile** match, the system applies the realm's **media-policy** to all traffic matching that policy.
3. If no **media-policy** is associated with the **rph-profile**, then the system refers to the common traffic **media-policy** configured at egress to handle NSEP traffic.

The SBC performs this function using the following steps when it receives an NSEP INVITE with an rph-header and the egress realm has a configured **nsep-media-policy** parameter:

1. Check the NMC rule to determine if it has an RPH profile (with r-values) assigned to it.
2. If so, the system compares the r-values in the **RPH-profile** with those in the request's RPH header.
3. If there is a match, and the **nsep-media-policy** parameter has an assigned **media-policy** on the egress **realm-config**, it performs realm-specific DSCP marking.
4. The system handles all traffic according to the **media-policy**, including marking all signaling traffic within the server and client dialogs, as well as the RTP packets for the session with the configured DSCP marking.

> **Note:**
>
> The SBC does not perform DSCP marking on locally generated responses, including 100 trying and 4xx related to the initial invite, using an **nsep-media-policy** because it has not yet determined it is handling an NSEP call.

Configuration

This feature requires the following configurations:

- Enable the **rph-feature** in the **sip-config**.
- Enable the **net-management-control** in the ingress **realm-config**.
- Configure an **rph-profile** to identify and handle NSEP calls based on RPH header match..
- Configure **net-management-control** rules for treating the NSEP calls properly.
- Enable the **rph-feature** in those NMCs.
- Associate the applicable configured **rph-profile** with each NMC.
- Configure a **media-policy** to mark NSEP calls that match that particular **rph-profile** with DSCP.
- Associate the configured **media-policy** to the egress realm by assigning it to the **nsep-media-policy** parameter in the applicable **realm-config**.

> **Note:**
>
> Although the applicable **rph-profile** may have an assigned **media-policy**, the SBC ignores that policy when it finds an **nsep-media-policy** configured on the applicable realm.

See Configuring Packet Marking by Media Type and ensuing tasks for instructions on creating a **media-policy** for media and signaling traffic.

Configure Realm-Specific DSCP Marking for NSEP Traffic

To Configure Realm-Specific DSCP Marking for NSEP Traffic, you enable the **rph-feature** in the **sip-config** and enable the **net-management-control** in the ingress **realm-config** just as you would to enable handling for all NSEP prioritization.

Procedures for this feature include you configuring an RPH Profile for your applicable NSEP Traffic. See Setting up and Applying an RPH Profile for instruction on how to configure your **rph-profile**, including identifying and prioritizing this traffic. The RPH profile contains information about how the system should act on the namespace(s) present in a Resource-Priority header. You can associate a **media-policy** to your **rph-profile**, but the system ignores that setting when performing this realm-specific function, using the **media-policy** you configure under the **nsep-media-policy** parameter instead.

In addition, you:

- Configure a Media Policy for your applicable NSEP Traffic.
- Enable NSEP and Apply the RPH Profile to the NMC.

> **Note:**
>
> You may apply an RPH Policy to the NMC if needed for your implementation.

- Associate the media policy to the egress realm under the **nsep-media-policy** configuration parameter.

Configure a Media Policy for NSEP Traffic

To establish realm-specific DSCP marking for NSEP traffic, you create a **media-policy** that you configure under a realm's **nsep-media-policy** parameter. This policy uses the same controls within **network-management-control** and **rph-profile** configurations, which identify, prioritize and route this NSEP traffic, using a **media-policy** that is specific to this NSEP traffic.
To set up a media policy configuration to mark audio-voice or video packets:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# media-manager
   ```

3. Type **media-policy** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(media-manager)# media-policy
   ORACLE(media-policy)#
   ```

   If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration you want to edit.

   From this point, you can configure media policy parameters. To view all configuration parameters for media profiles, enter a **?** at the system prompt.

4. **name**—Create a reference name for this policy and press Enter.

   ```
   ORACLE(media-policy)# name myPolicy
   ```

5. Type **tos-settings** and press Enter to configure your TOS settings sub-element. The system prompt changes appropriately.

```
ORACLE(media-policy)# tos-settings
ORACLE(tos-settings)#
```

6. **media-type**—Enter the media type that you want to use for this group of TOS settings. You can enter any of the IANA-defined media types for this value: audio, example, image, message, model, multipart, text, and video. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

```
ORACLE(tos-settings)# media-type message
```

7. **media-sub-type**—Enter the media sub-type you want to use for the media type. This value can be any of the sub-types that IANA defines for a specific media type. This value is not case-sensitive and can be up to 255 characters in length; it has no default.

```
ORACLE(tos-settings)# media-sub-type sip
```

8. **media-attributes**—Enter the media attribute that will match in the SDP. This parameter is a list, so you can enter more than one value. The values are case-sensitive and can be up to 255 characters in length. This parameter has no default.

   If you enter more than one media attribute value in the list, then you must enclose your entry in quotation marks ().

```
ORACLE(tos-settings)# media-attributes sendonly sendrecv
```

9. **tos-value**—Enter the TOS value you want applied for matching traffic. This value is a decimal or hexidecimal value. The valid range is:

   - 0x00 to 0xFF.

```
ORACLE(tos-settings)# tos-value 0xF0
```

10. Save and activate your configuration.

Enable NSEP and Apply the RPH Profile to the NMC

In addition to setting the RPH profile for an NMC rule, you also need to enable this feature for the NMC rule.

See "Network Management Controls" in the service provider Configuration Guide for explanation and instruction on how to configure your **net-management-control** for its additional functions, including routing. For this feature, you must have already defined the name of the **rph-profile** that you are using for this traffic.
To enable NSEP for an NMC rule:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **net-management-control** and press Enter.

```
ORACLE(session-router)# net-management-control
ORACLE(net-management-control)#
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **rph-feature**—Enable this parameter if you want to turn the NSEP feature on for this NMC rule. The default is **disabled**. This feature requires this parameter be enabled.

```
ORACLE(net-management-control)#rph-feature enable
```

5. **rph-profile**—Enter the name of the **rph-profile** you have configured for handling incoming NSEP traffic.

```
ORACLE(net-management-control)#rph-profile myRphProfile
```

6. Navigate to the **sip-config**.

```
ORACLE(configure)# session-router
ORACLE(session-router)#sip-config
ORACLE(sip-config)#
```

7. **rph-feature**—Enable this parameter on the applicable to turn the NSEP feature on for this **realm-config**. The default is **disabled**. This feature requires this parameter be enabled.

```
ORACLE(sip-config)#rph-feature enable
```

8. Save and activate your configuration.

Specify a Media Policy for a Realm's NSEP Traffic

To apply a media policy for NSEP traffic egressing this realm:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **media-manager** and press Enter to access the system-level configuration elements.

```
ORACLE(configure)# media-manager
```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# realm-config
ORACLE(realm)#
```

4. **nsep-media-policy**—Enter the unique name of the **media-policy** that you want to apply to your NSEP traffic.

```
ORACLE(realm)#nsep-media-policy MyNsepMediaPolicy
```

5. Type **done** to complete the configuration.

6. Save and activate your configuration.

Reserving Session Capacity for NSEP

You can reserve session capacity for NSEP traffic, which includes WPS traffic, to reserve sessions from the system's total session capacity pool. The SBC uses this reserved session pool for NESP calls after the general session capacity is utilized. You reserve these sessions by configuring a percentage RPH calls using the **reserved-nsep-session-capacity** parameter.

The SBC identifies NSEP calls using the system's network management controls (NMC) functionality. With NMC and Resource-Priority header (RPH) support enabled on your system, the SBC detects NSEP calls and provides the appropriate treatment for them. When a SIP INVITE for a call arrives at the SBC on an ingress realm where network management controls have been enabled, the SBC checks the NMC rules for a match to the call. If there is none, the call proceeds normally; if there is a match it handles the call according to the rule.

When the SBC identifies an NSEP call, it normally allocates resources for the call from the general session capacity pool. This pool is shared among all kinds of traffic. When this pool gets exhausted, the SBC would begin rejecting calls, including high priority NSEP calls.

To avoid dropping NSEP calls because the system is exhausting session capacity, you can configure the **reserved-nsep-session-capacity** parameter in the **system-config** element. Your configured value specifies the percentage of the total licensed session capacity that the SBC reserves for NSEP sessions. The SBC calculates the number of NSEP reserved sessions from this percentage. By default, this setting is 0%, meaning there are no resources reserved solely for NSEP sessions. When configured to a value over 0%, the SBC reserves session capacity resources for NSEP traffic.

After this configuration, the SBC derives its general session pool by simply subtracting the number of NSEP reserved sessions from the total session capacity. The SBC starts to use this NSEP reserved session pool when it exhausts the general session pool. The SBC continuously monitors this general session pool. When sessions become available from this pool again, the SBC moves ongoing NSEP calls from the NSEP-reserved pool to the general pool. This reduces the number of calls being used by the NSEP pool, further ensuring session availability if the general pool becomes exhausted again.

The SBC rejects your **reserved-nsep-session-capacity** configuration during the save process if you specify a value that exceeds the percentage capacity of sessions currently available. You can also check this error using **verify-config**.

When you configure **reserved-nsep-session-capacity** to a non-zero value, the system also monitors current NSEP traffic and issues alarms and SNMP traps, using critical, major and minor thresholds, to notify you when you are running low on your reserved NSEP session capacity. The default thresholds are 70%, 80% and 90%, equating to minor, major and critical levels of busy NSEP sessions. You can customize these thresholds using the **reserved-nsep-sessions** sub-element type in the **system-config**, **alarm threshold**.

Below is an example of a Reserved NSEP session alarm.

```
ID Task Severity First Occurred Last Occurred
327684 3068 5 2021-06-18 03:01:25 2021-06-18 03:01:25
Count Description
1 Reserved NSEP session usage (80%) is exceeded threshold of 70%.
```

The system issues these alarms simultaneously with the apSysResrvdNsepSessionCapacity trap within the apSysMgmtGroupTrap group to notify you when session pool usage exceeds

these thresholds over SNMP. The system issues the apSysMgmtGroupClearTrap when the reserved session usage falls below this threshold, as documented in the *MIB Guide*.

Related Configuration

The following configurations, which enable and define network management behavior, are also required for this feature:

- Enable the **rph-feature** in the **sip-config**.
- Enable the **net-management-control** in the ingress **realm-config**.
- Enable the **rph-feature** in your target **net-management-control**.
- Configure an **rph-profile** to handle NSEP calls containing RPH headers in the **session-router**.
- Apply your **rph-profile** to your **net-management-control**.

Reporting NSEP Reserved Capacity Statistics

The SBC provides reporting on NSEP reserved capacity using the **show sessions** command on the ACLI. Reported data includes the number of reserved NSEP sessions and the number of inbound NSEP sessions.

```
SBC# show sessions
03:21:47-165 Capacity=2000
General Session Capacity=1500
Session Stats                                -- Period -- -------- Lifetime
--------
                                  Active     High   Total      Total
PerMax   High
Total Sessions                       0         0      0          0
0       0
SIP Sessions                         0         0      0          0
0       0
H.323 Sessions                       0         0      0          0
0       0
IWF Stats                                    -- Period -- -------- Lifetime
--------
                                  Active     High   Total      Total
PerMax   High
H.323 to SIP Calls                   0         0      0          0
0      0
SIP to H.323 Calls                   0         0      0          0
0      0
SIP Audio/Video Stats                        -- Period -- -------- Lifetime
--------

                                  Active     High   Total      Total
PerMax   High
Audio Calls                          0         0      0          0
0      0
Video Calls                          0         0      0          0
0      0
Messaging Sessions                   0         0      0          0
0      0
Reserved NSEP Session Capacity=500
Session Stats                                ---- Lifetime---
```

```
                                    Current    Total PerMax
NSEP Inbound Sessions                 0          0     0
```

The system also reports on lifetime values of these statistics using SNMP. You can get this information using SNMP queries to the apSysMgmtMIBNSEPStatsObjects MIB, as documented in the *MIB Guide*.

Reject Non-Emergency Traffic using Emergency DSCP

You can configure the SBC to reject traffic that uses emergency DSCP codes to designate itself as emergency traffic. This function applies to calls from both registered and unregistered endpoints and for both UDP and TCP traffic.

When configured, the SBC checks initial INVITE packets to see if it is using any of the DSCP codes you configured in an **emergency-dscp-profile** to signal an emergency call. When there is a match, the SBC validates the use of that code by checking whether the INVITE also includes an ETS dial number (DN) and/or the SIP Resource-Priority header (RPH) as a SIP emergency designation. If not, the SBC drops the INVITE, logs the attempt to improperly use that code, and, if configured, replies to the sender with an error message. You can specify the contents of this message. If you do not configure an error code and text, the SBC sends the default SIP error code and message “403 unauthorized attempt to use reserved resources”.

To enable this functionality, you configure an **emergency-dscp-profile** under the **session-router** branch. These multi-instance profiles include codes you specify for matching and, optionally, error codes/text to send back towards the sender. Parameters include:

- **name**—Establishes a label for individual emergency-dscp-profiles. You use this label to apply these profiles to session-agents, sip-interfaces or the sip-config. This field supports a maximum of 128 characters.
- **tos-values**—A space-separated string of decimal or hex numbers, that the SBC searches for within a packet. If it finds a value configured here, and the packet does not have any SIP information identifying the call as an emergency call, the system rejects the call.
- **error-code**—This optional field can include an integer that specifies the error code you send back to any endpoint that sends a non-emergency INVITE that includes a DSCP value you configured in this profile.
- **error-message**—This optional field can include a string that specifies the error text that you send back to any endpoint that sends a non-emergency INVITE that includes a DSCP value you configured in this profile.

You apply these profiles to a **session-agent**, a **sip-interface** or the **sip-config**, by configuring the parameter in those elements, which has the same name as the profile name (**emergency-dscp-profile**), with the name of the applicable profile. The system using that order as precedence for which profile, if any, applies.

As a prerequisite, you must have also configured the SBC for NSEP traffic identification and have enabled emergency treatment using NMC rule configuration.

The SBC uses this feature on initial INVITEs only. If a call fails this check based on the initial INVITE, there would be no further traffic for the call. For any call that proceeds beyond the initial INVITE, the SBC assumes the call is progressing properly and does not reject messages based on DCSP.

This feature imposes no changes to the system's handling of properly designated emergency calls.

Reporting

When the SBC rejects a non-emergency call based on this feature, it:

- Increments the “Drop Unauth NSEP DSCP” counter in the **show sipd error** command.
- Increments your configured error codes, unless they are well known codes, under the “4XX Client Error” statistics in the **show sipd invite** output.
- Includes debug/trace/error/info level logging in all required log files (log.sipd).

Reporting on NSEP Traffic Statistics

The SBC provides you with NSEP traffic statistics from the ACLI and SNMP. You can access system wide NSEP traffic reports when you configure the system for applicable network management controls (NMC). In addition, you can configure the system to provide realm-specific reporting on a per-realm basis by configuring the **nsep-stats-profile** on the **session-router** and enabling **nsep-stats** on the applicable realms.

The system-wide NSEP statistics provide global incoming/outgoing success/reject sessions. You can filter your results to a specific or all r-values. Per RFC-4412, the SBC treats r-value names as case insensitive strings. The SBC presents these statistics using current window statistics and lifetime statistics:

- In the current window, which uses a duration timeframe of 30 minutes, the SBC displays:
  - Currently active sessions
  - The highest number of sessions in the current window
  - Total sessions in the current timeframe
- The SBC categorizes lifetime statistics using:
  - Total sessions
  - The highest number recorded among all windows reported
  - The highest number of sessions in the lifetime window

The SBC reports NSEP statistics simultaneously through SNMP. To support this the SBC uses a set of nested MIB index and value objects that correspond to the ACLI statistics and display.

When you use the ACLI **show nsep-stats** command without further arguments, the system displays counters on inbound and outbound sessions. You extend this command with the **all** argument or a specific r-value (namespace and r-priority combination).

The system presents realm-based NSEP statistics using the same timeframe/data scheme presented for system-wide statistics and allows you to filter based on dialed number in addition to r-values:

- Dialed Number Statistics—You configure a set of dialed numbers with a country-code in your **nsep-stats-profile**. The country code is common for all dialed number, similar to the STD code. Whenever the SBC processes NSEP traffic, it matches a combination of country-code and dialed number with the req-uri of received/sent messages and increments the corresponding counters with the match results.
- r-values—The system records, increments and displays realm-based r-values in the same manner as it does for system-wide statistics.

Use these show commands with the following arguments to display realm-based NSEP statistics:

- show nsep-stats realms <realm-name>
- show nsep-stats realms <realm-name> <rvalue-name>
- show nsep-stats realms <realm-name> dialed-numbers

You can reset any or all NSEP statistics counters. You reset these statistics to zero using the **reset** command with same arguments above.

Presentation examples of this reporting is available for the ACLI in the *Maintenance and Troubleshooting Guide* and for SNMP in the *MIB Guide*.

Configuring Realm-based NSEP Reporting

For the system to produce realm-level statistics on NSEP traffic, you configure the **nsep-stats-profile** on the **session-router** and enable **nsep-stats** on the applicable realms.

The **nsep-stats** parameter allows you to specify the realms on which you collect NSEP statistics individually. The system does not collect these NSEP statistics for any realm that has this parameter disabled.

Applicable **nsep-stats-profile** parameters include:

- **state**—Enabled/Disabled
- **rvalues**—Add the r-values on which you want to collect NSEP statistics within realms
- **dialed-numbers**—Optionally add the dialed number(s) on which you want to collect NSEP statistics for realms.
- **feature-code**—Add the country STD Code, appended with each configured dialed number. This must be configured if you have configured a **dialed-numbers**.

If you do not configure the **feature-code** parameter in conjunction with the **dialed-number**, the system throws a verify error when you use the **done** command on your **nsep-stats-profile** element.

```
ERROR: feature code must be configured when dialed number is configured
```

RPH Configuration

This section shows you how to configure RPH profiles and policies that enable the Oracle Communications Session Border Controller to act on SIP calls that have an ETS DN and/or an RPH carrying ETS resources values. There are also settings for the global SIP configuration and for the NMC rule configuration that support this feature.

In addition, note that:

- You must set a media policy for the RPH profile to use. Check your system configuration and note the name of the media policy that best suits your needs.
- Valid values for the parameters that take r-values are wps.x and ets.x, where x is 0 through 4.

Remember to save and activate your configuration after you have completed the processes detailed in this section.

Setting Up and Applying RPH Policy

The RPH policy is a configuration on the Oracle Communications Session Border Controller that you apply to NMC rules. It designates the following for ETS/WPS namespaces:

- An override resource value—Resource value used to override the incoming RPH's resource value
- An insert resource value—Resource value inserted when the Oracle Communications Session Border Controller does not recognize the RPH, the incoming request has no RPH, or the call is H.323 and matches an NMC rule based on the ETS DN

Note that RPH policies do not apply for DSN, DRSN, Q.735, or any other type of namespace; these remain untouched in outgoing requests.

To configure an RPH policy:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **rph-policy** and press Enter. From here, you can configure the individual parameters for the RPH policy.

   ```
   ORACLE(session-router)# rph-policy
   ORACLE(rph-policy)#
   ```

4. **name**—Enter the name that uniquely identifies this RPH policy. This is the value you use to apply the policy in the NMC rules configuration. There is no default for this parameter, and you are required to set it.
5. **override-r-value**—Enter the value that the system uses to override r-values in the original RPH.

   ```
   ORACLE(rph-policy)# override-r-value ets.1
   ```

6. **insert-r-value**—Enter the value that the Oracle Communications Session Border Controller inserts into the RPH.

   ```
   ORACLE(rph-policy)# insert-r-value wps.1
   ```

7. **rph-policy**—Enter the name of the RPH policy that you want to apply for this NMC rule. This parameter is empty by default; if you do not set an RPH policy, none will be applied.

Setting Up and Applying RPH Profile

The RPH profile contains information about how the system should act on the namespace(s) present in a Resource-Priority header (if any). The list of resource values in this configuration calls out the resource values (or r-values) recognizable to the Oracle Communications Session Border Controller; the ETS and WPS namespaces are supported.

You also set a media policy for the RPH profile to use; it defines the Differentiated Services Code Point (DSCP) that the Oracle Communications Session Border Controller uses for media or signaling packets belonging to the egress call leg for the ETS session.

The call treatment parameter tells the Oracle Communications Session Border Controller what to do with a non-ETS call that has RPH in its request; the call can be allowed, rejected, or treated as a priority call.

To configure an RPH profile:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **rph-profile** and press Enter. From here, you can configure the individual parameters for the RPH policy.

```
ORACLE(session-router)# rph-profile
ACMEORACLEPACKET(rph-profile)#
```

4. **name**—Enter the name that uniquely identifies this RPH profile. This is the value you use to apply the profile in the NMC rules configuration. There is no default for this parameter, and you are required to set it.
5. **r-values**—Enter one or more r-values that the Oracle Communications Session Border Controller is to recognize for matching purposes. When you enter more than one value in the list, you type the name of the parameter followed by a Space, open quotation mark, the values for the list separated by spaces, a closed quotation mark. Then press Enter.

   You must enter them in the order reflected below (a WPS and then an ETS value). A WPS call always has to have an ETS namespace.

```
ORACLE(rph-profile)# r-values "wps.0 ets.2"
```

6. **media-policy**—Enter the name of a media policy configuration that you want applied for this RPH profile. The Oracle Communications Session Border Controller implements this media policy for the ETS call, and this media policy overrides any media policy set in the realm configuration.
7. **call-treatment**—Enter the call treatment method for a non-ETS call that contains RPH matching it to this profile. The default is accept. The valid values are:
   - **accept**—The call proceeds as it normally would
   - **reject**—The Oracle Communications Session Border Controller rejects the call with the 417 Unknown-Resource Priority status code
   - **priority**—The Oracle Communications Session Border Controller treats the call as a priority call

Enabling NSEP for an NMC Rule

In addition to the RPH policy and RPH profile you can set for an NMC rule, you also need to set the state of this feature for the NMC rule.

To enable NSEP for an NMC rule:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **net-management-control** and press Enter.

```
ORACLE(session-router)# net-management-control
ORACLE(net-management-control)#
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **rph-feature**—Enable this parameter if you want to turn the NSEP feature on for this NMC rule. The default is **disabled**. The valid values are:
   - enabled | disabled

Global SIP Configuration Settings Enabling NSEP

For the global SIP configuration, you can turn the NSEP feature on, and you can also set parameters that support call admission and congestion control.

In addition, you can enable the insertion of the ARPH header in a response when the resource-priority tag is present in the Require header and the Oracle Communications Session Border Controller rejects the request with a 417 Unknown Resource-Priority response. The ARPH value is the list of r-values you set in the RPH profile.

To enable NSEP for the global SIP configuration:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **rph-feature**—Enable this parameter if you want to turn the NSEP feature on for the global SIP configuration. The default is **disabled**. The valid values are:
   - enabled | disabled

Global SIP Configuration Settings Enabling CAC and Congestion Control

To set call admission and congestion control parameters for NSEP:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **nsep-user-sessions-rate**—Enter the maximum INVITEs per second to admit for ETS calls on a per-user basis. To enable NSEP call admission control (CAC), you must change the parameter value from 0; if you leave this parameter set to 0, then it is the same as disabling CAC for ETS calls. The default is **50**. The valid range is:

   - Minimum—0
   - Maximum—999999999

5. **options**—To enable congestion control for ETS calls, you configure an option that sets the CPU threshold. If this threshold is exceeded, the Oracle Communications Session Border Controllerrejects new ETS calls with the 503 Service Unavailable response. The value you set here should be larger than the load limit value for normal calls; ETS calls are allowed even when the load limit threshold for normal calls is exceeded.

   The threshold value can be between 0 and 100. Using a value of 0 or 100 for this parameter disables ETS call congestion control.

   Set the options parameter by typing **options**, a Space, the option name **nsep-load-limit** with a plus sign in front of it, then the equal sign and the ETS call threshold you want to set. Then press Enter.

   ```
   ACMEPACKET(sip-config)# options +nsep-load-limit=50
   ```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

Global SIP Configuration Settings Enabling ARPH Insertion

To enable ARPH insertion in responses:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

If you are adding support for this feature to a pre-existing configuration, then you must select (using the ACLI **select** command) the configuration that you want to edit.

4. **options**—To enable ARPH insertion in responses type **options**, a Space, the option name **insert-arp-header** with a plus sign in front of it, and then press Enter.

```
ORACLE(sip-config)# options +insert-arp-header
```

If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

Setting Up NSEP for Session Agents

In earlier releases, the Oracle Communications Session Border Controller supports NSEP-related CAC for users and for NMC. You can now configure a sessions-per-second rate for session agents. Set in the global SIP configuration, this rate applies to all SIP session agents. When session exceed the limit, the Oracle Communications Session Border Controller rejects them with a 503 Service Unavailable message.

To configure NSEP limits for SIP session agents:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. **nsep-sa-sessions-rate**—Enter maximum acceptable number of SIP INVITES (NSEP sessions) per second to allow for SIP session agents. This parameter defaults to 0, meaning there is no limit.
5. Save and activate your configuration.

Configure NSEP Resource Reservation

To specify the session capacity to be reserved for NSEP calls, you configure the **reserved-nsep-session-capacity** parameter in the **system-config** element. Your configured value specifies the percentage of the total licensed session capacity that the SBC reserves for NSEP traffic sessions. The SBC calculates the number of NSEP reserved sessions from this percentage. The default is 0%.

When you configure **reserved-nsep-session-capacity** to a non-zero value, the system uses default thresholds to trigger minor, major and critical alarms and SNMP traps when session utilization exceeds these thresholds. You can customize these thresholds by configuring the **reserved-nsep-sessions alarm threshold** type in the **system-config**.

```
ORACLE(alarm-threshold)# type reserved-nsep-sessions
```

To reserve 15% of total session capacity for NSEP sessions, and customize its minor alarm to trigger at 50% of NSEP sessions:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **system** and press Enter.

   ```
   ORACLE(configure)# system
   ORACLE(system)#
   ```

3. Type **system-config** and press Enter.

   ```
   ORACLE(configure)# system-config
   ORACLE(system-config)#
   ```

4. Type **reserved-nsep-session-capacity**, followed by a percentage value of session resources you want to reserve for NSEP sessions. The example below uses 15%.

   ```
   ORACLE(system-config)# reserved-nsep-session-capacity 15
   ```

5. To customize NSEP session utilization alarm and trap thresholds, type **alarm threshold** and press Enter.

   ```
   ORACLE(system-config)# alarm threshold
   ORACLE(alarm threshold)#
   ```

6. Type **type**, followed by the value **reserved-nsep-sessions**, then press Enter.

   ```
   ORACLE(alarm threshold)# type reserved-nsep-sessions
   ORACLE(alarm-threshold)# severity minor
   ORACLE(alarm-threshold)# value 50
   ```

7. Type **done** to complete the **alarm threshold** configuration.
8. Type **done** to complete the **system-config** configuration.
9. Save and activate your configuration.

E-CSCF Emergency Setting Precedence for NMC

When the Oracle Communications Session Border Controller acts as an E-CSCF, it can route emergency or priority calls (i.e., 112, 911, 999 calls) to the corresponding ECS/PSAP based on the calling party's information. However, for registered users, this ability mixes with the Oracle Communications Session Border Controller's NMC function so that the Service Routes takes precedence over the NMC. So rather than routing the emergency call to the ECS/PSAP, the call ends up at the S-CSCF of the Service Route.

For non-registered users where there no Service Route exists, this is not an issue.

When you configure the **treatment** parameter within the **network-management-control** configuration to **apply-local-policy**, you allow the NMC to take precedence over cached Service Route when a session matches an NMC rule. Instead, it locates a matching local policy.

Without the NMC configured to take precedence, the Oracle Communications Session Border Controller does not function optimally as an E-CSCF for registered users.

Consider the following scenario in which a UE registers as a P-CSCF to the S-CSCF via the Oracle Communications Session Border Controller. In this case, the registrar returns a Service Route header in a 200 OK response to the REGISTER message to the Oracle Communications Session Border Controller. Or, if an implicit service route is enabled, the Oracle Communications Session Border Controller generates a Service Route that it saves in the register cache before forwarding the 200 OK on to the UA. Then when a new INVITE comes from the UA, the Oracle Communications Session Border Controller checks its register cache and uses the Service Route as the next hop—without taking local policy into consideration.

Configuring he **treatment** parameter to **apply-local-policy** requires local policy's consideration in deciding the next hop. If you configure this value and the Oracle Communications Session Border Controller receives a new INVITE, it will decide whether the session is priority, registered, or with Service Route. Then it will determine if the call is E-CSCF. If so and the first matching local policy has E-CSCF enabled, the priority local policy is applied over the Service Route. The Oracle Communications Session Border Controller stays with the Service Route if not.

E-CSCF Emergency Configuration

This section shows you how to configure a network management control rule to take precedence over a Service Route.

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **net-management-control** and press Enter.

```
ORACLE(session-router)# net-management-control
ORACLE(net-management-control)#
```

4. **treatment—Follow your entry with this value:**

   - apply-local-policy

```
ORACLE(net-management-control)# treatment apply-local-policy
```

   This value allows a network management control rule to take precedence over a service route for an emergency or priority call.

5. Type **done** and continue.

SIP TCP Connection Reuse

You can configure your Oracle Communications Session Border Controller to reuse TCP connections created by SIP peering devices for outgoing SIP in-dialog and out-of-dialog request transactions.

The SIP draft draft-ietf-sip-connect-reuse-07.txt describes a way for SIP UAs to reuse connections created by a remote endpoint for outgoing requests for TLS. The Oracle Communications Session Border Controller does not support the model connection reuse signalled by a parameter; rather, it is provisioned on a per-session-agent basis.

You enable SIP TCP connection reuse on a per-session-agent basis. The Oracle Communications Session Border Controller checks incoming TCP connection request to determine if they are from session agent that has this feature turned on. When it is, the Oracle Communications Session Border Controller adds the connection's source address to its list of alias connections. This is a list of connections that the Oracle Communications Session Border Controller can use for outgoing requests rather than creating its own connection (as it does when this feature is not enabled). So if a preferred connection fails, the Oracle Communications Session Border Controller can refer to this list and use the alias connection.

The presence of an alias parameter in the Via header is just one mechanism that will call the Oracle Communications Session Border Controller to use the inbound TCP/TLS connection for outbound requests. The Oracle Communications Session Border Controller will automatically add an alias for the inbound connections in the following circumstances:

- The other end of the connection is behind a NAT. When the Oracle Communications Session Border Controller sees that the Via sent-by does not match the source address of the connection, it will automatically reuse the connection to deliver requests to the UA.
- The Contact address of a REGISTER request received on a TCP connection matches the source address and port. This is because the contact adress is the ephemeral port the UA used to form the connection to the Oracle Communications Session Border Controller and, therefore, will not be listening on that port for inbound connections.
- The presence of reuse-connections in the options field of the sip-interface will cause the Oracle Communications Session Border Controller to reuse all inbound TCP connections for sending rquests to the connected UA.

SIP TCP Connection Reuse Configuration

This section describes how to enable SIP TCP connection reuse for a session agent. Currently there are two options for the new **reuse-connections** parameter: none (which turns the feature off) and tcp (which enables the feature for TCP connections). You also set the re-connection interval.

To enable SIP TCP connection reuse for a session agent:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

   If you are adding support for this feature to a pre-existing session agent, then you must select (using the ACLI **select** command) the session agent that you want to edit.

4. **reuse-connections**—Enable or disable SIP TCP connection reuse. The default is **none**. This value disables the feature. The valid values are:
   - tcp | sctp | tls |none
5. **tcp-reconn-interval**—Enter the amount of time in seconds before retrying a TCP connection. The default for this parameter is **0**. The valid range is:
   - Minimum—0, 2
   - Maximum—300
6. Save and activate your configuration.

SIP TCP Keepalive

The Oracle Communications Session Border Controller supports a special TCP keepalive mechanism for SIP. By enabling this feature either for a session agent or for a SIP interface, you allow the Oracle Communications Session Border Controller to use standard keepalive probes to determine whether or not connectivity with a remote peer has been lost.

This feature adds to the Oracle Communications Session Border Controller's pre-existing TCP keepalive functionality that you can enable in the network parameters configuration. Using existing functionality, you can customize keepalive timing by:

- Specifying the number of unacknowledged packets the Oracle Communications Session Border Controller sends to the remote peer before it terminates the TCP connection.
- Specifying the number of seconds of idle time before TCP keepalive messages are sent to the remote peer.

You can now set three modes for TCP keepalive for session agents and SIP interfaces:

- none—(Default) Keepalives are not enabled for use with the session agent/SIP interface; when you select this setting for a session agent, it will use the setting for this feature from the SIP interface.
- enabled—Keepalives are enabled for the session agent/SIP interface.
- disabled—Keepalives are disabled for the session agent/SIP interface.

Note that the setting for this feature for a session agent takes precedence over that for a SIP interface. In addition, the session agent offers you a way to set the re-connection interval.

SIP TCP Keepalive Configuration for Session Agents

To enable SIP TCP keepalive for session agents:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **session-agent** and press Enter.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

   If you are adding support for this feature to a pre-existing session agent, then you must select (using the ACLI **select** command) the session agent that you want to edit.

4. **tcp-keepalive**—Enable or disable standard keepalive probes to determine whether or not connectivity with a remote peer is lost. The default value is **none**. The valid values are:
   - none | enabled | disabled

   ```
   ACMEPACKET(session-agent)# tcp-keepalive enabled
   ```

5. Save and activate your configuration.

SIP TCP Keepalive Configuration for SIP Interfaces

To enable SIP TCP keepalive for SIP interfaces:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

If you are adding support for this feature to a pre-existing SIP interface, then you must select (using the ACLI **select** command) the SIP interface that you want to edit.

4. **tcp-keepalive**—Enable or disable SIP TCP keepalive. The default value is **none**. The valid values are:
   - none | enabled | disabled

```
ORACLE(session-agent)# tcp-keepalive enabled
```

5. Save and activate your configuration.

SIP Enforcement Profile and Allowed Methods

For this feature, you use a configuration called an enforcement profile that allows you to configure sets of SIP methods that you want applied to: the global SIP configuration, a SIP interface, a realm, or a SIP session agent. The enforcement profile is a named list of allowed methods that you configure and then reference from the configuration where you want those methods applied.

SIP Enforcement Profile Configuration

To use the enforcement profile, you need configure it with a name and the list of SIP methods you want to designate as allowed. Then you need to configure the global SIP configuration, a SIP interface, a realm, or SIP session agent to use the set.

Setting Up and Enforcement Profile

To set up an enforcement profile:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **enforcement-profile** and press Enter.

```
ORACLE(session-router)# enforcement-profile
ORACLE(enforcement-profile)#
```

4. **name**—Enter the name for the enforcement profile. This parameter has no default, but you must note it so that you can apply this set of allowed SIP headers in: the global SIP configuration, a SIP interface, a realm, or SIP session agent.

   ```
   ORACLE(enforcement-profile)# name EnfProfile1
   ```

5. **allowed-methods**—Enter a list of SIP methods that you want to allow for this set. The default value is **none**. Valid values are:

   - INVITE | REGISTER | PRACK | OPTIONS | INFO | SUBSCRIBE | NOTIFY | REFER | UPDATE | MESSAGE | PUBLISH

     To enter multiple methods for the list, type the parameter name followed by a space, then the names of all methods you want to include each separated by a only a comma and in capital letters.

     ```
     ORACLE(enforcement-profile)# allowed-methods INVITE,REGISTER,PRACK
     ```

6. Save and activate your configuration.

Applying an Enforcement Profile

You can apply an enforcement profile to: the global SIP configuration, a SIP interface, a realm, or SIP session agent. This section shows you how to do all four. Remember that if you are adding this functionality to a pre-existing configuration, you need to select the configuration you want to edit.

To apply an enforcement profile to the global SIP configuration:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

4. **enforcement-profile**—Enter the name of the enforcement profile you want to apply to the global SIP configuration.
5. Save and activate your configuration.

   To apply an enforcement profile to a SIP interface:

6. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

7. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

8. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

9. **enforcement-profile**—Enter the name of the enforcement profile you want to apply to this SIP interface.
10. Save and activate your configuration.

    To apply an enforcement profile to a SIP session agent:

11. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

12. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

13. Type **session-agent** and press Enter.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

14. **enforcement-profile**—Enter the name of the enforcement profile you want to apply to this session agent.
15. Save and activate your configuration.

    To apply an enforcement profile to a realm:

16. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

17. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

18. Type **realm-config** and press Enter.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

19. **enforcement-profile**—Enter the name of the enforcement profile you want to apply to this realm.
20. Save and activate your configuration.

Local Policy Session Agent Matching for SIP

When you enable the local policy session agent matching option in your global SIP configuration, you change the way local policies match session agents. Normally, the Oracle Communications Session Border Controller looks up and stores matched session agents configured as next hops so it does not need to perform the lookup while processing requests. In this type of matching, the Oracle Communications Session Border Controller does take the realm set in the local policy attributes into consideration. When the Oracle Communications Session Border Controller performs its regular matching method and you have enabled overlapping IP addresses for session agents, the Oracle Communications Session Border Controller might match session agents to different realms than the ones you intended when creating your configuration.

Local policy session agent matching provides a way to match session agents differently, taking realms and nested realms into consideration during the matching process. This difference is key to deployments with multiple peering partners that use the overlapping IP address feature, and have multiple local policies routing to the same IP address in different realms where some target next hops require session constraints but others do not. In the cases where no session constraints are required, session agents are not needed. But session agents still match the local policy, applying their constraints, because they match the next hop IP address.

In addition to modifying this behavior, this feature also affects the use of realms and nested realms. It triggers the use not only of realms, but of all the realms nested however deeply—thereby improving matching efficiency.

You can set the local policy session agent matching option with values that define how the Oracle Communications Session Border Controller performs session agent matching:

- **any**—The Oracle Communications Session Border Controller looks up and stores matched session agents configured as next hops so it does not need to perform the lookup while processing requests, without regard to realms.
  This behavior is the default when the SIP configuration does not have the local policy session agent matching option set.
- **realm**—The Oracle Communications Session Border Controllerselects session agents in the realm that the local policy attribute indicates; this provides an exact match, rather than not taking the realm into consideration during session agent selection.
  For example, the session agent is a match if the session agent **realm-id** and the local policy attribute **realm** parameters are an exact match.
- **sub-realm**—Session agents in the same realm or the same realm lineage—where session agents and realms are related to one another via realm parent-child relationships no matter the depth of realm nesting configured
  For example, the session agent is a match if the local policy attribute **realm** is a sub-realm of the realm specified in the session agent **realm-id** parameter.
- **interface**—Session agents in the same realm or same realm lineage via the realm set in the local policy attribute, and whose realm uses the same signaling interface as the realm set in the local policy attribute
  For example, the session agent is a match if the session agent **realm-id** is a sub-realm of the local policy attribute **realm**, and both referenced realms use the same SIP signaling interface.
- **network**—Session agents whose realm is in the realm lineage for the same realm set in the local policy attributes, and whose realm is associated with the same network interface as the realm set in the local policy attributes

For example, the session agent is a match if the session agent **realm-id** is a sub-realm of the local policy attribute **realm**, and realm reference by both use the same network interface.

If it cannot find a match, the Oracle Communications Session Border Controller will use the IP address as the next hop. Further, requests matching local policy attributes will not be associated with session agents, and so their constraints will not be applied.

The Oracle Communications Session Border Controller stores session agent information that it looks up when performing local policing session agent matching. To perform the lookup, it uses the session agent hostname as a key. When the hostname is an FQDN and there is a configured IP address in the **ip-address** parameter, the Oracle Communications Session Border Controller uses the ip-address value as a secondary key. Given this implementation, the following are true when selecting session agents:

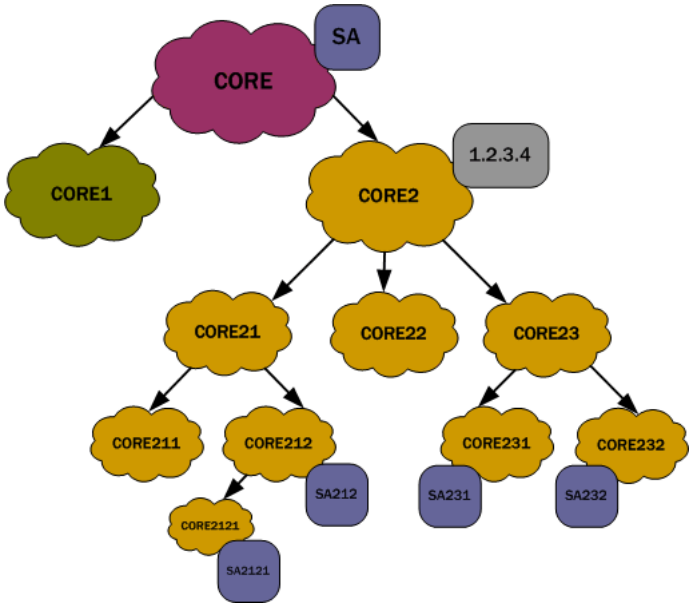
- If multiple session agents share the same IP address, the one with an IP address in the hostname parameter takes precedence.
- If all session agents with the same IP address have an FQDN as their hostname, the one whose name is alphabetically lower will take precedence, where alphabetically lower means earlier in the alphabet (closer to A than to Z).
- For non-global session agents (whose realms are configured but not wildcarded) with an IP address, the Oracle Communications Session Border Controller uses a key that is a combination of the IP address and the realm in the form <address>:<realm>.
- For a session agent whose realm has a parent realm, the Oracle Communications Session Border Controller uses a combination of the IP address, realm, and realm-path (or lineage for the realm) in the form <address>:<realm-path>. For example, the realm path for a realm core3 with a parent core2, which in turn has a parent core would be core:core2:core3.

When it looks up a session agent with a realm, the Oracle Communications Session Border Controller first searches for an exact match for the IP address and realm combination. If this fails, it performs a second search if the desired realm has parents or children. The Oracle Communications Session Border Controller locates an entry in its repository of session agent information that is greater than or equal to the IP address with the base realm, which is the ancestor of the desired realm without a parent. Having gathered this set of candidates, the Oracle Communications Session Border Controller narrows down the search for a match by comparing sub-realms and determines there is a match if either:

- The desired realm path is a sub-string of the entry's realm path, or
- The entry's realm path is a substring of the desired realm path (i.e., the desired realm is a sub-realm of the entry's realm)

Then the Oracle Communications Session Border Controller orders the candidates by depth of the entry's realm-path, or number of levels from the base realm relative to the depth of the desired realm. By searching the ordered set until the entry's realm depth equals the desired realm's depth, the Oracle Communications Session Border Controller determines a parent candidate, all subsequent entries being sub-realms of the desired realm. The Oracle Communications Session Border Controller only considers entries at the first level deeper than the desired realm. If at this point there is only one entry, the Oracle Communications Session Border Controller deems it a match. Otherwise, it selects the parent candidate as the matching entry. In the event the search does not yield a matching realm, the Oracle Communications Session Border Controller uses the global session agent for the IP address, if there is one.

The following diagram shows the realm tree, where the clouds are realms and squares are session agents, representing a group of session agents sharing the IP address 1.2.3.4. The Oracle Communications Session Border Controller searches for the session agents lower in the tree along the session agent realm-path and the desired realm.



For the diagram above, the following shows how the hostname would look for this group of session agents.

Key	Session Agent (hostname[realm])
1.2.3.4 (This session agent owns the primary key for the IP address because its hostname is the IP address.)	1.2.3.4[CORE2]
1.2.3.4:CORE (IP+realm key entry)	SA[CORE]
1.2.3.4:CORE (IP+realm key entry)	1.2.3.4[CORE2]
1.2.3.4:CORE212 (IP+realm key entry)	SA212[CORE212]
1.2.3.4:CORE2121 (IP+realm key entry)	SA2121[CORE2121]
1.2.3.4:CORE231 (IP+realm key entry)	SA231[CORE231]
1.2.3.4:CORE232 (IP+realm key entry)	SA232[CORE232]
1.2.3.4:CORE: (IP+realm-path key entry)	SA[CORE]
1.2.3.4:CORE:CORE2: (IP+realm-path key entry)	1.2.3.4[CORE2]
1.2.3.4:CORE2:CORE21:CORE212 (IP+realm-path key entry)	SA212[CORE212]
1.2.3.4:CORE2:CORE21:CORE212:CORE2121 (IP+realm-path key entry)	SA2121[CORE2121]
1.2.3.4:CORE2:CORE23:CORE231 (IP+realm-path key entry)	SA231[CORE231]
1.2.3.4:CORE2:CORE23:CORE232 (IP+realm-path key entry)	SA232[CORE232]

For each realm in the table above, the search results for each realm would look like this:

IP Address	Realm	Session Agent (hostname[realm])
1.2.3.4	CORE	SA[CORE]
1.2.3.4	CORE2	1.2.3.4[CORE2]
1.2.3.4	CORE21	SA212[CORE212[
1.2.3.4	CORE211	1.2.3.4[CORE2]
1.2.3.4	CORE212	SA212[CORE212]
1.2.3.4	CORE2121	SA2121[CORE2121]
1.2.3.4	CORE22	1.2.3.4[CORE2]
1.2.3.4	CORE23	1.2.3.4[CORE2]
1.2.3.4	CORE231	SA231[CORE231]
1.2.3.4	CORE232	SA232[CORE232]

Local Policy Session Agent Matching Configuration

When you enable local policy session agent matching, remember that you can choose from five different ways to use the feature: **all**, **realm**, **sub-realm**, **interface**, and **network**.

This example shows you how to use the **realm** selection.

To enable local policy session agent matching using the realm method:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

4. **options**—Set the options parameter by typing options, a Space, the option name **lp-sa-match=X (where X is the local policy session agent matching method you want to use)** with a plus sign in front of it. Then press Enter.

   Remember that if you do not specify a method, the system uses the **all** method.

   ```
   ORACLE(sip-config)# options +lp-sa-match=realm
   ```

   If you type **options** and then the option value for either of these entries without the plus sign, you will overwrite any previously configured options. In order to append the new options to this configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

- Unordered—Meaning that the endpoint can deliver data within regard for their stream sequence number

You set this preference in the network parameters configuration.

About Wildcarding

The Oracle Communications Session Border Controller supports wildcarding the event type in the **subscribe-event** configuration. To wildcard the value, you enter an asterisk (*) for the **event-type** parameter instead of typing in the name of an actual event type.

When you wildcard this value, the Oracle Communications Session Border Controller applies the subscription limitations you set across all event types. Or, if you have entered multiple subscribe-event configurations, the Oracle Communications Session Border Controller applies the wildcard limits across the event types for which you have not set limits.

Consider the following example of a configured enforcement profile with a wildcarded **subscribe-event** configuration:

```
enforcement-profile
        name                            rulefour
        allowed-methods
        sdp-address-check               disabled
        subscribe-event
                 event-type                     *
                 max-subscriptions              1
        subscribe-event
                 event-type                     xyz
                 max-subscriptions              0
        last-modified-by                admin@console
        last-modified-date              2008-11-11 12:49:27
```

In this example, the enforcement profile allows all subscriptions that are event type xyz for a user. But it allows only one maximum for every other subscription event type.

Monitoring

You can display the number of subscription dialogs per SUBSCRIBE event type using the ACLI **show registration sipd subscriptions-by-user** command. You can display this information per event type, or you can show data for all event types by wildcarding the event type argument.

Enforcement Profile Configuration with subscribe-event

This section shows you how to configure an enforcement profile with a **subscribe-event** configuration. Remember that you can set up multiple **subscribe-event** configurations to correspond with the event types you want to control. It also shows you how to apply these limitations to a realm.

Setting Up Subscribe Dialog Limits

Setting up subscribe dialog limits means setting up an enforcement profile. For the sole purpose of setting up the subscription event limits, you only need to configure the name parameters and then as many **subscribe-event** configurations as you require. The enforcement profile has other uses, such as SIP SDP address correlation, so only configure the parameters you need.

To configure subscribe dialog limits:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **enforcement-profile** and press Enter.

```
ORACLE(session-router)# enforcement-profile
ORACLE(enforcement profile)#
```

4. **name**—Enter a name for this enforcement profile. You will use this name later when you apply the enforcement profile to a realm; it is the value you enter into the **enforcement-profile** parameter in the realm configuration.
5. Still in the enforcement profile configuration, type **subscribe-event** and press Enter.

```
ORACLE(enforcement profile)# subscribe-event
ORACLE(subscribe-event)#
```

6. **event-type**—Enter the SIP subscription event type for which you want to set up limits. You can also wildcard this value (meaning that this limit is applied to all event types except the others specifically configured in this enforcement profile). To use the wildcard, enter an asterisk (*****) for the parameter value.

   By default, this parameter is blank.

> **Note:**
>
> The value you enter must be configured as an exact match of the event type expected in the SIP messages (except for the wildcard). Further, the value conforms to the event type BNF specified in RFC 3265.

7. **max-subscriptions**—Enter the maximum number of subscriptions allowed to a user for the SIP subscription event type you entered in the **event-type** parameter. Leaving this parameter set to 0 (default) means that there is no limit. You can set this parameter to a maximum value of 65535.
8. If you are entering multiple **subscribe-event** configurations, then you save them each by using the ACLI **done** command and then repeat Steps 6 and 7 to configure a new one. If you do not save each, then you will simply overwrite the first configuration repeatedly.

```
ORACLE(subscribe-event)# done
```

9. When you finish setting up **subscribe-event** configurations and have saved them, exit to return to the enforcement profile configuration.

```
ORACLE(subscribe-event)# exit
```

10. You also need to save the enforcement profile configuration.

```
ORACLE(enforcement profile)# done
```

Applying an Enforcement Profile to a Realm

For the Oracle Communications Session Border Controller to use the limits you have set up, you need to apply them to a realm.

To apply an enforcement profile to a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter. If you are adding this feature to a pre-existing realm configuration, you will need to select and edit your realm.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. **enforcement-profile**—Enter the name of the enforcement profile you want to apply to this realm. This value corresponds to the **name** parameter in the enforcement profile configuration. This parameter has no default value.
5. Save and activate your configuration.

STUN Server

The Oracle Communications Session Border Controller supports RFC 3489, which defines Simple Traversal User Datagram Protocol (UDP) through Network Address Translators (NATs). Known as STUN, this lightweight protocol that allows applications to:

- Discover the presence and types of both NATs and firewalls between themselves and the public Internet
- Determine the public IP addresses allocated to them by the NAT

SIP endpoints use the STUN protocol to find out the public IP addresses and ports for SIP signaling and RTP media transport. Then they can use the address and port information to create multimedia sessions with other endpoints on the public network.

You can define STUN servers functionality on a per-realm basis, allowing you set up multiple STUN servers.

About STUN Messaging

STUN messages uses six messages, three of which are used for Binding and three of which are uses for the Shared Secret. While it supports all three Binding messages (request, response, and error), the Oracle Communications Session Border Controller does not support

the Shared Secret Request or the message integrity mechanism that relies on the shared secret. When acting as a STUN server, the Oracle Communications Session Border Controller responds to STUN binding requests in accordance with RFC 3489 and the rfc3489bis draft.

STUN messages can contain the following attributes:

Message Type	Attribute Description
MAPPED-ADDRESS	Appears in the Binding Response; contains the source IP address and port from which the Binding Request was sent to the STUN server.
XOR-MAPPED-ADDRESS	Appears in the Binding Response; contains the MAPPED-ADDRESS information encoded in a way the prevents intelligent NAT devices from modifying it as the response goes through the NAT.
SOURCE-ADDRESS	Appears in the Binding Response; contains the IP address and port from which the STUN server sent its response.
CHANGED-ADDRESS	Appears in the Binding Response; contains an alternate STUN server IP address and port, different from the primary STUN server port. The STUN client might use this attribute to perform the NAT tests described in RFC 3489.
CHANGE-REQUEST	Appears in the Binding Request; instructs the STUN server to send its response from a different IP address and/or port. The STUN client might use this attribute to perform the NAT tests described in RFC 3489.
RESPONSE-ADDRESS	Appears in the Binding Request; defines an IP address and port to which the STUN server should send its responses. Appears in the Binding Request;
REFLECTED-FROM	Appears in the Binding Response; reflects the IP address and port from which a Binding Request came. Only included when the Binding Request has used the RESPONSE-ADDRESS attribute.
UNKNOWN-ATTRIBUTES	Appears in the Binding Error; reflects the mandatory attributes in a Binding Request message that the server does not support.
ERROR-CODE	Appears in the Binding Error; indicates an error was detected in the Binding Request, and contains an error code and reason phrase.

To perform NAT discovery, the endpoint (STUN client) sends a Binding Request to the STUN server port (IP address and port) with which it is configured. The STUN server then returns either a;

- Binding Response—Allows the transaction to proceed
- Binding Error—Halts the transaction, and prompts the client to take the action appropriate to the response given in the ERROR-CODE attribute

When the transaction proceeds and the STUN server sends the Binding Response, that response contains the MAPPED-ADDRESS attribute, which contains the IP address and port from which the server received the request. The STUN client then uses the MAPPED-ADDRESS when sending signaling messages.

For example, a SIP endpoint sends Binding Requests from its SIP port to determine the public address it should place in SIP headers, like the Via and Contact, of the SIP requests it sends. When this SIP endpoint prepares to make or answer a call, it sends Binding Requests from its RTP port to find out the public address it should place in SDP included in an INVITE request or response.

STUN Server Functions on the Oracle Communications Session Border Controller

When the Oracle Communications Session Border Controller receives a STUN message, it first determines its message type. Only STUN Binding Requests are processed, and all other message types are dropped without response.

Then the Oracle Communications Session Border Controller examines the Binding Request's STUN attributes. It returns error responses if it finds any unsupported mandatory attributes. This takes the form of a Binding Error Response, containing the ERROR-CODE attribute with reason 420 (Unknown Attribute) and an UNKNOWN-ATTRIBUTES attribute with a list of the unsupported attributes. If the Oracle Communications Session Border Controller receives a Binding Request with attributes that do not belong in STUN Binding Requests, it returns the Binding Error Response with the ERROR-CODE attribute with reason 400 (Bad Request).

Next the Oracle Communications Session Border Controller determines whether to follow RFC 3489 procedures or rfc3489bis procedures. If the Transaction ID contains the STUN cookie, then the Oracle Communications Session Border Controller follows rfc3489bis procedures; if not, the it follows RFC 3489 procedures. Because it defines the procedures for testing the NAT to see what type of NAT it is, RFC 3489 procedures are most complex. Issues with reliability of those results have caused testing procedures and attributes to be deprecated in fc3489bis.

RFC 3489 Procedures

The Oracle Communications Session Border Controller (the STUN server) constructs the Binding Response and populates it with these attributes:

- MAPPED-ADDRESS and (optionally) XOR-MAPPED-ADDRESS—Containing the source IP address and port from which the server saw the request come
- SOURCE-ADDRESS—Containing the IP address and port from which the server will send the Binding Response
- CHANGED-ADDRESS—Containing the STUN server port that has a different address and different port from the ones on which the server request was received

If the Binding Request contains a RESPONSE-ADDRESS attribute, the server adds the REFLECTED-FROM attribute with the IP address and port from which the server saw the request come. Then the server sends the Binding Response to the IP address and port in the RESPONSE-ADDRESS attribute. If the RESPONSE-ADDRESS attribute's IP address and port are invalid, the server sends a Binding Error Response with an ERROR-CODE attribute reason 400 (Bad Request) to the client.

If the Binding Request contains a CHANGE-REQUEST attribute, the server sends Binding Response from the IP address and port matching the information in the CHANGE-REQUEST. The following variations can occur:

- If the IP address and port flags are set, the server selects the server port with a different IP address and different port.
- If only the IP address flag is set, the server selects the server port with a different IP address but with the same port.
- If only the port flag is set, the server selects the server port with the same IP address but with a different port.

The selected server port appears in the Binding Responses's SOURCE-ADDRESS attribute. When there is no CHANGE-REQUEST attribute, the server uses the server port on which the Binding Request was received.

Finally, the server encodes the outgoing message and sends it to the client at either:

- The destination IP address and port in the REPONSE-ADDRESS attribute, if it was present in the Binding Request.
- The MAPPED-ADDRESS.

rfc3489bis Procedures

If the Binding Request contains the appropriate cookie in its Transaction ID, the server constructs a Binding Response populated with the XOR-MAPPED-ADDRESS attribute. That attribute will contain the source IP address and port from which the server saw the request come. Then the server encodes and sends the message to the client from the IP address and port on which the request was received. The message is sent to the IP address and port from which the request came.

Monitoring

- STUN Server Statistics—You can display statistics for the STUN server using the ACLI **show mbcd stun** command when the STUN server has been enabled. However, if the STUN server has not been enabled since the last system reboot, the command does not appear and no statistics will be displayed.
- STUN Protocol Tracing—You can enable STUN protocol tracing two ways: by configuration or on demand.
  - By configuration—The Oracle Communications Session Border Controller's STUN protocol trace file is called stun.log, which is classified as a call trace. This means that when the system configuration's call-trace parameter is set to enabled, you will obtain STUN protocol information for the system. As with other call protocol traces, tracing data is controlled by the log-filter in the system configuration.
  - On demand—Using the ACLI **notify mbcd log** or **notify mbcd debug** commands, you enable protocol tracing for STUN. Using **notify mbcd debug** sets the STUN log level to TRACE. You can turn off tracing using the **notify mbcd onlog** or **notify mbcd nodebug** commands. Using **notify mbcd nodebug** returns the STUN log level back to its configured setting.

STUN Server Configuration

You configured STUN servers on a per-realm basis, one server per realm. To support that various NAT tests it describes, RFC 3489 requires that two different IP addresses and two different UDP port numbers be used for each server. So your STUN server will listen on a total of four STUN server ports. Although newer work does away with this requirement, the Oracle Communications Session Border ControllerC supports it for the purpose of backwards compatibility.

For each realm configuration with an enabled STUN server, untrusted ACL entries will be added to forward all packets received on the four STUN Server Port.

To enable STUN server support for a realm:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
ORACLE(configure)# media-manager
ORACLE(media-manager)#
```

3. Type **realm-config** and press Enter. If you are adding this feature to a pre-existing realm configuration, you will need to select and edit your realm.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. **stun-enable**—Set this parameter to **enabled** to turn STUN server support for this realm on. This parameter defaults to **disabled**, meaning STUN server support is off.
5. **stun-server-ip**—Enter the IP address for the primary STUN server port. The default for this parameter is 0.0.0.0.
6. **stun-server-port**—Enter the port to use with the **stun-server-ip** for primary STUN server port. The default is 3478.
7. **stun-changed-ip**—Enter the IP address for the CHANGED-ADDRESS attribute in Binding Requests received on the primary STUN server port. This IP address must be different from than the one defined for the **stun-server-ip** parameter. The default for this parameter is 0.0.0.0.
8. **stun-changed-port**—Enter the port combination to define the CHANGED-ADDRESS attribute in Binding Requests received on the primary STUN server port. The default for this parameter is 3479.
9. Save and activate your configuration.

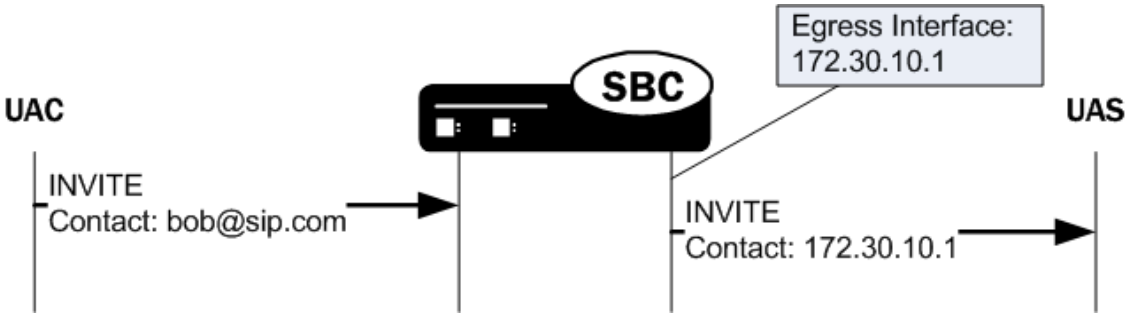
SIP GRUU

SIP Globally Routable User Agent (UA) URIs (GRUU) are designed to reliably route a SIP message to a specific device or end user. This contrasts with a SIP AoR which can refer to multiple UAs for a single user, thus contributing to routing confusion. The Oracle Communications Session Border Controller can perform different behaviors when it finds SIP GRUUs in Contact headers.

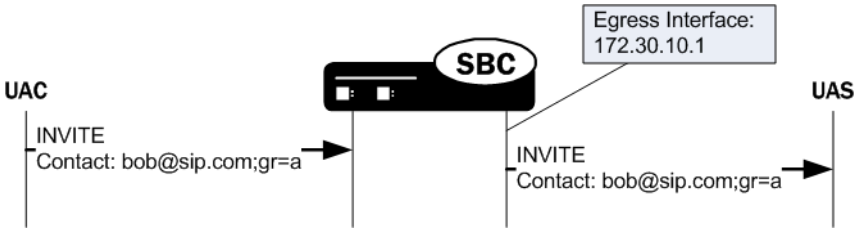
User agents supporting GRUU include a GRUU-identifying parameter in the Contact header of dialog forming and target refresh requests. The Oracle Communications Session Border Controller scans for the GRUU parameter in the Contact header either when the message is received on a realm or interface configured for registered endpoints or when the pass-gruu-contact parameter is enabled. Configure an interface for registered endpoints by enabling nat-traversal or registration caching.

Contact Header URI Replacement

When no GRUU is encountered in the contact header, and when a SIP message is forwarded to the egress realm, the contact header's URI is replaced with the Oracle Communications Session Border Controller's egress interface. For example:

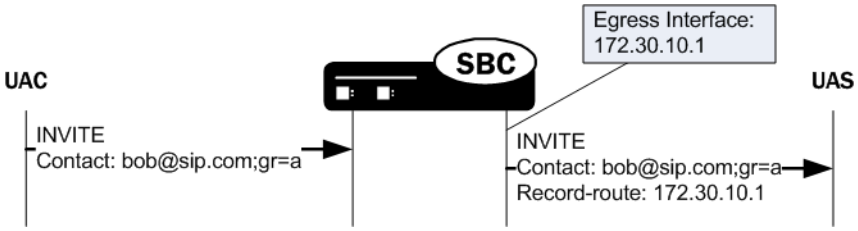


When the Oracle Communications Session Border Controller forwards a request where the original Contact header contains a GRUU, the contact header's URI is forwarded unchanged on the egress side of the call. For example:



Record-Route Addition

When the request is forwarded to a realm where the endpoint's registrar does not exist, the Oracle Communications Session Border Controller adds a Record-Route header containing the egress SIP interface address. This causes subsequent replies or requests addressed to the GRUU to be routed through the Oracle Communications Session Border Controller first.



When the request is forwarded to the realm where the registrar exists, adding the Record-Route header is unnecessary and does not occur. This is because subsequent requests are directed to the registrar which will ultimately forward them to the Oracle Communications Session Border Controller using the registered Contact in the Request-URI.

GRUU URI Parameter Name

The Oracle Communications Session Border Controller scans for a gr URI parameter in the contact header to identify it as a GRUU as defined in the ietf draft[2]. The Oracle Communications Session Border Controller can be configured to scan for a gruu URI parameter in the contact header too. This alternate behavior is enabled with the scan-for-ms-gruu option and is used to interact with the Microsoft Office Communications Server unified communications product. When scan-for-ms-gruu is enabled, the Oracle Communications Session Border Controller scans first for the gruu URI parameter. If not found, it then scans for gr URI parameter.

SIP GRUU Configuration

This section shows you how to configure the GRUU support for non-registered contacts. Enabling GRUU functionality to parse for gr URI parameter rather than the IETF standard gruu parameter is also provided.

To configure SIP GRUU functionality:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

   If you are adding this feature to an existing configuration, you need to select the configuration (using the ACLI **select** command) before making your changes.

4. **pass-gruu-contact**—Set this parameter to enabled to parse for gr URI parameter in the contact header in non-registered endpoints' messages and then pass the messages thought the system.
5. **options**—Set the options parameter by typing **options**, a Space, the option name **scan-for-ms-gruu.** This option forces the Oracle Communications Session Border Controller to first scan for the gruu URI parameter, then the gr URI parameter.
6. Save and activate your configuration.

SIP SIP-I Interworking

The Oracle Communications Session Border Controller (SBC) supports the Interworking function (IWF) between SIP and SIP-I networks by including ISUP message information in the body of SIP messages, and formatting SIP message information for SIP-I, from which subsequent devices use for ISUP. The SBC has broad support for ITU Specification Q.1912.5, which defines SIP-I. This specification defines ISUP message encapsulation and the mapping between SIP headers and ISUP parameters. This ITU specification is considered a superset of the IETF's SIP-T specification. The SBC also complies with IETF specifications on the use of MIME within SIP messages.

Within the context of SIP SIP-I IWF, the Oracle Communications Session Border Controller (SBC) operates between the SIP network and a Media Gateway Controller Function (MGCF) generating and interpreting SIPI as an interim step for originating and/or terminating services between SIP and ISUP. The configurable categories of interworking information include:

- Signaling Message and Parameter IWF
- Diversion Information IWF
- ISUP Version IWF

You configure **sip-profiles** and **sip-isup-profiles** and apply them to **session-agent**, **sip-interface** or **realm** to enable interworking. These configurations determine the base actions taken on the target traffic. The SBC supports three methods refining the interworking. You can them use the following configuration methods to refine the interworking by specifying information, such as header parameter detail, for ingress and/or egress traffic:

- Interworking with Header Manipulation Rules (HMR)
- Interworking with Session Translation
- Native SIP SIP-I Interworking Support

You configure the SBC to use one or a combination of these methods. Note the processing order in which the SBC executes these functions, explained in this document, as each subsequent function operates on the results of the prior function.

By default, you configure HMR for all SIP to SIP-I interworking, with the exception of IAM interworking. This is a legacy means of configuring this interworking, and is widely deployed.

Session translation configuration is similar to HMR, but is for less complex message manipulation. You configure session translation elements to perform specific text changes on a limited number of SIP and/or SIP-I objects using offsets to find your target objects, and add, change or delete the text you specify. You can also use session translation for called and calling number manipulation for SIP to SIP signaling.

Native SIP SIP-I interworking features automatically perform interworking on messages in addition the IAM. For native SIP SIP-I interworking, you simply enable it and the SBC performs the changes described herein. Advantages of Native IWF configuration include:

- Avoids the complexity of HMR configuration, reducing implementation time and resources
- Provides session statefulness within the SBC for these interworked sessions
- Overcomes the HMR limitation of HEX to decimal arithmetic, simplifying reason code mapping
- Allows better system performance

Regardless of the method you choose, at a high level, for SIPI to SIP interworking, the SBC constructs the SIP headers based on the SIPI information, then removes the entire SIPI MIME block. For the SIP to SIPI direction, the SBC interworks IAM parameters as described in this document and inserts the block.

> **Note:**
>
> The SBC does not comply with every aspect of ITU Specifications Q.1912.5, which defines SIP-I.

SIP-SIPI IWF Operational Overview

The SBC uses the ITU Q.1912.5 specification for guidance on this IWF. The following sections describe key SBC behavior that is not defined by any external specification.

Function Processing Order

There are three configurable objects that you can use to perform SIP-SIPI IWF. When designing your IWF, ensure you configure each object using the understanding of which functions the SBC has already performed. Doing this ensures that your configuration performs each step on the data based on which functions are already completed.

For ingress, the SBC acts on these objects in the following order:

1. HMR rules
2. **in-translationid** rule(s)
3. **sip-isup-profile**

For egress, the SBC acts on these objects in the following order:

1. **sip-isup-profile**
2. **out-translationid** rule(s)
3. HMR rules

The **sip-isup-profile** is applicable only on the SIP-I side of the call.

IAM Message Interworking

The SBC performs IAM message insertion and deletion, using the version specified in that applicable **sip-profile**, without requiring HMR when your configuration invokes a valid **sip-isup-profile**. This includes diversion information. The SBC also interworks the IAM parameters documented herein. Extended IAM support, including number portability interworking support requires that you configure the native inter-working method.

Additional Message Interworking

When enabled, Native interworking mode interworks additional ISUP messages:

- ACM
- CPG
- ANM
- CON
- REL
- RLC

Applicable parameter interworking is documented below.

BYE and REL

The SBC inserts an REL as an application/isup “content-type” with the header parameters based on the applicable **sip-isup-profile**, and formats the message according to the ISUP version configured in the **sip-isup-profile**.

In addition, if a Reason header, as described in IETF RFC 6432, is included in a 4xx, 5xx, 6xx response, the SBC maps the Cause Value of the Reason header to the ISUP Cause Value field in the REL message.

200OK and RLC

The SBC inserts an RLC as an application/isup content-type, with the header parameters based on the applicable **sip-isup-profile**. It does not include any ISUP parameters in this message.

CON Message Workaround

It is possible for an SIP-I node to receive a CONNECT (CON) without receiving any Address Complete Message (ACM) or Call Progress (CPG) message, such as when the call is answered automatically. In these cases, the SIP user does not receive a 18x provisional

response, and does not hear ringtone before the callee answers. To support these cases, the SBC inserts a CON message into the outgoing 200 OK response.

High Availability

By design, the SBC replicates session level data to the standby after the 200 OK message. Because the SBC processes ISUP signaling prior to the 200 OK, there is no HA replication of these messages. Specifically, the ACM and CPG get processed with provisional (18x) responses and the ANM or CON ISUP get processed with the 200 OK response. If an HA pair fails over between the IAM and ANM messages, the SBC cannot maintain state for these sessions.

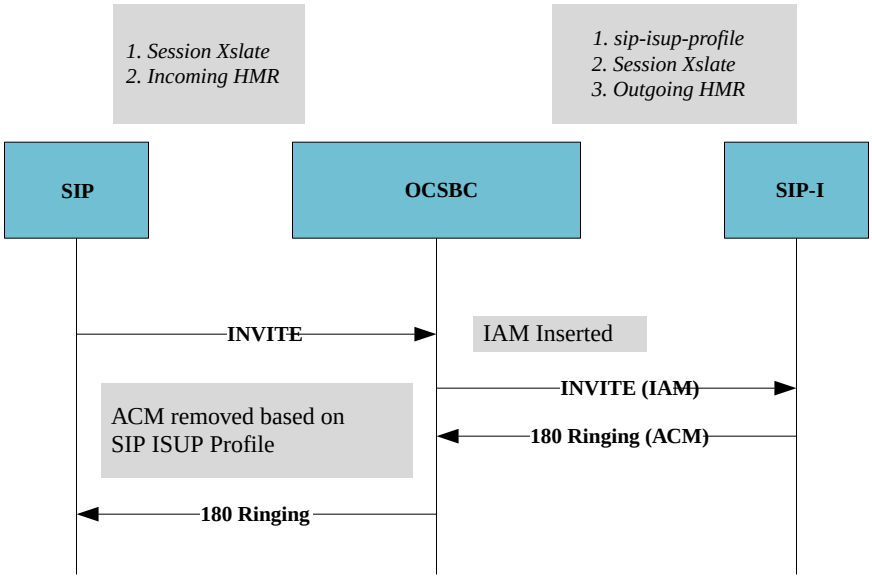
State Machine

The SBC maintains state for SIP to SIP-I sessions only when configured for native ISUP message interworking; not for the HMR method.

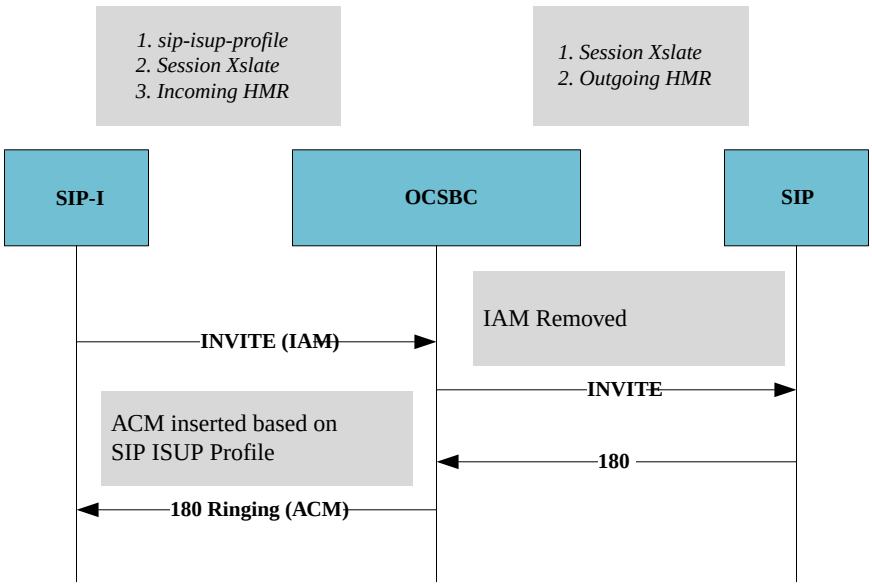
SIP-SIPI Interworking Call Flows

When configured for SIP-SIP-I interworking, the SBC inserts and removes ISUP signaling information into SIP signaling messages as MIME bodies. You can also configure manipulation and/or translation rules to refine your interworking. The diagrams below present the order in which the SBC processes the relevant configuration objects, resulting in incremental changes. You must configure interworking manipulation ensuring that the changes caused by the latter processing are based on the results of preceding processing.

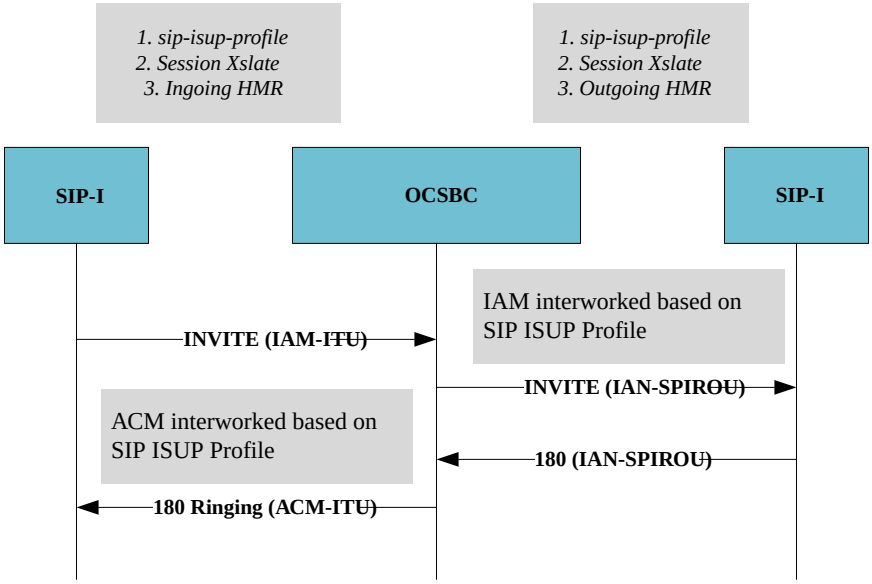
The diagram below shows a call initiated by a SIP endstation. The SBC interworks the call to SIP-I using your configuration and passes the call to the media gateway for SIPI to ISUP interworking. The SBC inserts the IAM as an ISUP MIME body part in the INVITE. The SBC also removes ACM presented by the SIP-I network from the 180 Ringing message.



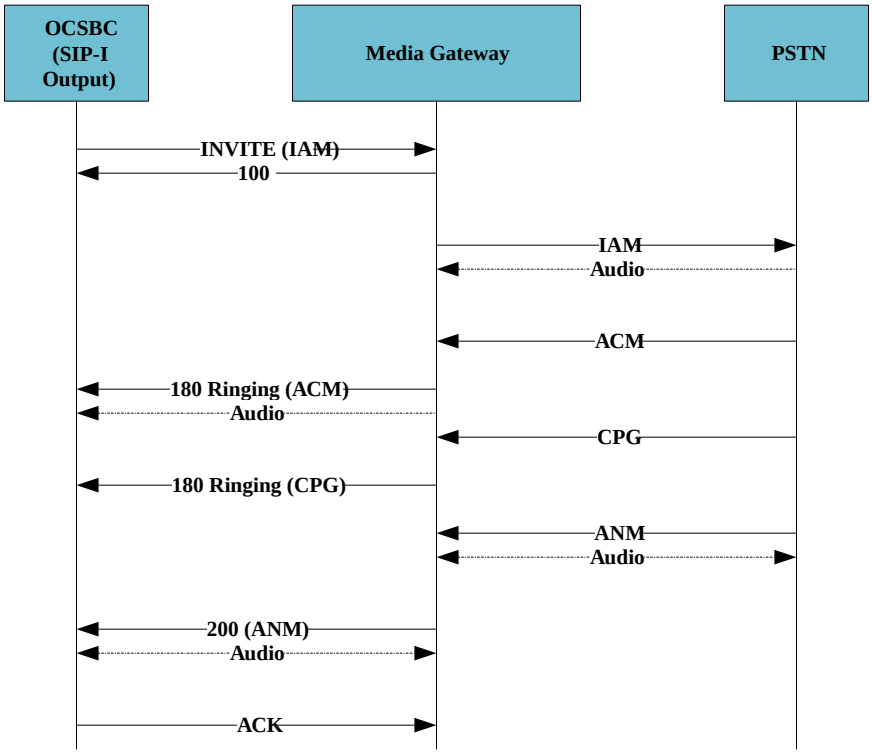
Similarly, the diagram below presents the opposite IWF behavior wherein the SBC detects an INVITE coming from SIP-I, removing the IAM and inserting the ACM, as appropriate.



Similarly, the diagram below presents the ISUP version (format) behavior wherein the SBC detects an INVITE coming from SIP-I, interworking the ITU-IAM to SPIROU-ACM, as appropriate.



To complete the picture, note the SBC providing SIP-I output to the media gateway, which interworks between SIP-I and the PSTN.



Refer to ITU-T Recommendation Q.1912.5 for SIP to ISUP message mapping tables to verify expected responses and their interworking.

Base SIP-SIPI IWF Functionality

By default, the SBC does not perform SIP-SIPI interworking. You configure one or more **sip-isup-profile** and **sip-profile** sub-elements within the **session-router** element, and then specify the profiles to use on a **session-agent**, **sip-interface** or **realm**. The SBC follows that order for the configuration's operation precedence.

- **sip-isup-profile**—This object specifies multiple SIP-SIPI IWF controls for the object to which it is applied. At a minimum, this parameter specifies the ISUP version for parameter interworking. Additional IWF configuration includes ISUP version interworking and disabling 183 message interworking.
- **sip-profile**—This object includes the **redirection** parameter that defines the basic SIP-SIPI insertion and removal behavior for the object to which it is applied. (You also use this object to configure functions not related to this IWF.)

The SBC performs the following insertion and removal actions based on the ingress and egress **sip-profile**, **redirection** settings:

- When you set the ingress **sip-profile**, **redirection** to **none** and the egress to:
  - **none**—Perform no action
  - **isup**—Add ISUP content and, if INVITE, generate the IAM ignoring diversion headers
  - **diversion**—Perform no action
- When you set the ingress **sip-profile**, **redirection** set to **isup** and the egress to:
  - **none**—Remove ISUP content
  - **isup**—Convert ISUP version if needed and enforce sip-isup-profile specific attributes

  - **diversion**—Remove ISUP content and, if INVITE, generate diversion header from the IAM
- When you set the ingress **sip-profile**, **redirection** set to **diversion** and the egress to:
  - **none**—Perform no action
  - **isup**—Add ISUP content and, if INVITE, generate IAM from the diversion headers.
  - **diversion**—Perform no action

You further specify your interworking behavior using other controls, including HMR, Session Translation and Native Interworking.

SIP-SIPI IWF using HMR

By default, interworking SIP-SIPI messaging requires that you create HMRs that recognize the message types and build messages appropriate for egress. You create these HMRs for each expected message type, with the exception of IAM messages. The Oracle Communications Session Border Controller (SBC) performs IAM interworking when it recognizes that a **sip-isup-profile** is applied. The *Header Manipulation Rules Resource Guide* includes full instructions on how to build all HMRs. This guide's MIME Support chapter includes a section on *HMR for SIP-ISUP* that directly addresses how to create HMRs for this interworking.

The SBC's HMR functionality can operate on ISDN user party (ISUP) binary bodies. Using the same logic and mechanisms that are applied to SIP header elements, HMR for SIP-ISUP manipulates ISUP parameter fields and ISUP message parts. You can create MIME rules that function in much the same way the SIP header rules do; whereas SIP header rules can change the specific headers of a SIP message, MIME rules can manipulate targeted body parts of a SIP message.

SIP-SIPI IWF Using Session Translation

You can use a feature called Number Translation function to perform simple changes to calling or called numbers for SIP-SIPI IWF calls. Number Translation uses **session-translation** elements to specify these translations. You use **session-translation** elements for SIP-SIPI IWF similarly to number translation to manipulate SIP-SIPI interworking information. Refer to "Number Translation" to for more on how Number Translation works and for additional instruction on **session-translation** configuration.

The **session-translation** element presents the list of SIP and ISUP objects that you can manipulate with session translation:

- **rules-calling**—Manipulates the SIP from header
- **rules-called**—Manipulates the SIP to header
- **rules-asserted-id**—Manipulates the SIP P-Asserted-Id header
- **rules-redirect**—Manipulates the SIP Diversion headers
- **rules-isup-cdpn**—Manipulates the ISUP Called Party Number parameter
- **rules-isup-cgpn**—Manipulates the ISUP Calling Party Number parameter
- **rules-isup-gn**—Manipulates the ISUP Generic Number parameter
- **rules-isup-rdn**—Manipulates the ISUP Redirecting Number parameters
- **rules-isup-ocn**—Manipulates the ISUP Original Called Number parameters
- **rules-history-info**—Manipulates the SIP History-Info header

The SBC only applies session-translation and translation-rule processing to a limited number of out-of-dialog requests, including:

- INVITE
- CANCEL
- REFER
- OPTIONS
- SUBSCRIBE

The SBC does not manipulate any header within in-dialog requests using session-translation or translation-rules.

As with number translation, the configuration steps for this process include:

1. Define **translation-rules**.
2. Apply **translation-rules** to the appropriate **session-translation** parameters.
3. Apply the applicable **session-translation** object on session-agents or realms. Apply these translations based whether you are targeting ingress or egress calls (**in-translationid** / **out-translationid**) and based on whether the call leg is SIP or SIPI.

Refer to "SIP-ISUP IWF Operational Detail" for processing sequences to ensure you are performing **session-translation** based on the expected state of each message object.

ISUP Session Translation and NOA Interworking

The SBC builds the ISUP-based number before translation, referring to the ISUP nature of address. Procedures performed at the SIPI egress include:

- Regardless of ISUP session translation configuration:
  - If the received URI userpart starts with +, the SBC removes it and sets the NOA to International.
- When you have configured any ISUP session translation:
  - If the received URI userpart starts with 0 (zero), the SBC removes it and sets the NOA to National.
  - If the received URI userpart does not start with either + or 0, the SBC does not make any change to the NOA. This case would most likely be a SIPI to SIPI interworking wherein the incoming NOA is neither national or international.

Nature of address	Example number	Number before translation
International	1234	+1234 (starts with +)
National	1234	01234 (starts with zero)
Other	1234	1234 (others)

After the translation, the ISUP parameters are filled back with the right nature of address.

Number after translation	New nature of address	Number in ISUP
+1234 (starts with +)	International	1234
01234 (starts with zero)	National	1234
1234 (others)	Do not change (keep previous one)	1234

Review the following conversion example.

Source ISUP called party number	Translation-rule #1 (convert to NATIONAL) called from rules-isup-cdpn	Result
• Nature of address INTERNATIONAL • Number 26226244555656	• Action replace • Delete-string +262 • Add-string 0	• Nature of address NATIONAL • Number 26244555656

Additional Controls on CDR Population

By default, the SBC does not populate CDRs with call information that ingress **translation-rules** and ISUP precedence values may change. This can present problems in environments where you use **translation-rules** to perform number normalization and the CDR fields are expected to be normalized. Also by default, the SBC populates CDRs prior to SIP-SIPI interworking. You can configure the SBC to include this non-default information in CDRs using the **sip-config** option **late-cdr-population**.

SBC can manipulate the following SIP header through session-translation:

- User part of To Header
- User part of Request-URI
- User part of From Header
- User part of Diversion Headers
- User part of P-Asserted-Id headers
- User part of History-Info headers

When configured, the SBC populates the following attributes with the values derived after ingress session-translation manipulation in CDRs.

- Calling-Station-Id
- Called-Station-Id
- Acme-P-Asserted-ID
- Acme-SIP-Diversion
- Acme-History-Info
- Acme-Primary-Routing-Number

> **Note:**
>
> If you have configured the accounting-config's **generate-start** parameter to INVITE, the SBC does not include ISUP precedence changes in the START CDR. Set **generate-start** to **OK** to include this information.

Set the options parameter by typing **options**, a space, the option name **late-cdr-population** with a plus sign in front of it, and then press Enter.

```
ORACLE(sip-config)# options + late-cdr-population
```

Header Population in CDRs

By default, the SBC does not populate CDRs with all diversion header values. You can set the **multiple-diversion-header-for-accounting** option in the **sip-config** to update the Diversion CDR field with all the Diversion headers present in SIP message. This option can be used in conjunction with the **late-cdr-population** option.

```
ORACLE(sip-config)# options + multiple-diversion-header-for-accounting
```

Header Integrity in CDRs

By default, the SBC may truncate diversion and history-info headers during insertion into CDRs. This is because the default CDR field character length is 246 characters. You can set the **cdr-attr-size-limit** option in the **sip-config** to ensure that no diversion and history-info CDR field are truncated.

When enabled, this option behaves differently for diversion and history-info headers:

- For diversion, the SBC removes the last headers
- For history-info, the SBC removes the first headers

This option can be used in conjunction with the **multiple-diversion-header-for-accounting** option.

```
ORACLE(sip-config)# options + cdr-attr-size-limit
```

If you type an option without the plus sign, you overwrite any previously configured options. Prepend new options with a plus sign, as shown in the previous example, to add new options to an options list.

SIP-SIPI IWF using Native Processing

The Oracle Communications Session Border Controller (SBC) can natively interwork ISUP parameters to and from SIP, as defined by 3GPP TS 129.163 *Interworking between IP Multimedia (IM) Core Network (CN) Subsystem and Circuit Switched (CS) Networks*, *Control Plane Interworking*. Support for the capabilities of SIP and SDP that are interworked with BICC or ISUP are defined in 3GPP TS 24.229. The information the SBC interworks is a subset of all possible interworking, but results in successful sessions for the vast majority of interworked calls. Configure deployments that need additional interworking with HMR.

You configure the SBC to natively interwork specific information in specific messages by setting the **sipi-behavior** option within the **sip-config** to **iam-anm**. This configuration also allows the SBC to achieve session stateful awareness for the applicable sessions.

The SBC supports native interworking for the following ISUP messages:

- Initial Address Message (IAM)—Interworks with SIP INVITE messages

> **Note:**
>
> The SBC performs IAM insertion regardless of the **sipi-behavior** setting. IAM removal, as well as all other ISUP message interworking requires the **iam-anm** setting.

- Address Complete Message (ACM)—Interworks with SIP 180 and 183 messages
- Call Progress Message (CPG)—Interworks with SIP 180 and 183 messages, as well as Re-INVITE and UPDATE messages, to support Hold/Resume flows
- Answer Message (ANM)—Interworks with SIP 200 OK messages
- Connect (CON), which is an alternate to ANM when no ACM is received—Interworks with the 200 OK of an INVITE
- Release (REL)—Interworks to SIP BYE and, if applicable, error responses
- Release Complete (RLC)—Interworks to the 200 OK of the BYE

IAM Interworking Support

When configured for IWF, the SBC supports SIP-SIPI IWF in both directions. For SIPI to SIP interworking, the SBC constructs the SIP headers based on the SIPI information, then removes the entire IAM block. For the SIP to SIPI direction, the SBC interworks IAM parameters as described here and inserts the block.

Assuming you have configured a **sip-isup-profile** and a **sip-profile** on the applicable interfaces, the SBC performs this interworking regardless of the **sipi-behavior** configuration. It is recommended that you do not configure IAM interworking using HMR or session translation.

The SBC supports the insertion of the IAM message based on the configured **redirection** parameter in the applicable **sip-profile** and the **version** field in the applicable **sip-isup-profile**. The SBC inserts the body after any application/sdp body parts, if that body is already in the **INVITE**.

When configured for native IWF, the SBC interworks the following IAM parameters:

- Called Party Number
- Nature of connection Indicator
- Forward Call Indicators
- Calling Party Category
- Transmission Medium Requirement
- Calling Party Number Parameter
- Generic Number

Called Party Number

For **Called Party Number**, mapping includes:

- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
  - **Special Number**, if there is a phone-context parameter in the request-uri user part, and that number does not start with a **+** or a **0** (encoded to 1110011).
- Internal Network Number Indicator, with a sole value of 1, indicates routing to an internal network number is not allowed.
- Numbering Plan, which is always **ISDN**.

Nature of connection Indicator

For Nature of connection Indicator,

- **No Satellite Circuit**—If the SIP messaging includes the Satellite Indicator
- **No continuity Check**—If the SIP messaging includes the Continuity Check indication
- **Outgoing Echo Device Included**—If the SIP messaging includes the Echo control device indicator

Forward Call Indicators

For Forward Call Indicators, the SBC inserts the following values into the IAM, based on the SIP indicators listed:

- **No end-to-end method available**—If the SIP messaging includes the End-to-end method indicator
- **Interworking encountered** —If the SIP messaging includes the Interworking indicator
- **No end-to-end information available**—If the SIP messaging includes the End-to-end information indicator
- **ISDN user part/BICC not used all the way**—If the SIP messaging includes the ISDN user part/BICC indicator
- **ISDN user part/BICC not required all the way**—If the SIP messaging includes the ISDN user part/BICC preference indicator
- **Non-ISDN Access**—If the SIP messaging includes the ISDN access indicator
- **No Indication**—If the SIP messaging includes the SCCP method indicator
- **Number not translated**—If the SIP messaging includes the Ported number translation indicator
- **No QoR routing attempt in progress**—If the SIP messaging includes the query on release attempt indicator

Calling Party Category

The SBC always inserts the value **Ordinary calling subscriber** for **Calling Party Category**, encoded as 000010101, regardless of the SIP signaling.

Transmission Medium Requirement

For Transmission Medium Requirement (TMR), the SBC inserts the TMR, coding it based on the content of the incoming SDP:

- **64 kbit/s unrestricted**—If the **Clearmode** codec is present in incoming SDP (encoded to 00000010).
- **3.1 kHz audio—**For all other cases (encoded to 00000011).

Calling Party Number

The IAM **Calling Party Number** equates to a combination of the ISUP **Address of Signal** and Address Presentation Restricted Indicator (**APRI**). The SBC maps this data based on the SIP **PAI**, **FROM URI**, and **Privacy Value**. as shown in the following table.

P-Asserted-Identity	From URI	Privacy Value	Address Of Signal	APRI
Not Present	Non E.164	Any	Omit	Omit
Not Present	Including E.164	Absent or with value “none”	Empty	Unavailable
Not Present	Including E.164	Value different than “none”	Empty	Unavailable
Present	Any	Absent or with value “none”	P-Asserted-Identity userpart	Presentation allowed
Present	Any	Value different than “none”	P-Asserted-Identity userpart	Presentation restricted

The SIP **P-Asserted-Identity** and **Privacy** headers may or may not be present in the INVITE. In addition the SIP **From** header is always be present, but it may contain an anonymous URI, often formatted as **anonymous@anonymous.invalid**.

In addition, the SBC always fills in other parameters as follows:

- Nature of address:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- Numbering Plan—Always **ISDN**.
- Screening Info—Always **Network Provided**.
- Number Incomplete Indicator— Always set as **Complete**.

Generic Number

The **Generic Number** parameter is mapped the similarly to the **Calling Party Number**. The table below shows this mapping.

P-Asserted-Identity	From URI	Privacy Value	Address Of Signal	APRI
Not Present	Including E.164	Any	Omit	Omit
Any	Non E.164	Any	Omit	Omit
Present	Including E.164	Absent or with value “none”	From userpart	Presentation allowed
Present	Including E.164	Value different than “none”	From userpart	Presentation restricted

The SIP **P-Asserted-Identity** and **Privacy** headers may or may not be present in the INVITE. In addition the SIP **From** header is always be present, but it may contain an anonymous URI, often formatted as **anonymous@anonymous.invalid**.

In addition, the SBC always maps the Generic Number, Number Qualifier Indicators to Additional Calling Party number parameters as follows:

- Nature of address:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- Numbering Plan—Always **ISDN**.

- Screening Info—Always user provided and not verified.
- Number Incomplete Indicator— Always set as **Complete**.

Number Portability Interworking Support for IAM

When the optional Number Portability Routing Number (NPRN) is present and supported, the SBC uses these procedures to code the ISUP Called Party Number.

For backward compatibility, and to handle deployments where this behavior is not expected (ITU- T1912.5 does not include this requirement), you set the SBC to use this behavior by configuring the **portability-method** parameter to **concatenate** within the **sip-isup-profile**. This attribute allows the SBC to map the different behaviors related to number portability in TS29.163.

In addition, the **sip-isup-profile** element includes the **country-code** parameter. When you have configured the **portability-method** parameter to **concatenate** and the SBC receives messages that include NPRN in the request URI of an incoming INVITE, the SBC formats the ISUP called number based on the text you configure in the **called-party number** parameter. The **called-party number** parameter accepts any string, but is typically configured with a country code. The format (coding) rules are presented below.

Called Party Number

If an NPRN is present as **rn** param in the **request-uri** of the incoming **INVITE**, and an NP Database Dip Indicator (NPDI) parameter is present, the SBC codes the Called Party Number as follows:

- Address Signal—The SBC inserts the following values and format into the IAM, based on the conditions described:
  - If the SIP called number starts with the same country-code as is in the egress **sip-isup-profile**::country-code:
    The format presented is **+CC** + **NPRN** + **Called party number** (NOA = International)
  - If the SIP called number starts with a different country-code as is in the egress **sip-isup-profile**::country-code, behave the same as when the portability method is configured as **none** (transparent), and:
    The format presented is **+CC2** + **Called party number** (NOA = International)
  - If the SIP called number does not start with **+**:
    The format presented is **NPRN** + **Called party number** (NOA = National)
- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
  - **Special Number**, if there is a phone-context parameter in the request-uri user part, and that number does not start with a **+** or a **0** (encoded to 1110011).
- Internal Network Number Indicator, with a sole value of 1, indicates routing to an internal network number is not allowed.
- Numbering Plan, which is always **ISDN**.

Examples of ISUP called party number results, assuming you set the **sip-isup-profile**, **country-code** to +33, include:

- If the Request-Uri is sip:+33454556677 and the **rn** is 10432;npdi@company.com
  Result: 3310432454556677 (NOA=International)

- If the Request-Uri is sip:+44454556677 and the **rn** is 10432;npdi@company.com
  Result: 44454556677 (NOA=International)
- If the Request-Uri is sip:0454556677 and the **rn** is 10432;npdi@company.com
  Result: 10432454556677 (NOA=National)
- If the Request-Uri is sip:0454556677 and the **rn** is 10432@company.com
  Result: 454556677 (NOA=National)
- If the Request-Uri is sip:+33454556677 and the **rn** is npdi@company.com
  Result: 33454556677 (NOA=International)

Number Portability Forward Information

The SBC codes this parameter as follows:

- If the NPDI is present, the SBC behaves as follows, in conjunction with the following conditions:
  - NPRN present—The SBC performs a number portability query for the called number, and inserts the ported called subscriber.
  - NPRN absent—The SBC performs a number portability query for the called number, and inserts the non-ported called subscriber.
- If the NPDI is absent—The SBC does not perform a number portability query.

BYE and REL Interworking Support

The SBC inserts an **REL** as an application/isup “content-type” with the header parameters based on the applicable **sip-isup-profile**, and formats the message according to the ISUP version configured in the **sip-isup-profile**.

If a Reason header, described in IETF RFC 6432, is included in the **BYE** request, the SBC maps the Cause Value of the Reason header to the ISUP Cause Value field in the **REL** message. If not included , the SBC inserts the following values:

- Location—Network beyond interworking point
- Cause Value—16 (Normal Call Clearing)

For BYEs received from the SIP-I side, the SBC inserts a Reason Header into the SIP body. This also requires that you have enabled the **add-reason-header** within the **sip-config**.

200OK (of BYE) and RLC Interworking Support

The SBC inserts an **RLC** as an application/isup content-type, with the header parameters based on the applicable **sip-isup-profile**. It does not include any ISUP parameters in this message. The SBC also formats the message according to the ISUP version configured in the **sip-isup-profile**.

Interworking 183 Message Content

The SBC supports interworking of 183 message content in both directions, creating the 183 on the SIP side and creating the ACM or CPG messages on the ISUP side. Via configuration, you can disable interworking of 183 messages or set the SIP to SIP-I interworking to be based on the presence of and the value of any PEM header present in a 183 Session Progress message.

Some standards do not require you to map 183 messages into ACM/CPG messages. When disabled, the **iwf-for-183** parameter in the applicable **sip-isup-profile** supports these environments. The default value is enabled. This parameter operates for native interworking, requiring that you set the **sipi-behavior** option in the **sip-config** to **iam-anm**.

Enabling vs. Disabling 183 Interworking

When enabled, the SBC:

- Inserts ACM to first 183 or 180
- Inserts a CPG into any subsequent 18x
- Inserts the REL into the SIP BYE
- Inserts the RLC into the 200 OK of the BYE, and
- Inserts the ANM into the 200 OK

When disabled, the SBC:

- Does not insert any ISUP body into 183s
- Inserts the ACM into the 180 instead of any 183
- Inserts a CPG into all further 180s, and
- Inserts the ANM into the 200 OK

If the session setup sequence uses only 183s, the SBC inserts a CON into 200 OK instead of an ANM.

Controlling 183 Messages using PEM

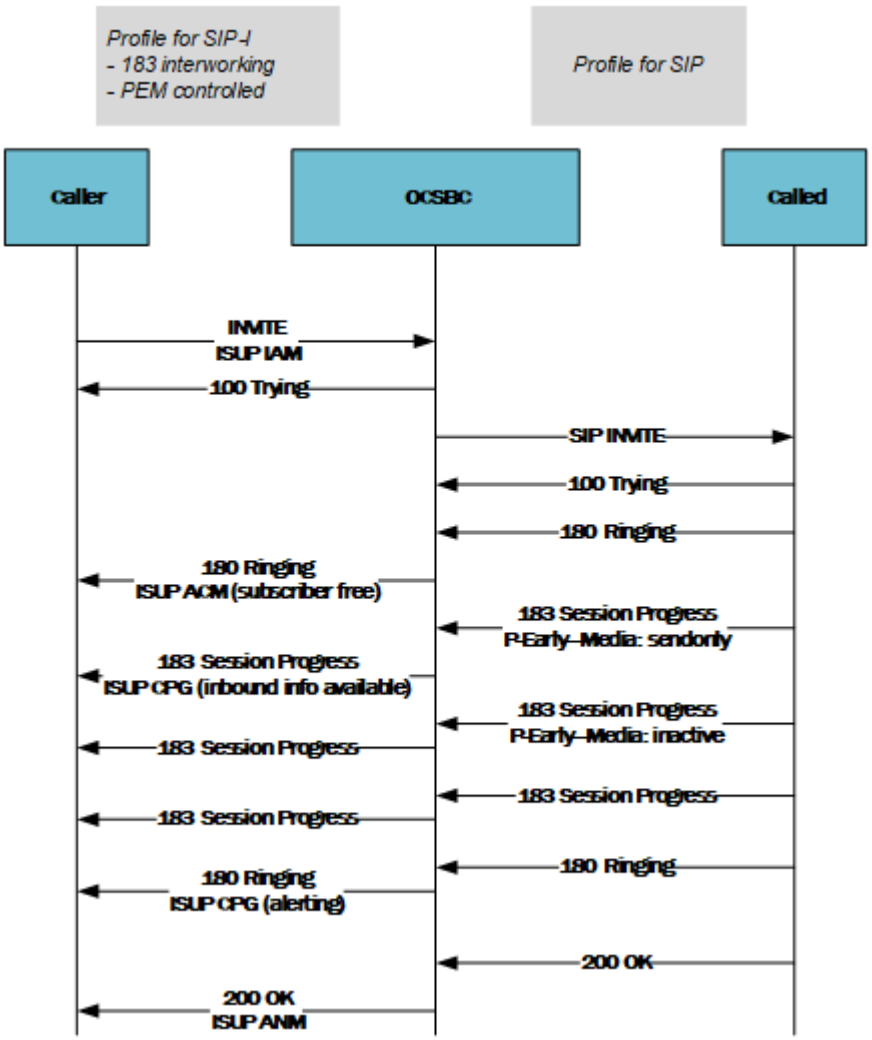
The SBC supports configuration that causes it to issue 183 Session Progress messages with or without an ISUP ACM toward the SIP-I side of an interworked call.

When the value of **iwf-for-183** parameter in **sip-isup-profile** configuration is set to **pem-controlled**, the SBC interworks 183 Session Progress responses received from IMS node as follows:

- If the received 183 Session Progress message contains P-Early-Media (PEM) header with value set to sendonly or sendrecv, the SBC behaves as if **iwf-for-183** is **enabled**.
- If the received 183 Session Progress message does not contain a PEM, the SBC behavior as if the **iwf-for-183** parameter is **disabled**.
- If the received 183 Session Progress message contains a P-Early-Media header with a value other than sendonly or sendrecv, the SBC behavior is the same as if the **iwf-for-183** parameter is **disabled**.

The call flow depicts the SBC configured to **pem-controlled**, receiving three 183 Session Progress messages, and forwarding messaging to the SIP-I side based on the contents of each 183:

1. Contains a PEM header with a value of sendonly, resulting in a 183 Session progress message that includes an ISUP CPG with inbound info available.
2. Contains a PEM header with a value that of inactive, resulting in a 183 Session progress message with no CPG.
3. Does not contain a PEM header, resulting in a 183 Session progress message with no CPG.



Interworking ACM/CPG Parameters for 180 and 183 Messages

When configured for native interworking, the SBC provides a fixed set of responses when presented with SIP to SIP-I and SIP-I to SIP-I calls that include ISUP progress messages, including user-configured ACM and CPG parameters. (The SBC only interworks an inbound-annoucement into a PEM header if it is present in the **extract-isup-params** list.) The SBC inserts interworked information into 180 and 183 messages.

For both SIP to SIP-I and SIP-I to SIP-I calls, the SBC checks for the presence of an in-band announcement in ISUP progress messages. It also checks to see if the `extract-isup-params` configuration contains the inband-announcement value. If it finds both these to be true, it interworks PEM headers while generating SIP 180 and 183 messages as follows:

- ACM message—The SBC confirms the presence of an in-band announcement if it finds an optional BCI parameter with the In-band information indicator bit set to 1.
- CPG message—The SBC confirms the presence of an in-band announcement if it finds an Event Information parameter with its Event indicator set to "In-band information" or "an appropriate pattern is now available" (0000011).

If an in-band announcement is present in the ACM/CPG message encapsulated in the received SIP 180 and 183 messages, the SBC may modify it as follows:

- If there is no PEM header, the SBC adds one with a value of sendonly.

- If there is a PEM header that does not have a value of sendonly, the SBC changes the value to sendonly.

Interworking Call Flows with History-Info Information

For interwork in which there are devices that support SIPI/SIP-T, the SBC supports SIP History-Info interworking. This feature enables such devices to function properly in instances that require SIP-T/SIP-I style ISUP message encapsulation in ISUP requests, and to receive any call forwarding information in the message according to ISUP standards.

For interwork in which there are device that support SIPI/SIP-T, the OCSBC support History-Info interworking

In the scenarios of call forwarding, when incoming INVITE, 180 or 200 OK messages contain "History-Info" header, the SBC encodes IAM, ACM (or CPG) and ANM (or CON) parameters described in the sections below.

Important configuration reminders with respect to the applicable sip-profiles include:

- If the ingress is set to ISUP and the EGRESS is set to SIP, the SBC removes ISUP content while forwarding request and add ISUP content using history-info headers while sending back response
- If the ingress is set to SIP and the EGRESS is set to ISUP, the SBC adds ISUP content using history-info headers while forwarding request and remove ISUP content while sending back response

Important operational behaviors include:

- The SBC only interworks History-Info headers in SIP or SIPS format, per RFC 4458. An example of this format, using SIPS, is below.

```
History-Info: <sips:UserA@ims.example.com;user=phone;cause=302?
Privacy=history>;index=1.1;mp=1.1
```

- If a History-Info header contains comma separated values, the SBC considers the first value as top most and the last one is the bottom most.

Interworking IAM with Redirection Parameters

When in receipt of History-Info information within a SIP to SIP-I INVITE call, the SBC interworking processes the following redirection parameter groups:

- Redirecting Number
- Redirection Information
- Original Called Number

Redirecting Number

Redirecting Number subfield interworking includes:

- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- Numbering Plan Indicator—ISDN (001)

- APRI—This interworking is dependent on the value of either the SIP privacy header or the priv-value presented in the History-info:
  - If the value is either 'History'. 'Session' or 'Header', map to **presentation restricted** (01).
  - If both values are absent or have values other than those above, map to **presentation allowed** (00).
- Address Signal—The SBC inserts the URI of the History-Info header whose hi-index matches the mp-parameter value of the last History-info header containing the "cause" URI parameter and the "mp" parameter.
  Furthermore, the SBC uses the hi-entry just before the last hi-entry with a cause parameter if:
  - The "mp" header field parameter is missing in the last hi-entry containing a "cause" URI parameter.
  - There is no HI entry with its hi-index matching the "mp" parameter of the last hi-entry and a "cause" parameter.

Redirection Information

Redirection Information subfield interworking includes:

- Redirecting Indicator—The SBC interworks this field based on context and value:
  - If the Privacy header or priv-value component in the History-Info header whose hi-index matches the "mp" parameter value of the last History-info header containing the "cause" URI parameter and the "mp" parameter, the SBC uses that value. Furthermore, the SBC uses the hi-entry immediately before the last hi-entry with a cause parameter if no HI entry with an hi-index matching the "mp" parameter of the last hi-entry with a "cause" parameter is present.
  - If the SBC identifies this value as 'History', 'Session' or 'Header', it interworks the value to **Call diverted, all redirection info presentation restricted** (100).
  - If both the Privacy Header and the priv-value components are absent or both present with value other than one mentioned above, the SBC interworks the value to **Call diverted** (011).
- Original Redirection Reason—Map to the value **Unknown/Not available** (0000)
- Redirecting Reason—The SBC maps this value based on the last HI header entry containing a cause parameter:
  - Cause Parameter 404—Map to the value **Unknown** (0000)
  - Cause Parameter 302—Maps to the value **Deflection immediate response** (0101)
  - Cause Parameter 486—Maps to the value **User Busy** (0001)
  - Cause Parameter 408—Maps to the value **No Reply** (0010)
  - Cause Parameter 480—Maps to the value **Deflection immediate response** (0101)
  - Cause Parameter 503—Maps to the value **Mobile Subscriber not reachable** (0110)
  - Cause Parameter 487—Map to the value **Deflection during alerting** (0100)
- Redirection Counter—The SBC inserts the sum of all History-Info headers in the SIP message that contain the Redirecting Reason cause parameters. This value never exceeds 5.

Original Called Number

Applicable Original Called Number subfields include:

- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- Numbering Plan Indicator—The SBC always inserts the ISDN (Telephony) numbering plan; (Recommendation E.164)
- APRI:
  - If the SIP **Privacy** value is absent or set to a value not listed below, map the **APRI** to **presentation allowed**.
  - If the SIP **Privacy** value is set to **History**, **Session**, or **Header** map to **presentation restricted**.

  If there are multiple history-info headers, the OCSBC selects the one with a hi-index that matches the "mp" parameter value of the first header that contains a "cause" URI parameter and an "mp" parameter. If the "mp" parameter is missing from the first history-info header that contains a "cause" URI parameter, the OCSBC uses the history-info header entry that precedes it.

  Furthermore, per the standard, the priv-value component in the history-info header can only have the values "history" or "none".
- Address Signal—The SBC inserts the URI of the first header with a hi-index that matches the "mp" parameter value of the first header that contains a "cause" URI parameter and an "mp" parameter.
  If the "mp" header field parameter is missing in the first hi-entry containing a "cause" URI parameter, the OCSBC uses the hi-entry just before it.

Interworking ACM or CPG with History-Info Headers

During a SIPI to SIP call, if the 180 RINGING response from SIP side contains a history-info header and the redirection mode on the egress side is set to "history-info", the SBC populates the following parameters from history-info header into the ACM/CPG message:

- Redirection Number
- Redirection Number Restriction
- Call Diversion Information
- Generic Notification Indicator

Redirection Number

Redirection Number subfield interworking includes:

- Nature of address indicator—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).

- Internal Network Number Indicator—The SBC always inserts the value **routing to internal network number not allowed** (1).
- Numbering Plan—The SBC always inserts the value **ISDN** (001.)
- Address Signal—The SBC inserts the URI of the last History-Info header containing a "cause" URI parameter.

Redirection Number Restriction

Redirection Number Restriction subfield interworking includes:

- APRI—This interworking is dependent on the value of either the SIP privacy header or the priv-value presented in the last History-info header with a cause parameter:
  - In the value is either 'History'. 'Session' or 'Header', map to **presentation restricted** (01).
  - If both values are absent or have values other than those above, map to **presentation allowed** (00).

Per standard, the priv-value component in the history-info header can only have values "history" or "none".

Call Diversion Information

Call Diversion Information subfield interworking includes:

- Notification subscription options—This interworking is dependent on the value of either the SIP privacy header or the priv-value presented in the History-info:
  - If there is a value in the Privacy header or priv-value component in the History-Info header, map to that value.
  - If the Privacy header received has the value "History", "Session" or "Header" or the SBC receives a priv-value of "History" in the headers component of both the diverted-to URI and the diverting URI(s), map to **presentation not allowed** (001).
  - If only the History-Info header with a priv-value of **history**, map to **presentation allowed without redirection number** (011).
  - In all other cases, map to **presentation allowed with redirection number** (010).
- Redirecting Reason—The SBC maps this value based on the cause parameter of the last HI entry that contains a cause parameter.
  - Cause Parameter 404—Maps to the value **Unknown** (0000)
  - Cause Parameter 302—Maps to the value **Unconditional** (0011)
  - Cause Parameter 486—Maps to the value **User Busy** (0001)
  - Cause Parameter 408—Maps to the value **No Reply** (0010)
  - Cause Parameter 480—Maps to the value **Deflection immediate response** (0101)
  - Cause Parameter 503—Maps to the value **Mobile Subscriber not reachable** (0110)
  - Cause Parameter 487—Maps to the value **Deflection during alerting** (0100)

Additional context information includes:

- The diverted-to URI corresponds to the hi-targeted-to-uri of the last hi-entry containing a "cause" URI parameter.
- The diverting URI corresponds to the hi-targeted-to-uri of the hi-entry containing a hi-index value that match the "mp" header field parameter value of the diverted-to URI. If the

diverted-to URI does not contain the "mp" header field parameter, the diverting URI corresponds to the hi-targeted-to-uri of the hi-entry before the last hi-entry containing a "cause" URI parameter.

- If there is no diverting URI (for example, an HI entry with hi-index matching "mp" param of last hi-entry with "cause" param is present) the hi-entry to use is the entry just before the last hi-entry with a cause parameter.
- If there is only a diverted-to URI and no other URI, the SBC only refer to the diverted-to URI while populating the "Notification subscription options" parameter.

Generic Notification Indicator

In addition, the SBC sets the Generic Notification Indicator in the ACM or CPG to **Call is Diverting** (1111011).

Interworking ANM or CON with History-Info Headers

This interworking applies to SIP-I to SIP calls. If the 200OK message from the SIP side contains one or more history-info headers and you have set the redirection mode on the egress side to **history-info**, the SBC populates these parameters into the ANM/CON message.

When configured for native IWF and in receipt of History-Info information, the SBC interworks the following parameter groups:

- Redirection Number
- Redirection Number Restriction

Redirection Number

The SBC only adds this parameter for ANM messages. Redirection Number subfield interworking includes:

- Nature of address indicator—The SBC inserts the following values, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- Internal Network Number Indicator—The SBC always inserts the value **routing to internal network number not allowed** (1).
- Numbering Plan Indicator—The SBC always inserts the value **ISDN** (001).
- Address Signal—The SBC inserts URI of the last History-info header with a cause parameter.

Redirection Number Restriction

The APRI is the only parameter interworked for this category:

- If the SIP **Privacy** or the priv-value component in the History-info entry containing a cause URI parameter is set to **History**, **Session**, or **Header** map the **APRI** to **presentation restricted** (01).
- If both the Privacy header or priv-value component in the last History-info header containing a "cause" URI parameter are absent or have any other value, map to **presentation allowed** (00).

Per the standard, the priv-value component in the history-info header can only have a value of either "history" or "none".

Interworking Call Flows with Diversion Information

For networks in which there are devices that do not support SIP-T or SIP-I (and support native SIP alone), the (SBC) supports SIP Diversion interworking. This feature enables such devices to function properly in instances that require SIP-T/SIP-I style ISUP message encapsulation in ISUP requests, and to receive any call forwarding information in the message according to ISUP standards.

The SBC interworks a SIP INVITE request to SIP-T one by inserting an ISUP IAM body based on the INVITE; this includes redirection information based on the Diversion header. This feature can also perform the reverse translation. That is, it can interwork a SIP INVITE that does have the ISUP IAM body to a non-ISUP INVITE. In this case, the SBC generates the necessary Diversion headers based on the IAM's Redirection information.

Criteria that generates this interworking includes:

- You have set the **sipi-behavior** option to **iam-anm** (Native interworking).
- There is a **sip-profile** applied to the call that has the **redirection** parameter set to **isup**.
- There is an accompanying **sip-isup-profile** applied to the call that specifies an ISUP version.
- SIP or ISUP signaling includes call forwarding information.

The SBC also performs additional processing for **IAM**, **ACM**, **CPG**, **ANM** and **CON** ISUP messages, interworking important information from SIP messages to ISUP. The SBC does not perform this interworking in the reverse direction, from SIP-I to SIP.

Interworking IAM with Diversion Information

When configured properly and in receipt of diversion information, the SBC interworks the following parameter groups in addition to those documented previously:

- Redirection Number
- Redirecting Information
- Original Called Number

For any overlapping interworking, the SBC uses the values in this diversion information list.

Redirection Number

Parameters interworked for this category include:

- Address Signal—The SBC inserts URI of the selected Diversion header. If there are multiple headers, it uses the first (top).
- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- **APRI**:
  - If the SIP **Privacy** value is absent or set to **none**, map the **APRI** to **presentation allowed**.

  - In all other cases, map to **presentation restricted**.

Redirecting Information

Parameters interworked for this category include:

- Redirecting Indicator—The SBC uses the following mapping:
  - Privacy header absent or set to **none**—The SBC inserts the value **Call diverted**.
  - Privacy header set to any other value—The SBC inserts the value **Call diverted, all redirection info presentation restricted**.
- Original Redirection Reason—The SBC always maps this value to **Unknown**.
- Redirection Counter—The SBC inserts the sum of the counters of all Diversion headers in the SIP message.

Original Called Number

For **Original Called Number**, mapping includes:

- Address Signal—The SBC inserts the URI of the selected History-Info or Diversion header. If there are multiple headers, it uses the last (bottom).
- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
  - Numbering Plan Indicator—The SBC always inserts the ISDN (Telephony) numbering plan; (Recommendation E.164)
  - **APRI**:
    * If the SIP **Privacy** value is absent or set to **none**, map the **APRI** to **presentation allowed**.
    * In all other cases, map to **presentation restricted**.

Interworking ACM or CPG with Diversion Information

When configured for native IWF and in receipt of diversion information, the SBC interworks the following parameter groups in addition to those documented previously:

- Redirection Number
- Redirection Number Restriction
- Generic Notification Indicator

For any overlapping interworking, the SBC uses the values in this diversion information list.

Redirection Number

Parameters interworked for this category include:

- Address Signal—The SBC inserts URI of the selected Diversion header. If there are multiple headers, it uses the first (top).
- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).

  - **International**, if there is a **+** in the number (encoded to 0000100).
- Internal Network Number Indicator—The SBC always inserts the value **1 routing to internal network number not allowed**.
- Numbering Plan—The SBC always inserts the value **ISDN**.

Redirection Number Restriction

Parameters interworked for this category include:

- APRI—The SBC maps the **Privacy** SIP header to the APRI.
  - If the SIP **Privacy** value is absent or set to **none**, map the **APRI** to **presentation allowed**.
  - In all other cases, map to **presentation restricted**.

Generic Notification Indicator

In addition, the SBC sets the Generic Notification Indicator in the ACM or CPG to **Call is Diverting**.

Interworking ANM or CON with Diversion Information

When configured for native IWF and in receipt of diversion information, the SBC interworks the following parameter groups in addition to those documented previously:

- Redirection Number
- Redirection Number Restriction

For any overlapping interworking, the SBC uses the values in this diversion information list.

Redirection Number

The SBC only interworks this category if it receives a Diversion header with Reason. Parameters interworked for this category include:

- Address Signal—The SBC inserts URI of the selected Diversion header. If there are multiple headers, it uses the first (top).
- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- Internal Network Number Indicator—The SBC always inserts the value **1 routing to internal network number not allowed**.
- Numbering Plan Indicator—The SBC always inserts the value **ISDN**.

Redirection Number Restriction

The APRI is the only parameter interworked for this category:

- APRI—The SBC maps the **Privacy** SIP header to the APRI.
  - If the SIP **Privacy** value is absent or set to **none**, map the **APRI** to **presentation allowed**.
  - In all other cases, map to **presentation restricted**.

Interworking User-Configured IAM Parameters into SIP INVITE Headers

You can configure the SBC to extract a specific set of ISUP parameters from the IAM message during SIP-I to SIP call processing, and interwork them into SIP headers while generating the SIP INVITE message. This list of IAM parameters can be configured in **extract-isup-params** parameter of **sip-isup-profile**.

By default, the SBC does not interwork any IAM parameters. You configure a list of parameters you want to interwork.

The parameters you can extract and interwork include:

- calling-party-number
- generic-number
- location-number
- user-to-user

You refine the list of parameters by setting the **extract-isup-params** parameter to add additional parameters, and by setting the **remove-isup-params** parameter to remove a single parameter from the list.

Keep in mind that the SBC is receiving SIP-I or SIP-T messages that contain encapsulated ISUP information. The SBC is, therefore receiving an INVITE and identifying ISUP parameters within the encapsulated information in each message. The specific operations performed by the SBC for this extraction/interworking are presented below. All operations assume you have configured extraction for the applicable parameter.

Extraction detail is compliant with T-REC-Q.1912.5.

calling-party-number

If the SBC finds a calling-party-number parameter, it interworks that information into a P-Asserted-Id SIP header, as follows:

- If no P-Asserted-Id header is present in received SIP INVITE, the SBC creates a new P-Asserted-Id with the user part extracted from the calling-party-number and domain name from the FROM URI. The SBC uses the same URI format (SIP, SIPS, TEL and so forth) as is used in the From URI in the SIP INVITE.
- If there is P-Asserted-Id header, the SBC replaces it with the calling-party-number parameter. If there are multiple P-Asserted-Ids, the SBC removes all instances except the first.
- If the "nature of address indicator" (NOA) in the calling-party-number indicates "international number" (0000100), the SBC adds a plus sign (+) as a prefix in the URI while generating/modifying the P-Asserted-Id.
- Interworks any APRI by modifying the Privacy header as follows:
  - If APRI is "Presentation restricted", adds the priv-value "id" to the Privacy header, if not already present.
  - If APRI is "Presentation Allowed" and the priv-value in the Privacy header is already "id" or "header", remove it. If the priv-value is "user', do not remove it.

generic-number

If the SBC finds the generic-number parameter with the number qualifier indicator set to "additional calling party number", (00000110), it interworks that information into the From URI

by replacing the user part of the "From" header URI with the generic-number. The SBC also prefixes the From header with a plus sign (+) if the nature of address (NOA) is set to international.

If there are multiple generic-numbers, the SBC selects the first one with its "number qualifier indicator" set to "additional calling party number".

The SBC also interworks any APRI by modifying the Privacy header as follows:

- If APRI is "Presentation restricted", adds the priv-value "user" to the Privacy header, if not already present.
- If APRI is "Presentation Allowed" and the priv-value in the Privacy header is already "user", remove it.

location-number

If the SBC finds a location-number parameter, it interworks it into a P-Access-Network-Information header by removing any exising P-Access-Network-Information and inserting a new one, as follows:

1. Set Access-type to "GSTN".
2. Set Operator-specific-GI to the text string between quotes with the sequence of digits found in octet 3 to N (except the filler) starting with the first digit.
3. Add "network-provided" if the screening indicator in location number is set to "network provided" (11).

user-to-user

If the IAM includes the user-to-user information parameter in the encapsulated IAM message, the SBC interworks this information into a User-to-User SIP header in SIP INVITE as follows:

1. Extracts the User-To-User-Information parameter (code 32) into the User-To-User SIP header, starting from the protocol discriminator.
2. Sets the encoding field to "hex" (encoding=hex)
3. Sets the content field to "isdn-uui" (content=isdn-uui)
4. Sets the purpose field to "isdn-uui" (purpose=isdn-uui)

Furthermore:

- The letters used for the hex digits are always capital letter.
- The SBC removes any existing user-to-user header from the SIP INVITE before adding a new one.

Interworking IAM Information into SIP INVITE History-info Headers

The SBC interworks the Redirecting Number, Called Party Number and Original Called Number from the ISUP IAM message into history-info headers. While interworking these parameters into a History-Info header, the SBC creates a SIP URI containing the "cause" URI parameter, an "hi-index" and an "mp" header field parameter.

Additional operational detail on this interworking includes the SBC:

- Setting the value of “Unknown User Identity” to “sip:unknown@unknown.invalid”, as defined in 3GPP TS 23.003.
- Limiting the redirection counter value from 1 to 5. The SBC does not perform interworking if this value is greater than 5, per specification.

- Using the domain name of the “From” header while generating the URI of the history-info header. If the “From” does not have a domain, such as when there is no from header or the header is in TEL URI format, the SBC uses “unknown.invalid” as the domain.
- Removing the identified Called Party Number prior to interworking if the last digit is an ‘F’, which indicates ST (Stop Sending), and if the identified number is not that actual Called Party Number.

Furthremore, the SBC follows these rules to populate cause URI parameter values:

- For placeholder history-info entries, the SBC uses the value 404.
- For history-info entries created from called party number (using the last HI entry), The SBC populates the cause parameter based on the redirecting reason, shown in the table below.

Redirecting Reason in Redirection Information	Cause
unknown/not available (0000)	404
unconditional (0011)	302
User Busy (0001)	486
No reply (0010)	408
Deflection during alerting (0100)	487
Deflection immediate response (0101)	480
Mobile subscriber not reachable (0110)	503

- For history-info entries created from the redirecting number (the penultimate History-info entry), The SBC populates the cause parameter based on the original redirection reason as mentioned in table below, referenced from ITU-T Q.1912.5.

Original Redirection Reason in Redirection Information	Cause
unknown/not available (0000)	404
unconditional (0011)	302
User Busy (0001)	486
No reply (0010)	408

Additional ISUP IAM Generation Functions

Additional IAM generation functions include interworking Clearmode calls, user-to-user headers, and PANI headers. These functions are specified by TS 29.163.

Clearmode Calls

While interworking a SIP INVITE message containing request for Clearmode call setup, the SBC adds the User-Service-Information parameter to the IAM message it generates. The applicable **User-Service-Information** subfield parameter values include:

- Coding Standard— ITU-T standardized coding (00)
- Information transfer capability—Unrestricted digital information (01000)
- Transfer mode—Circuit mode (00)
- Information transfer rate— 64 kbits/s (10000)

User to User Header Interworking

The SBC interworks user-to-user headers if the received SIP INVITE contains a user-to-user header field with the following:

- A **purpose** header field parameter set to **isdn-uui**, (or without a **purpose** parameter)
- An **encoding** header field parameter set to **hex** (or without an **encoding** parameter)
- A "content" header field parameter set to "isdn-uui" (or without a "content" parameter)

If all of the above are true, the SBC maps the content of the **uui-data** field to the **protocol discriminator** and **user information** parameters of the **user-to-user** information element as it generates the IAM message.

The applicable **user-to-user** Information subfield parameter values include:

- user-to-user information element identifier—0100000
- protocol discriminator—Convert the received User-to-User header to ASCII and add the first two nibbles.
- user information—Remove the first two nibbles (protocol discriminator) from the received user-to-user header and convert all the digits from hex to ASCII.

PANI Header Interworking

The SBC adds the location-number parameter to the IAM message if the SIP INVITE contains a P-Access-Network-Information (PANI) header that uses the format shown in the example below.

```
P-Access-Network-Info:GSTN;operator-specific-GI="5522300";network-provided
```

The SBC follows these rules while interworking the PANI to location number:

- Only interwork PANI headers that have an **operator-specific-GI** parameter.
- Only interwork PANI headers with an **operator-specific-GI** parameter that contain a sequence of digits.
- If multiple instances of PANI are present, only interwork the instance that has the access network specific component that contains a **network-provided** parameter.
- If there are multiple instances that contain a **network-provided** parameter, use the first.
- If none of the PANIs are **network-provided**, interwork the first PANI that is a GSTN type.

The SBC interworks **location number** subfields as follows:

- Nature of address indicator—**National (significant) number (national use)** (0000011)
- Internal Network Number indicator—**Routing to internal number not allowed** (1)
- Numbering Plan indicator—**ISDN** (001)
- APRI:
  - If the Privacy header is present with a value of **header**, use **Presentation Restricted** (01)
  - Otherwise, use **Presentation Allowed** (00)
- Screening Indicator:
  - If the **network-provided** parameter is present, use **Network Provided** (11)

  - Otherwise, use **user provided, verified and passed** (01)
- Address Signal—Value of **operator-specific-GI**

Interworking SIP Response to ISUP Cause Values

If a Reason header as described in IETF RFC 6432 is included in a SIP 4xx, 5xx, 6xx response, and you have enabled the **sip-config**, **sip-response-code** parameter, theSBC maps the Cause Value of the Reason header to the ISUP Cause Value field in the **REL** message, as follows:

SIP Response	ISUP Cause Value
400, 414, 416, 420, 421	111 (Protocol Error, Unspecified)
403, 417, 501	79 (Not implemented, Unspecified)
404, 485	1 (Unallocated number)
408, 504	102 (Timer expiry)
410	22 (Number Changed)
422	31 (Normal, Unspecified)
433	24 (Call Rejected due to feature at destination)
480	20 (Subscriber Absent)
483	25 (Exchange routing Error)
484	28 (Invalid Number Format)
486, 600	17 (User Busy)
488	50 (Request Facility Not Supported)
502	27 (Destination Out of order)
503	41 (Temporary Failure)
513	95 (Invalid Message, Unspecified)
603	21 (Call Rejected)
604	2 (No route specified)
606	88 (Incompatible Destination)
Other	127 Interworking Unspecified)

For errors received from the SIP-I side, the SBC inserts a Reason Header into the SIP body, if it is not generated by some other process. This also requires that you have enabled the **add-reason-header** within the **sip-config**. The SBC inserts the SIP Reasons according to the ISUP Cause Value (cause attribute and reason) mapping from ITU-T Q.850.

In-Band Announcement Indication

You can configure the SBC to add the Event Indicator parameter with value "progress" while generating a CPG by enabling the applicable **iwf-for-183** parameter.

When enabled, the SBC performs this function if the received "183 Session Progress" message either:

- Doesn't contain a PEM header, or
- Contains a PEM with the value inactive or recvonly

The SBC adds the OBCI parameter to the generated ACM if it receives a 180 or 183 message with a PEM header with value sendonly or sendrecv. The SBC always performs this interworking for 180 messages. For 183 messages, you must have also set the `iwf-for-183` parameter to `enabled` or `pem-controlled`.

Supplementary Service for COLP and COLR

During SIP-I to SIP calls, if the 200 OK message received from the IMS node contains a P-Asserted-Identity header, the SBC encodes some parameters of ISUP messages. The SBC only performs this function if the P-Asserted-Identity header is in SIP, SIPS or Tel-URI format. If Tel-URI format is accompanied by SIP and/or SIPS format, theSBC uses the header in Tel-URI format.

Connected Number

Connected Number subfield interworking includes:

- Nature of address—The SBC inserts the following values into the IAM, based on the conditions described:
  - **National**, if there is no **+** in the number (encoded to 0000011).
  - **International**, if there is a **+** in the number (encoded to 0000100).
- Numbering Plan Indicator—ISDN (001)
- APRI—This interworking is dependent on the value of either the SIP privacy header or the priv-value presented in the History-info:
  - If the privacy header is present and contains a value other than 'none', map to **restricted** (01).
  - If the privacy header is absent, or present with the value 'none', map to **allowed** (00).
- Screening Indicator—Network Provided (11)
- Address Signal—P-Asserted-Id user-part

Interworking for Call Hold and Resume Cases

IMS nodes can send UPDATE or Re-INVITE messages to the SBC during a call to put the session on hold or to resume it. In turn, the SBC encapsulates these messages, into INVITE, re-INVITE, or UPDATE messages as call progress messages (CPG) within MIME content and sends them for interworking out the SIP-I side of the call.

A caller can put a call on hold at any time after the alerting phase has begun using an UPDATE. A callee can only put a call on hold or resumed after it has answered the call. Both caller and callee can initiate hold/resume using an UPDATE or Re-INVITE. As a result, a call can only be put on hold in the SIP to SIPI direction by the caller before the call is answered. After the call is answered, either side can hold and resume the call. Furthermore, after the call is in progress, either side can effectively put the other side on hold. These actions are signaled using the a attribute in the SDP.

To put a session on hold, an IMS node sends an UPDATE or re-INVITE message with an "inactive" or a "sendonly" SDP attribute. Upon receipt of the hold request, the SBC encapsulates a CPG message containing the Generic notification indicator parameter with notification indicator set to "remote hold" while forwarding the UPDATE or re-INVITE towards the SIP-I side.

The SBC populates the following Event Information and Generic Notification Indicator subfields for hold cases in the CPG:

- Event Information:
  - Event Indicator—PROGRESS (0000010)

  - Event Presentation—No indication (0)
- Generic Notification Indicator:
  - Notification Indicator—REMOTE HOLD (1111001)

To resume a session, an IMS node sends an UPDATE or re-INVITE message with a "recvonly" or "sendrecv" SDP attribute, depending on the current state of the session. Upon receipt of the resume request, the SBC encapsulates a CPG message containing the Generic notification indicator parameter with notification indicator set to "remove retrieval" while forwarding UPDATE / re-INVITE towards SIP-I side.

The SBC populates the following subfields of Event Information for remote resume cases:

- Event Information:
  - Event Indicator—PROGRESS (0000010)
  - Event Presentation—No indication (0)

ISUP Version Interworking

ISUP messages can be carried in SIP messages through either a standard body or through a multipart MIME encoded body. While ANSI and ITU are the two major ISUP format types, each contains many specific variants. To facilitate instances where two sides of an ISUP-to-ISUP call use different ISUP versions, the Oracle Communications Session Border Controller (SBC) supports interworking between the following ISUP formats: ANSI, ITU, ETSI-356 (an ITU variant), GR-317 (an ANSI variant) and (Signalisation Pour l'Interconnexion des Réseaux Ouverts/Signaling for the Interconnection of Open Networks) SPIROU. To do so, the SBC can move, delete, and add parameters to various sections of the message.

The ISUP message version is determine by one of two things:

- The content type of the SIP message
- The MIME content-type

When the base and version parameters do not match, the SBC first uses the base parameter value to determine the format. If there is no base, the SBC then checks the version parameter. If there is neither, the SBC uses the **isup-version** configured in the **sip-isup-profile** configuration from the inbound realm, session agent, or SIP interface. Available values for that parameter are **ansi-2000**, **itu-99**, **gr-317**, **etsi-356**, or **spirou**. The SBC considers unknown any value for the version that fails to match one of these or is missing.

An example of the base and version information set to SPIROU is as follows:

```
application/ISUP;base=spirou;version=spirou
```

Messages that contain an unknown ISUP format pass through the SBC untouched. If there are operations to be performed on them, however, SIP-SIPI interworking takes place. After the body has been converted, the SBC updates both the base and version parameters of the content-type.

Custom formats are not supported.

Configuring SIP-SIPI Interworking

The following tasks explain how to configure SIP-SIPI Interworking on the SBC.

Configuring SIP SIPI IWF using HMR

Descriptions and procedures for using Header Manipulation Rules (HMR) to perform SIP-SIPI interworking are documented in the *Header Manipulation Rules Resource Guide*.

Configuring SIP-SIPI IWF using Session Translation

Session Translation for SIP-SIPI IWF configuration consists of three procedures performed in order:

1. Create **translation-rules** elements
2. Apply your **translation-rules** to **session-translation** elements
3. Apply your **session-translation** elements to **session-agents** or **realms**

Each of these tasks are presented below.

Configuring translation rules

Use this procedure to create one of more translation rules to apply to the SIP-SIPI IWF components of a **session-translation**.

1. In Superuser mode, navigate to the **session-router** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#session-router
ORACLE(session-router)#
```

2. Type **translation-rules** and press Enter.

```
ORACLE(session-router)# translation-rules
ORACLE(translation-rules)#
```

3. **ID**—Set a descriptive ID name for this translation rule.
4. **type**—Set the type of translation rule you want to configure. The default value is **none**. The valid values are:
   - **add**—Adds a character or string of characters to the address
   - **delete**—Deletes a character or string of characters from the address
   - **replace**—Replaces a character or string of characters within the address
   - **none**—Translation rule is disabled
5. **add-string**—Enter the string to be added during address translation to the original address. The value in this field should always be a real value; i.e., this field should not be populated with at-signs (@) or dollar-signs ($). The default value is a blank string.
6. **add-index**—Enter the position, 0 being the left most position, where you want to add the string defined in the **add-string** parameter. The default value is zero (**0**). The valid range is:

- Minimum—0
- Maximum—999999999

7. **delete-string**—Enter the string to be deleted from the original address during address translation. Unspecified characters are denoted by the at-sign symbol (@).

   The @ character only works if the type parameter is set to delete. This parameter supports wildcard characters or digits only. For example, valid entries are: delete-string=@@@@@, or delete-string=123456. An invalid entry is delete-string=123@@@. When the type is set to replace, this value is used in conjunction with the add-string value. The value specified in the delete-string field is deleted and the value specified in the add-string field is inserted. If no value is specified in the delete-string parameter and the type field is set to replace, then nothing will be inserted into the address. The default value is a blank string.

8. **delete-index**—Enter the position, 0 being the left most spot, where you want to delete the string defined in the **delete-string** parameter. This parameter is only used if the **delete-string** parameter is set to one or more at-signs. The default value is zero (**0**). The valid range is:

   - Minimum—0
   - Maximum—999999999

9. Save your work.

Next, you apply your **translation-rules** to a **session-translation**.

Applying translation-rules to session-translations

These steps assume you have created **translation-rules** elements.

1. In Superuser mode, navigate to the **session-router** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)#
```

2. Enter the **session-translation** element.
3. **ID**—Set a descriptive ID name for this session translation.
4. **rules-asserted-id**—Enter the applicable rules in the order in which they should be applied. Multiple rules should be included in quotes and separated by spaces. The example output below displays rules applied to the **rules-asserted-id** and **rules-isup-cdpn** SIPI objects to modify. Refer to the description of each session-translation object that you can manipulate to identify the signaling changes you are targeting.

```
ORACLE(session-translation)# rules-asserted-id "rule1 rule2 rule3"
```

   The following is an example of what a session translation configuration might look like:

```
session-translation
        id                              lrules-out
        rules-asserted-id               rule1 rule2 rule3
        rules-isup-cdpn                 rule4
```

5. Save your work.

Next, you apply your **session-translation** to a **realm** or a **session-agent**.

Applying session-translations to realms or session-agents

These steps assume you have created **session-translation** elements. Identify and employ the criteria by which you choose whether to apply the translations to **realms** or **session-agents**. In addition, determine whether you want to apply your translations to ingress of egress traffic.

1. In Superuser mode, navigate to the **session-router** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)#
```

2. Navigate to the chosen element, in this example a session-agent.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

3. Specify the appropriate **session-translation** object as the **in-translationid** and/or the **out-translationid** in the **session-agent** element.

```
session-agent
        in-translationid
        out-translationid               lrules-out
```

   Consider the following parameter descriptions to determine how to apply your translation rule(s):

   - **in-translationid**—Enter the configured session translation that you want to affect the incoming traffic in this parameter.
   - **out-translationid**—Enter the configured session translation that you want to affect the outgoing traffic in this parameter.

4. Save your work.

Configuring the OCSBC for Native SIP-SIPI Interworking

You set the **sipi-behavior** option in the **sip-config**.

1. In Superuser mode, access the **sip-config** using the following navigation.

```
ORACLE#configure terminal
ORACLE(configure)#session-router
ORACLE(session-router)#sip-config
ORACLE(sip-config)#
```

2. Select the **sip-config**.

```
ORACLE(sip-config)# select
ORACLE(sip-config)#
```

3. Set the **sipi-behavior** option using the following syntax.

```
ORACLE(sip-config)# + options sipi-behavior=iam-anm
ORACLE(sip-config)#
```

4. Save your work.

Configuring the SIP-ISUP Profile

To set up a SIP ISUP profile:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-isup-profile** and press Enter.

```
ORACLE(session-router)# sip-isup-profile
ORACLE(sip-isup-profile)#
```

4. **name**—Enter the name of the SIP ISUP profile. You will use this name when you apply this profile to realms, session agents, and SIP interfaces. This parameter is required, and it has no default value.
5. **isup-version**—Specify the ISUP version you want used in this profile in order to support SIP-T: **ansi-2000** (default), **itu-99**, **gr-317**, **etsi-356**, or **spirou**.
6. **convert-isup-format**—Enable this to convert outgoing ISUP messages to isup-version format
7. **iwf-for-183**—Disable to prevent the SBC from adding ACM or CPG for 183.
8. **country-code**—Specify the text string to use for country code interworking, specifying the string inserted into the IAM as the code party number parameter. This happens when the NPRN parameter is present in the Req-URI of an incoming INVITE, and requires that **portability-method** be set to **concatenate**.
9. **portability-method**—Specify whether the SBC performs number portability interworking on the IAM by encoding the called-party-number in the IAM based on the NPDI and NPRN parameters. Values include **none** (default) or **concatenate**.
10. Save your work.

Configuring to Prevent the Interworking of 183 Messages to ACMs

To use this option, you must have previously set **sipi-behavior** option to **iam-anm**.

1. In Superuser mode, access the **sip-isup-profile** using the following navigation.

```
ORACLE# configure terminal
ORACLE# (configure) session-router
ORACLE# (session-router) sip-isup-profile
```

2. Create a new profile, or select the desired **sip-isup-profile**.

3. Disable **iwf-for-183** within the profile using the following syntax.

```
ORACLE(sip-isup-profile)#iwf-for-183 disabled
```

4. Save your work.

Configuring Number Portability Support for IAM Interworking

This section show you how to set up Number Portability Support for IAM Interworking. First, you configure a SIP ISUP profile, and then you apply it to a realm, session agent or SIP interface.

To set up a SIP ISUP profile:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-isup-profile** and press Enter.

```
ORACLE(session-router)# sip-isup-profile
ORACLE(sip-isup-profile)#
```

4. **name**—Enter the name of the SIP ISUP profile. You will use this name when you apply this profile to realms, session agents, and SIP interfaces. This parameter is required, and it has no default value.
5. **country-code**—Specify the text string to use for country code interworking, specifying the string inserted into the IAM as the code party number parameter. This happens when the NPRN parameter is present in the Req-URI of an incoming INVITE, and requires that **portability-method** be set to **concatenate**
6. **portability-method**—Set this parameter to **concatenate** if you want to perform interworking for Number Portability Support within the IAM. The default is **disabled**, meaning that this feature is turned off.
7. Save your work.

Configuring SIP-ISUP Redirection Interworking

To use this feature, configure:

- sip-profile—Defines the redirection behavior
- sip-isup-profile—Defines the ISUP version to use when supporting SIP-I (and SIP-T)

You can then apply these profiles to realms, session agents, and SIP interfaces where you want this feature enabled.

The **sip-profile** configuration contains information that defines redirection behavior for the configuration where you apply it. You can set the redirection behavior to: **none**, **isup**, or **diversion**. You also uniquely identify the profile so that you can apply it by name in other

configurations. This is a multiple-instance configuration, meaning that you can set up as many SIP profiles as needed.

To set up a SIP profile:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-profile** and press Enter.

```
ORACLE(session-router)# sip-profile
ORACLE(sip-profile)#
```

4. **name**—Enter the name of the SIP profile. You will use this name when you apply this profile to realms, session agents, and SIP interfaces. This parameter is required, and it has no default value.
5. **redirection**—Choose the redirection mode you want to use: **none** (default), **isup**, **diversion**, or **history-info**. The **inherit** value is reserved for future use. Note that when you set this parameter to **isup**, you should configure along with it a SIP ISUP profile; this will avoid any possible incompatibility when support for this feature expands (as expected).
6. Save your work.

Configuring ISUP Format Interworking

To use this feature, set the version for the applicable interface using **isup-version** and enable the **convert-isup-format** parameter in the **sip-isup-profile**.

To set ISUP format interworking:

1. In Superuser mode, access the **sip-isup-profile** using the following navigation.

```
ORACLE# configure terminal
ORACLE# (configure) session-router
ORACLE# (session-router) sip-isup-profile
```

2. Create a new profile, or select the desired **sip-isup-profile**.
3. Set the **isup-version** within the profile using the following syntax to, for example, spirou.

```
ORACLE(sip-isup-profile)#isup-version spirou
```

4. Enable **convert-isup-format** within the profile using the following syntax.

```
ORACLE(sip-isup-profile)#convert-isup-format enabled
```

5. Apply your **sip-isup-profile** to the appropriate **sip-interface**.
6. Save your work.

Configuring ISUP Parameter Extraction

Configure this parmameter to define a list of ISUP parameters the SBC extracts and interworks during IAM to INVITE interworking for SIP-I to SIP and SIP-I to SIP-I calls. In addition, for SIPI outbound calls, both SIP to SIPI and SIPI to SIPI calls, the SBC interworks parameters from ACM/CPG messages into 18x messages.

To use this feature, set the parameters to extract for the applicable interface using the **extract-isup-params** parameter in the **sip-isup-profile**.

To set ISUP format interworking:

1. In Superuser mode, access the **sip-isup-profile** using the following navigation.

   ```
   ORACLE# configure terminal
   ORACLE# (configure) session-router
   ORACLE# (session-router) sip-isup-profile
   ```

2. Create a new profile, or select the desired **sip-isup-profile**.
3. Set the **extract-isup-params** within the profile referring to the following syntax.

   ```
   ORACLE(sip-isup-profile)#extract-isup-params calling-party-number
   ```

   - calling-party-number
   - generic-number
   - location-number
   - user-to-user
   - inband-announcement
4. Repeat the step above to add additional ISUP values for extraction. (This parameter accepts only one value at a time.)
5. Apply your **sip-isup-profile** to the appropriate **sip-interface**.
6. Refine you list, if necessary, using the **remove-isup-params** command followed by the parameter name you want to remove.

   ```
   ORACLE(sip-isup-profile)#remove-isup-params user-to-user
   ```

7. Save your work.

Apply Your Profiles to a Session Agent

When you want to enable this feature for a realm, session agent, or SIP interface, you configure the **sip-profile** and **sip-isup-profile** parameters with the name of the profile you want applied.

The following example shows this feature being applied to a session agent, but the realm and SIP interface configurations also have the same two parameters you use to set up the feature.

To apply a SIP profile and a SIP ISUP profile to a session agent:

1. In Superuser mode, type **configure terminal**, and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router**, and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-agent** , and press Enter.

```
ORACLE(session-router)# session-agent
ORACLE(session-agent)#
```

4. **sip-profile**—Enter the name of the SIP profile, which defines the redirection behavior. This is the value you entered in the **name** parameter of the SIP profile configuration. This parameter has no default value.
5. **sip-isup-profile**—Enter the name of the SIP ISUP profile, which defines the ISUP version to use for SIP Diversion SIP-ISUP interworking. This is the value you entered in the **name** parameter of the SIP ISUP profile configuration. This parameter has no default value.
6. Save your work.

Configuring SIP-ISUP Reason Header IWF

To use this feature, enable the **add-reason-header** parameter in the **sip-config**.

To enable SIP-ISUP reason header interworking:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **sip-config** and press Enter.

```
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

4. **add-reason-header**—Enable this parameter to perform reason header interworking during native SIP-ISUP interworking. The default is disabled.
5. Save your work.

SIP Session Timer Feature

SIP does not have a keepalive mechanism for established sessions and it does not have the capability of determining whether a session is still active. User agents (UAs) may be able to

determine whether a session has timed out by using session specific mechanisms, but proxies cannot always determine when sessions are still active.

The Oracle Communications Session Border Controller provides a SIP session timer feature that, when enabled, forwards the re-INVITE or UPDATE requests from a User Agent Client (UAC) to a User Agent Server (UAS) in order to determine whether or not a session is still active. This refresh feature works for both UAs and proxies. The following paragraphs provide additional information about the session timers on the Oracle Communications Session Border Controller.

How the Session Timer Feature Works

During an active SIP call session, when a UA fails to send a BYE message at the end of the session, or when the BYE message gets lost due to network problems, the proxy cannot determine when the session has ended. Therefore, the proxy may hold onto resources associated with the call session for indefinite periods of time causing the session to never time out.

The SIP session timer feature adds the capability to periodically refresh SIP sessions by sending repeated INVITE (re-INVITE) or UPDATE Session Refresh Requests. These requests are sent during active call legs to allow UAs or proxies to determine the status of a SIP session. The Session Refresh Requests along with the session timers determine if the active sessions stay active and completed sessions are terminated.

When you enable the session timer feature on the Oracle Communications Session Border Controller, it periodically sends out a Session Refresh Request (re-INVITE or UPDATE). The Response that is returned to the Oracle Communications Session Border Controller contains a success status code (2xx) that contains a session timer interval. The Oracle Communications Session Border Controller then refreshes the session timer each time it receives the 2xx Response containing that session timer interval.

The initial INVITE message sent from the UAC to the UAS contains two fields that make up the session timer interval in the SIP Session Header:

- Session-Expires (SE) - Specifies the maximum amount of time, in seconds, that can occur between session refresh requests in a dialog before the session is considered timed out.
- Minimum-SE (Min-SE) - Specifies the minimum allowed value, in seconds, for the session expiration.

The following displays the session timer interval values inserted in the SIP session INVITE message per RFC 4028:

```
INVITE sip:9109621001@192.168.200.99 SIP/2.0
Via: SIP/2.0/UDP 192.168.200.49:5060;branch=z9hG4bK0g6t23200gd0res4l580.1
Max-Forwards: 69

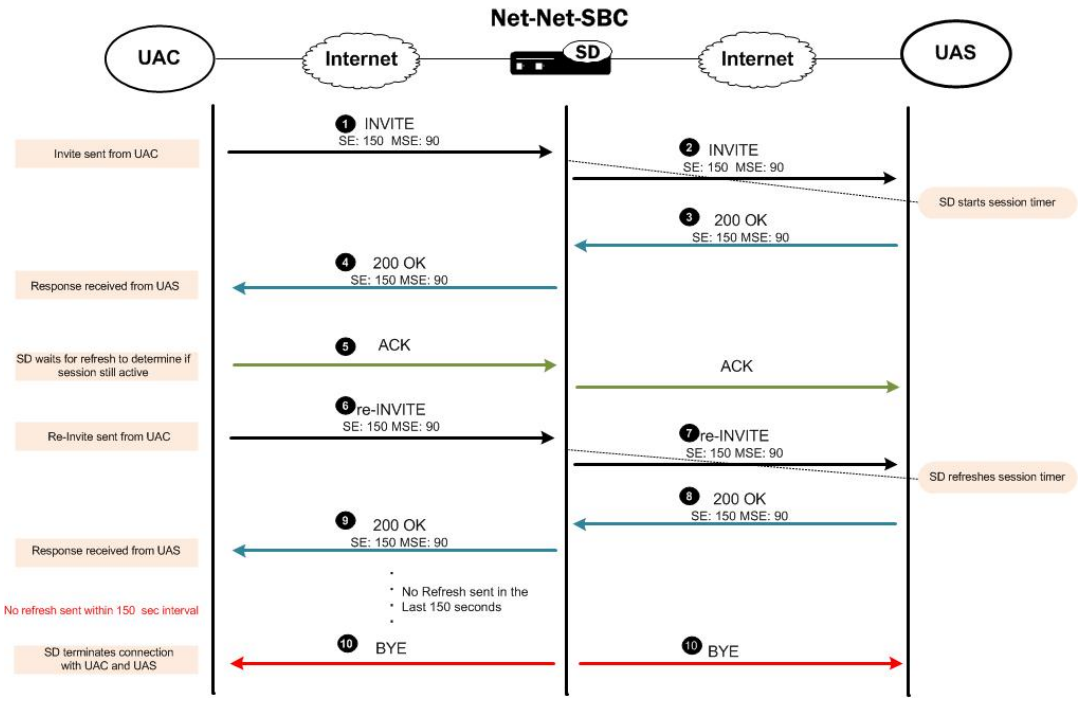
a=fmtp:101 0-15
```

If the Oracle Communications Session Border Controller receives an INVITE from the UAC with a Session-Expires header, it starts a new session timer, or refreshes an existing session timer and then forwards the INVITE to the UAS. The subsequent 2xx Responses and re-INVITES also include the session timer intervals. If the Oracle Communications Session Border Controller does not receive a session refresh within the time specified in the session timer interval, the session timer expires, and the Oracle Communications Session Border Controller terminates the session between the UAC and the UAS.

The following occurs when you enable the session timer feature on the Oracle Communications Session Border Controller:

1. The UAC sends an INVITE to the Oracle Communications Session Border Controller with the SE and min-SE values (session timer interval). The Oracle Communications Session Border Controller starts a session timer.
2. The Oracle Communications Session Border Controller forwards the INVITE to the User Agent Server (UAS) with the same values.
3. The UAS sends the 200 OK Response to the Oracle Communications Session Border Controller with the session interval values.
4. The Oracle Communications Session Border Controller forwards the Response to the UAC.
5. The UAC sends an ACK (Acknowledge) to theOracle Communications Session Border Controller, and the Oracle Communications Session Border Controller forwards the ACK to the UAS.
6. The UAC sends out a re-INVITE (Session Refresh Request) to the Oracle Communications Session Border Controller with the session interval values. The Oracle Communications Session Border Controller refreshes the session timer.
7. The Oracle Communications Session Border Controller forwards the re-INVITE to the UAS.
8. The UAS sends the 200 OK response to the Oracle Communications Session Border Controller with the session interval values.
9. The Oracle Communications Session Border Controller sends the 200 OK response to the UAC.
10. If the Oracle Communications Session Border Controller does not receive a Response within the session interval (150 seconds in the following illustration), the timer expires, and the Oracle Communications Session Border Controller terminates the session between the UAC and the UAS. The following illustration shows an example of a dialog between the UAC, the Oracle Communications Session Border Controller, and the UAS during an active session.



When the Oracle Communications Session Border Controller terminates a session it sends a BYE to both the ingress and egress call legs. If accounting is configured, the Oracle Communications Session Border Controller also sends a RADIUS stop record with Acct-Terminate-Cause = Session-Timeout. You can enable or disable the use of the session timers using the ACLI interface at **session-router**, **sip-config**, **options**.

SIP Session Timer Configuration

You can configure the session timer feature on the Oracle Communications Session Border Controller to periodically refresh SIP sessions and determine whether or not a session is still active. If the Oracle Communications Session Border Controller determines that a session is no longer active, it terminates the session based on the session timer interval settings.

To configure the session timer feature on the Oracle Communications Session Border Controller:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session router-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **sip-config** and press Enter to access the SIP config-related configurations. The system prompt changes to let you know that you can begin configuring individual parameters for this object.

   ```
   ORACLE(session-router)# sip-config
   ORACLE(sip-config)#
   ```

4. Enter options followed by the following value:

- +session-timer-support

```
ORACLE(sip-config)# options +session-timer-support
```

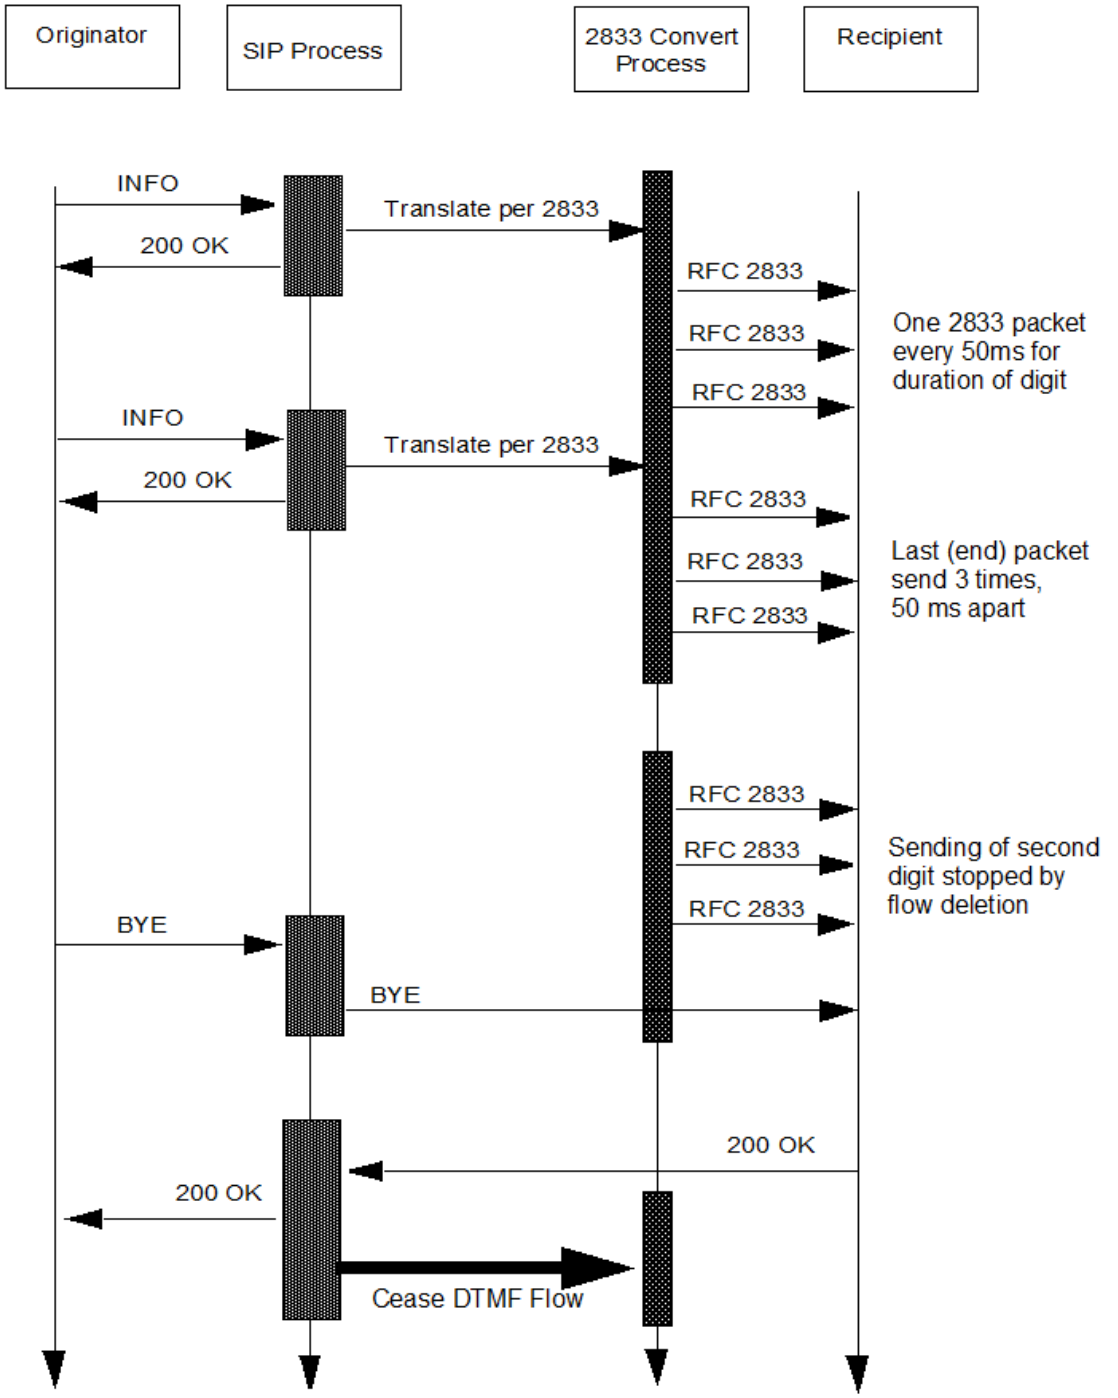
This value enables the system to start the session timer for session refreshes coming from the UAC. The system determines whether or not a session is active based on session refreshes or responses. It terminates the session when no session refreshes occur within the session timer interval. To disable the session timer feature, enter options followed by **-session-timer-support**.

```
Oracle Communications Session Border Controller(sip-config)# options -
session-timer-support
```

> **Note:**
>
> To disable session timers, you must add a minus sign (-) before the session-timers-support value.

DTMF Conversion Processing

Release S-CX6.3F1 provides a configurable SIP option to implement DTMF-to-RFC2833 tone translation. The current, default implementation, which performs well in most network topologies is shown below.



When the Oracle Communications Session Border Controller receives an INFO DTMF request, the SIP process determines whether or not it needs to perform DTMF-to-RFC2833 translation. If translation is required, the process forwards the DTMF to the 2833 convert process for translation and transmission to the recipient. Immediately after off-loading the DTMF, the SIP process sends a 200 OK response for the INFO. As shown in the figure, the 2833 convert process generates a number of RFC2833 packets to represent received DTMF digits.

Specifically, the 2833 convert process generates one RFC 2833 packet every 50 milliseconds for the duration of the DTMF digit, whose length is specified in the INFO request, and two retransmits of the last packet (known as the end packet) 50 milliseconds apart.

Consequently, the time interval between the 200 OK and the actual transmission of the RFC 2833 translation is the sum of the DTMF duration and 100 ms.

> **Note:**
>
> This time interval can be shortened to 100 ms by enabling the rfc2833-end-pkts-only-for-non-sig parameter in media-manger which results in SD only generating the last packet and its two retransmits.

The early 200 OK allows the endpoint to send the next DTMF digit before the SD has sent all the RFC2833 packets, resulting in the next digit being queued internally by the 2833 convert process before being sent.

A problem arises if the SIP process receives a BYE request from the DTMF originator while queued digits are awaiting translation and transmission. In such an event, the SIP process immediately forwards the BYE request to the recipient, ending the session with DTMF digits awaiting translation and transmission.

An alternative DTMF conversion model provides for a feedback mechanism from the 2833 convert process to the SIP process. With this model enabled, the SIP process buffers a received BYE until it obtains confirmation that all queued DTMF digits have been translated and transmitted. Only after obtaining confirmation, does it forward the BYE to terminate the session.

This processing model is enable by a SIP option, **sync-bye-and-2833**, and requires that **rfc2833-mode** parameter on the egress interfaces is NOT set to dual , any value other than dual , is supported.

1. From superuser mode, use the following command sequence to access sip-config configuration mode.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# sip-config
ORACLE(sip-config)#
```

2. Use the SIP option **sync-bye-and-2833** to delay BYE processing until DTMF-to-RFC2833 translation has been completed.

```
ORACLE(sip-config)# options +sync-bye-and-2833="enabled"
ORACLE(sip-config)#
```

3. Use the **done** and **exit** commands to complete configuration.

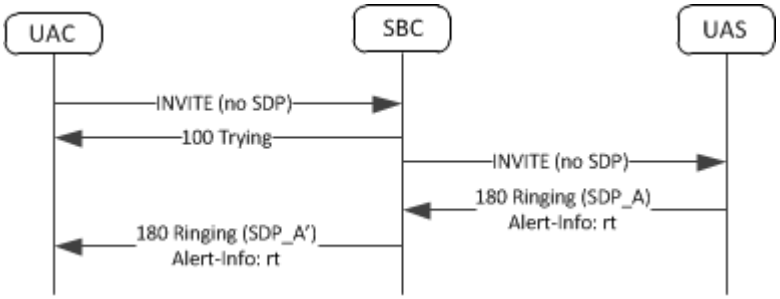
```
ORACLE(sip-config)# done
ORACLE(sip-config)# exit
ORACLE(session-router)#
```

LMSD Offerless INVITE handling

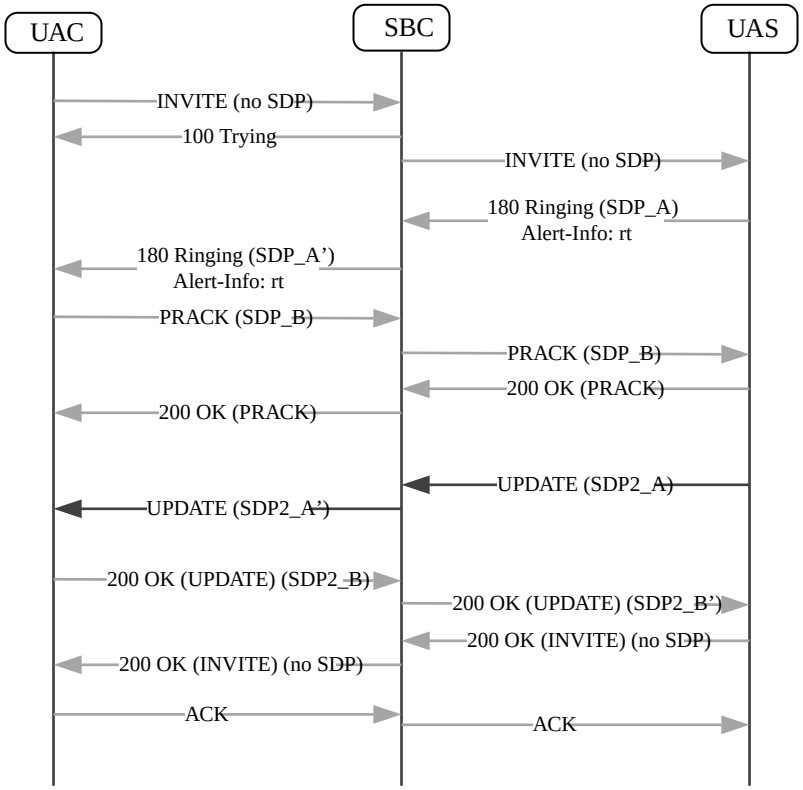
To enhance LMSD interworking, the Oracle Communications Session Border Controller does not remove SDP from a 180 response sent back to the UAC when the initial request did not

contain SDP. The Oracle Communications Session Border Controller also forwards UAS-side UPDATE requests to the UAC; it does not respond locally. These represent behavioral changes and require no configuration.

When LMSD Interworking is configured on a SIP interface, and when the UAS includes SDP in the 180 Ringing message (and the Alert-Info header is set to rt), the Oracle Communications Session Border Controller no longer strips the SDP when forwarding the 180 back to the UAC.



When LMSD interworking is configured on a SIP interface, and in the case that an early dialog has been established (a dialog where the final 2xx class response to INVITE request has not yet arrived), some call flows include an UPDATE later in the call. The Oracle Communications Session Border Controller now forwards the Update message, SDP included, directly to the UAC, whereas before it responded to the UAS's UPDATE locally.



RFC 4028 Session Timers

The Oracle Communications Session Border Controller supports RFC 4028 Session Timers. In this role, it acts as a B2BUA between two endpoints and then enforces the timer values on each call leg independently. The RFC 4028 abstract states:

This document defines an extension to the Session Initiation Protocol (SIP). This extension allows for a periodic refresh of SIP sessions through a re-INVITE or UPDATE request. The refresh allows both user agents and proxies to determine whether the SIP session is still active. The extension defines two new header fields:

- Session-Expires—which conveys the lifetime of the session
- Min-SE—which conveys the minimum allowed value for the session timer

The following parameters in the session-timer-profile configuration element are used for this feature:

session-expires—The value of the session expires header in seconds

min-se—The value of the Min-SE header in seconds (this is a minimum session expires value)

force-reinvite—Sets if the Oracle Communications Session Border Controller will send a reINVITE to refresh the session timer when applicable.

request-refresher—Set on the outbound side of a call what the Oracle Communications Session Border Controller sets the refresher parameter to. Valid values are uac, uas, or none.

response-refresher—Set on the inbound side the value of the refresher parameter in the 200OK message. Valid values are uac or uas.

In this section, the notion that a UAC or UAS supports Session Timers is indicated by the presence of the Supported: timer header and option tag.

Ingress Call Leg

Setting 200 OK's Session-Expire value

The session timer is based on the negotiation between each side's session expires value. The final value on the ingress leg is returned by the Oracle Communications Session Border Controller to the UAC, unless there is an error.

The Oracle Communications Session Border Controller can always reduce the session expires value it returns to the UAC. It checks that the Session-Expires: header is larger than the SIP Interface's min-se value. The Oracle Communications Session Border Controller then compares the received Session-Expires: header to the configured session-expires configuration element and uses the lower value for the 200 OK's Session-Expires: header. If this outbound Session-Expires: value is lower than the received Min-SE: header, it will be bumped up to the Min-SE: header's value.

If the Oracle Communications Session Border Controller's Min-SE value is larger than the Session-Expires: header, a 422 (Session Interval Too Small) message is returned to the UAC containing the Oracle Communications Session Border Controller's configured Min-SE value.

When the UAC supports (but does not require) Session Timers and the Oracle Communications Session Border Controller does not support session timers, a 200 OK is returned to the UAC with no indication of session timer support.

Refresher

The initial UAC, the side that sends the INVITE, can set itself to be the refresher (uac) or the Oracle Communications Session Border Controller as the refresher (uas). Whoever is the refresher is indicated in the 200 OK. If the UAC does not specify any refresher, the Oracle Communications Session Border Controller uses it's response-refresher value in the 200 OK. If

that value is set to uas, the Oracle Communications Session Border Controller creates and sends a re-INVITE toward the UAC with previously negotiated session expiration values.

Once the Oracle Communications Session Border Controller becomes the refresher, it does not relinquish that role. Then, when the Oracle Communications Session Border Controller sends refresh requests, it does not change any parameters (refresher role & timers) from the initial request negotiation.

UAC does not Support Session Timers

If the UAC's initial request does not include a Session-Expires: header, then the 200 OK will include the **session-timer-profile**, **session-expires** value on the ingress leg in the Session-Expires: header.

The Oracle Communications Session Border Controller also inserts the refresher parameter as configured. The orientation of UAC/UAS on the Oracle Communications Session Border Controller's view of a call leg can change if later in the call flow the endpoint designates the Oracle Communications Session Border Controller as the refresher.

> **Note:**
>
> When the request doesn't support Session Timers, the Oracle Communications Session Border Controller's reply adds session timer support according to configuration.

If the Oracle Communications Session Border Controller receives a message with a Require: timer header, and the inbound SIP interface or the final UAS do not support session timers, a 420 (Bed Extension) is returned to the UAC.

Egress Call Leg

Outbound INVITE Message

When the Oracle Communications Session Border Controller's outbound interface is configured with session timers, it forwards an INVITE to the UAS with the following headers:

Session-Expires— Oracle Communications Session Border Controller inserts the outbound SIP interface's session-timer parameter

Session-Expires refresher parameter— Oracle Communications Session Border Controller inserts the request-refresh parameter

Min-SE— Oracle Communications Session Border Controller inserts the outbound SIP interface's session-timer parameter

Supported—Supported header has the timer option tag

> **Note:**
>
> Require/Proxy-Require—If the timer parameter is present in the Require or Proxy-Require: header field in the request received from the UAC, it will be removed.

No Session Timer Configuration

If the ingress SIP interface supports session timers, and the original INVITE from the UAC included session timer support, the INVITE request sent to the UAS will have no session timer support. However, the Supported: timer header will be created. This ensures that the Oracle Communications Session Border Controller does not get a 421 response for 'timer' from the UAS.

If the ingress SIP interface supports session timers, and the UAC's initial INVITE did not include session timer support, then the INVITE sent to the UAS will have no session timer support (headers) as well.

If the ingress SIP interface does not support session timers, the INVITE is forwarded with no Session Timer alteration.

UAS Initial Response

Upon receiving a 200 OK from the UAS, if the response specifies uac as the refresher, the 200 OK includes a Session-Expires header and specifies uac as the refresher, the Oracle Communications Session Border Controller will assume the refresher role. If the 200 OK does not include a Session-Expires header, and the egress interface supports session timers, then the Oracle Communications Session Border Controller assumes the refresher role.

UAS Returns Errors

422 Session Interval Too Small—The Oracle Communications Session Border Controller in response sends the request again with new values in the 'Session-Expires' header field based on the 'Min-SE' value present in the 422 response.

421 Extension Required for 'timer'—This response can only happen if none of the other three entities (UAC, ingress SIP interface and egress SIP interface) support session timers. The 421 is forwarded through the system to the original UAC.

420 Bad Extension for 'timer'—This response should never happen because the Oracle Communications Session Border Controller will never send Require: timer header. But the event this error is received, it will be forwarded to the original UAC.

Session Refreshes

On either side of the call, the Oracle Communications Session Border Controller can be responsible for initiating the session refreshes or responding to the session refreshes.

Oracle Communications Session Border Controller as Refresher

The Oracle Communications Session Border Controller sends the refresh request when half the session expiration has elapsed. The Oracle Communications Session Border Controller always wants to remain the refresher and maintain the initially agreed upon session expiration timers.

Creating the Refresh Message

The refresh message takes the form of a re-INVITE when the force-reinvite parameter in the session timer profile is enabled. If this parameter is disabled and the remote end supports UPDATE requests, an UPDATE message will be sent.

UPDATE messages contain no SDP information.

Re-INVITE messages contain the SDP that is the same as what was sent before.

The refresh request's Session-Expires: header value is set to the existing value for the session. The refresher parameter is set to uac since the Oracle Communications Session Border Controller acts like a UAC for this refresh transaction. The Min-SE header is also included.

Processing the Refresh Response

The session expires value in the 2xx response is accepted and the timer restarts.

If the remote end does not include any session expiration parameters, the Oracle Communications Session Border Controller continues to support session timers, and assumes that the refresh interval is the same as before.

Any response that is 422 Session Interval Too Small is handled as expected. The Oracle Communications Session Border Controller resends the refresh request again with new values based on the 422 response. Any other response to the refresh request that is not a dialog/ usage destroying response is treated like a 200 OK response.

Subsequent refresh requests are created and sent after half the previous refresh interval. If non-2xx, dialog / usage destroying responses are received, the Oracle Communications Session Border Controller reduces the following refresh intervals by half, as long as the final interval is not less than 32 seconds. The Oracle Communications Session Border Controller then uses this period for sending refresh requests until it successfully receives a 2xx response.

Oracle Communications Session Border Controller as Refresh Responder

Processing the Refresh

The refresh request is processed similarly to the initial request regarding the session timer parameters. The session timer for this call leg is restarted when the Oracle Communications Session Border Controller when it sends the 200 OK response for the refresh request.

Forwarding the Refresh

When the Oracle Communications Session Border Controller receives an UPDATE request, it is forwarded to the other end since the Oracle Communications Session Border Controller cannot determine whether this request is only for session refreshing, or for other purposes as well.

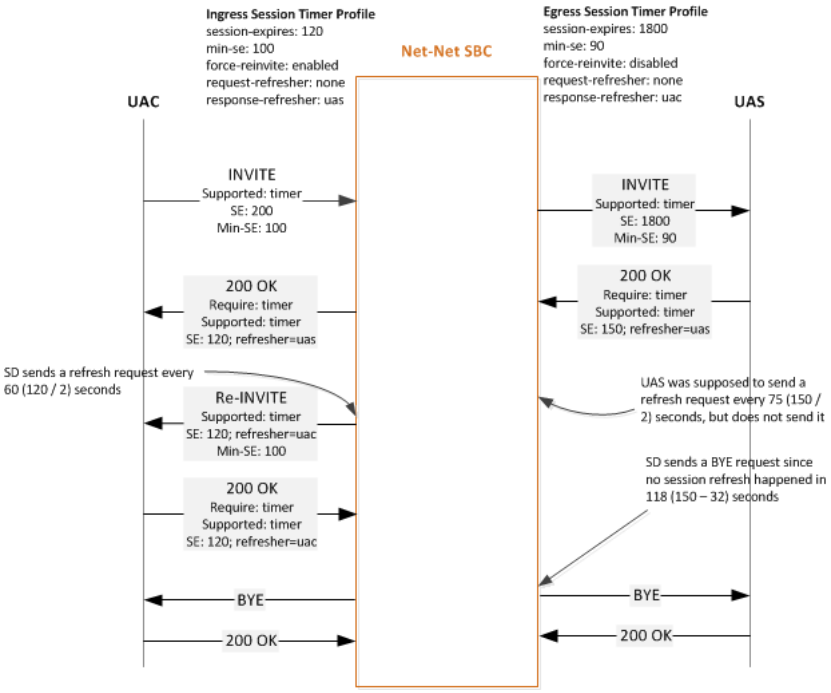
When the Oracle Communications Session Border Controller receives a re-INVITE request, it will determine whether this request needs to be suppressed, or should it be forwarded to the other end.

Timer Expiration

If the Oracle Communications Session Border Controller fails to receive a session refresh request before the session expiration, the session will be terminated before the full session time. This is computed according to:

```
time=period-min(period/3,32)
```

After the real expiration time elapses, the Oracle Communications Session Border Controller sends a BYE request in both directions to terminate the session.



Interaction with SIP Features

Consider the following sections that have interactions with RFC 4028 Support.

sip-config option session-timer-support

A configured session-timers-profile on a SIP interface overrides the session-timer-support option in the SIP config. The Oracle Communications Session Border Controller can still act in proxy mode for some calls and B2BUA for other calls considering which SIP interfaces session timer profiles are not configured for.

sip-feature Support

When the UAC sends a Require: timer header is in the initial request and the Oracle Communications Session Border Controller does not support session timers, and no sip-feature configuration element is configured for 'timer' for that realm, the Oracle Communications Session Border Controller replies with a 420 (Bad Extension) response for 'timer'.

When the UAC sends a Require: timer header is in the initial request and the Oracle Communications Session Border Controller does support session timers, the timer tag is removed from the Require: header even if a sip-feature configuration element is configured for 'timer'. This also applies for the Proxy-Require: header.

Oracle recommends you do not configure a sip feature configuration element while using the Session Timers feature.

sip-interface option suppress-reinvite

SIP re-INVITE suppression is automatically enabled for a SIP interface when session timers are enabled. This behavior prevents re-INVITEs whose purpose is only for session refreshes from being forwarded to the other call leg. The first re-INVITE received from a UAS on the

terminating call leg will be passed to the UAC on the originating call leg since the Oracle Communications Session Border Controller has no prior INVITE request coming from the UAS to match against.

Re-INVITEs are suppressed only when the Oracle Communications Session Border Controller receives the same INVITE request back-to-back without any intervening re-INVITE request in the opposite direction, or an UPDATE or PRACK request in either direction.

> **Note:**
>
> The SIP reINVITE Supression parameters are not replicated on the standby system in an HA environment. The first re-INVITE after a switchover will be forwarded to the far end.

Examples

RADIUS Interim record Generation

When refresh requests (UPDATE or Re-INVITE) are sent by the Oracle Communications Session Border Controller , no RADIUS Interim records are generated because session parameters do not change when these requests are sent.

When UPDATE requests are received by the Oracle Communications Session Border Controller , no RADIUS Interim records are generated.

When Re-INVITE requests are received by the Oracle Communications Session Border Controller , RADIUS Interim records are generated if the generate-interim parameter is enabled.

ACLI Configuration

To configure a session timer profile object:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **session-timer-profile** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# session-timer-profile
ORACLE(session-timer-profile)#
```

4. **name**—Enter a name for this session timer profile.
5. **session-expires**—Enter the session timer value in seconds you wish this object to use natively.
6. **min-se**—Enter the minimum session timer value in seconds for this object.
7. **force-reinvite**—Leave the default of enabled for the Oracle Communications Session Border Controller to always use reINVITEs for session refreshes. Set this parameter to disabled for the Oracle Communications Session Border Controller to try using UPDATEs for session refreshes.
8. **request-refresher**—Set this to the value to insert in the refresher parameter in the Session-Expires: header on the originating call leg that the Oracle Communications Session Border Controller includes in the 200 OK response message. Valid values are **uac** and **uas**.
9. **response-refresher**—Set this to the value to insert in the refresher parameter in the Session-Expires: header on the terminating call leg that the Oracle Communications Session Border Controller includes in the INVITE message. Valid values are **uac**, **uas**, **none**.
10. Type **done** to save your work and continue.

    To apply a session timer profile to a SIP interface:

11. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

12. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

13. Type **sip-interface** and press Enter.

```
ORACLE(session-router)# sip-interface
ORACLE(sip-interface)#
```

    If you are adding this feature to an existing configuration, then you will need to select the configuration you want to edit.

14. **session-timer-profile**—Enter the name of a session timer profile object you have configured and want applied to this SIP interface.
15. Type **done** to save your work and continue.

Verify Config Validation

The Oracle Communications Session Border Controller's verify-config function checks that the value configured in all sip-interfaces' session-timer-profiles correspond to a configured session-timer-profile name. The following is be generated when this check fails:

```
ERROR: sip-interface [id] has reference to session-timer-profile [xyz] which
does not exist
```

show sipd status

The show sipd status command now contains new statistic, called Refreshes Sent which reflects the number of refresh requests that the Oracle Communications Session Border Controller has sent. For example:

```
ORACLE#show sipd status
SIP Status                -- Period -- -------- Lifetime --------
                Active     High   Total      Total  PerMax     High
Sessions             0        1       0          2       1        1
Subscriptions        0        0       0          0       0        0
Dialogs              0        2       0          4       2        2
CallID Map           0        2       0          4       2        2
Rejections           -        -       0          0       0
ReINVITEs            -        -       0          2       1
ReINV Suppress       -        -       0          1       1

```

305 Response to Registrations on Secondary Interfaces

Certain devices are provisioned with point of contact (POC) lists for registration. In the context of geographic redundancy, if a UE is unable to register with its primary POC, it proceeds to its secondary POC. It is desirable to designate certain Oracle Communications Session Border Controller as secondary in order to redirect the UE to re-register with the primary SBC.

This feature is designed for Oracle Communications Session Border Controllers sitting behind Oracle Communications Subscriber-Aware Load Balancers (SLBs). This feature allows users to designateSBCs sitting behind SLBs as secondary. When registered endpoints in a realm attempt to register with the primary POC, and registration fails, the UEs proceed to their secondary point of contact (POC). Once connection to the primary POC has been restored, users can execute a command to offload the UE registrations in a given realm with a 305

response to the UEs in order for the UEs to re-register with the next POC. When the scenario consists of two POCs, the endpoint re-registers with the primary POC.

You enable this feature with an option through the SIP interface of the secondary SBC. The **notify sipd offload-users <realm>** command marks endpoints associated with a given realm to receive a 305 message. Once this command is executed, any subsequent requests from UEs in this designated realm receive a 305 message. Once a 305 message is issued, the registration cache is cleared to allow the UE request to be forwarded to the primary SBC. If the UE re-registers again with the secondary SBC, it will not receive a second 305 message. The **notify sipd offload-users <realm>** command must be executed again in order to repeat the process.

The **show registration** command is expanded to include a counter for the number of registrations received on secondary interfaces, as well as the number of endpoints marked to receive a 305.

SNMP support for this feature tracks the total count of registrations on secondary interfaces. The **apSipSecInterfaceRegThresholdExceededTrap** is generated when the total number of registrations on secondary interfaces exceeds the configured threshold, and **apSipSecInterfaceRegThresholdClearTrap** is generated when the total count falls below the configured threshold.

ACLI Instructions and Examples

To enable this feature, you must select an option for the SIP-interface of the secondary Oracle Communications Session Border Controller:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ACMEPACKET# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ACMEPACKET(configure)# session-router
   ```

3. Type **sip-interface** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ACMEPACKET(session-router)# sip-interface
   ACMEPACKET(sip-interface)#
   ```

4. **options**—Type **secondary** to designate this system as the secondary point of contact.

   ```
   ACMEPACKET(session-router)# options secondary
   ```

5. Save and activate your configuration.

notify sipd offload-users

The **notify sipd offload-users <realm>** command marks the endpoints associated with the given <realm> to receive a 305 message. Once this command is executed, any re-registrations received from an endpoint in that realm receives a 305 message.

A confirmation message is sent if the command succeeds:

```
Realm <realm> is marked to offload users at HH:MM:SS
```

If the given <realm> is not a secondary realm, the following message is displayed:

```
Realm <realm> is not secondary
```

If the given <realm> does not exist, the following message is displayed:

```
Realm <realm> is not found
```

> **Note:**
>
> This command is only valid for secondary systems. If the secondary option is not enabled for theOracle Communications Session Border Controller, this command produces an error message.

show registration

The **show registration** command displays the total number of endpoints associated with secondary interfaces, and the total number of endpoints marked to receive a 305 response.

> **Note:**
>
> The total number of SIP calls to receive a 305 response are included in the Registrations marked for 305 counter.

The total number of SIP calls associated with secondary realms are included in this count.

```
AcmePacket# show registration
11:02:13-102
SIP Registrations          -- Period -- -------- Lifetime --------
                 Active    High   Total      Total  PerMax    High
User Entries          1       1       1          1       1       1
...
Secondary Interface Registrations=NNN
Registrations marked for 305=MMM
access1: N1
access2: N2
```

show registration sipd

The **show registration sipd** command includes the following parameters:

show registration sipd sec-by-ip—displays the registrations sent to secondary interfaces by IP address.

```
Registration Cache                    MON FEB 06 2012  16:33:49
                                                        Num
  IP Address      User                                  Contacts Registered at
---------------- ------------------------------ -------- ---------
. . . .
```

show registration sipd sec-by-user—displays the registrations sent to secondary interfaces by user name.

```
Registration Cache                    MON FEB 06 2012  16:33:49
                                                        Num
  Phone Number    User                                  Contacts Registered at
---------------- ------------------------------ -------- ------------
. . . .
```

show sipd endpoint-ip

If the registered endpoint is associated with a secondary SIP interface, the show sipd endpoint-ip command displays SIP Interface: secondary.

```
# show sipd endpoint-ip 1
User <sip:12341@172.16.101.67>
  Contact exp=290
    UA-Contact: <sip:12341@172.16.26.1:5060> UDP keep-acl
         realm=net172 local=172.16.101.67:5060 UA=172.16.26.1:5060
    SD-Contact: <sip:12341-2k86jbp9bj925@192.168.101.67:5060> realm=net192
    Call-ID: 1-839@172.16.26.1'
    SA=192.168.26.2
    Service-Route='<sip:h19216806003.dg.com;lr>'
  SIP Interface: secondary
```

SNMP Configuration

To configure the threshold for the number of registrations on secondary SIP interfaces in order to generate a trap:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ACMEPACKET# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ACMEPACKET(configure)# session-router
   ```

3. Type **sip-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ACMEPACKET(session-router)# sip-config
   ACMEPACKET(sip-config)#
   ```

4. **options**—Type **sec-reg-threshold =X,** where X equals the number of registrations received on all secondary interfaces. Once that number has been reached, the apSipSecInterfaceRegThresholdExceededTrap is generated.

   ```
   ACMEPACKET(session-router)# options secondary
   ```

5. **options**—Type **sec-reg-threshold-clear =Y.** When the number of registrations received on all secondary interfaces drop below Y, the apSipSecInterfaceRegThresholdExceededClearTrap is generated.

> **Note:**
>
> The value of sec-reg-threshold-clear =Y must be less than sec-reg-threshold =. The values cannot be equal.

```
ACMEPACKET(session-router)# options secondary
```

6. **options**—Type **sec-reg-threshold-alarm-severity =** [minor | major | critical] to set the alarm severity for APP_ALARM_SEC_INTF_REG_EXCEED.
7. Save and activate your configuration.

SNMP

The apSipSecInterfaceRegThresholdExceededTrap trap is generated when the total count of all registrations on the secondary interfaces cross **sec-reg-threshold-exceed** is exceeded.

Object Identifier Name: apSipInterfaceRegNotificationsGroup

Trap Name	Object Identifier Name: Number	Description
apSipSecInterfaceRegThresholdExceededTrap	.1.3.6.1.4.1.9148.3.15.2.1.2.0.1	The trap will be generated if the total number of registrations on all secondary SIP interfaces exceed threshold.
apSipSecInterfaceRegThresholdClearTrap	.1.3.6.1.4.1.9148.3.15.2.1.2.0.2	The trap will be generated if the total number of registrations on all secondary SIP interfaces go below clear threshold.

A hardware alarm is also generated for this event. The severity of the alarm is configured in the **sec-reg-threshold-alarm-severity** option.

Alarm Name	Alarm ID	Alarm Severity	Cause(s)	Example Log Message	Trap Generated (Trap Reference)
APP_ALARM_SEC_INTF_REG_EXCEED	0X50018	Minor by default. The severity is configurable.	The total number of registrations on all secondary SIP interfaces exceeds the configured threshold.	Number of Secondary Interface registrations <total> has exceeded the secondary interface registration threshold of <max>.	apSyslogMessageGenerated (ap-slog.mib) apEnvMonStatusChangeNotification (ap-env-monitor.mib) apSysMgmtFanTrap (ap-smgmt.mib)

The following objects, with the object identifier name apSipInterfaceRegObjectsGroup, monitor the number of registrations on secondary interfaces:

SNMP GET Query Name	Object Identifier Name: Number	Description
apSipSecInterfaceTotalRegistrations	.1.3.6.1.4.1.9148.3.15.1.1.1.1.0	The total number of registrations on all secondary SIP interfaces.

SNMP GET Query Name	Object Identifier Name: Number	Description
apSipSecInterfaceRegThreshold	.1.3.6.1.4.1.9148.3.15.1.1.1.2.0	The max threshold for registrations on all secondary SIP interfaces beyond which trap and alarm will be raised
apSipSecInterfaceClearThreshold	.1.3.6.1.4.1.9148.3.15.1.1.1.3.0	The threshold for registrations on all secondary SIP interfaces below which if alarm was raised before, it will be cleared.

6

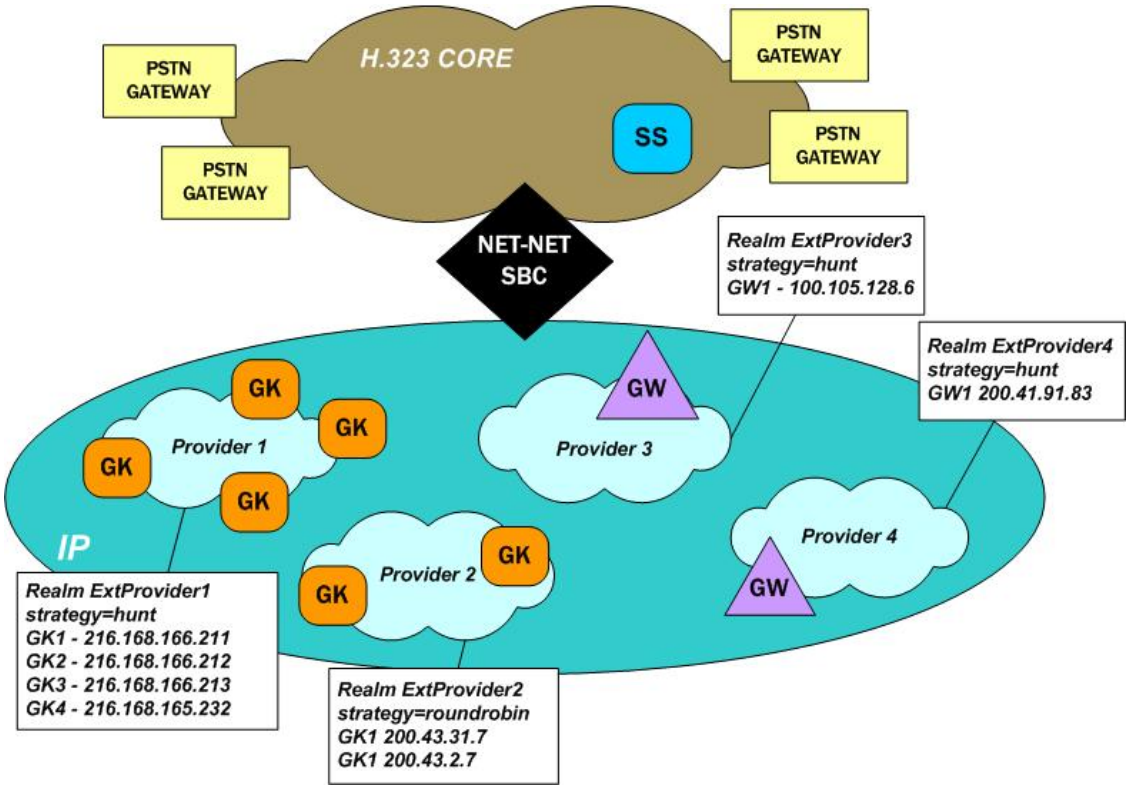
H.323 Signaling Services

The Oracle Communications Session Border Controller supports H.323 signaling in a way that permits interworking between different H.323 configurations from different providers and carriers. H.323 signaling capabilities on the Oracle Communications Session Border Controller include:

- H.323 V4—Improves on previous versions of the protocol in functionality, scalability, and reliability
- H.225 call signaling with RAS—Establishes connections between H.323 endpoints so real-time data can be exchanged
- H.245—Establishes the type of media flow and manages that flow after it has started
- H.245 tunneling—Encapsulates H.245 messages within H.225/Q.931 messages; when enabled and used with a firewall, one less TCP port is needed for incoming connections
- Fast Start (and Fast Start with parallel H.245)
- H.323 Annex E support for UDP signaling—Provides for multiplexed call signaling over UDP to increase potential call volume and enhance performance

Peering Environment for H.323

The following diagram shows a peering environment for H.323, with the Oracle Communications Session Border Controller positioned between the H.323 core and external providers.



The configuration information shown in the diagram can help you to understand how some basic Oracle Communications Session Border Controller concepts work. The providers in this depiction are configured as realms, and the strategies you see are for session agent group. What you do not see in this diagram is the fact that the Oracle Communications Session Border Controller is configured with sets of H.323 interfaces within it. These interfaces are internal (for an internal provider) and external (for the external providers you see).

Overview

Using H.323 on your Oracle Communications Session Border Controller, you can implement different signaling modes and use features to enhance H.323 capabilities. In the information that follows, you will find detailed explanations of the H.323 signaling mode and of the features available. This chapter gives operational details and later outlines the steps you need to take when features require configuration.

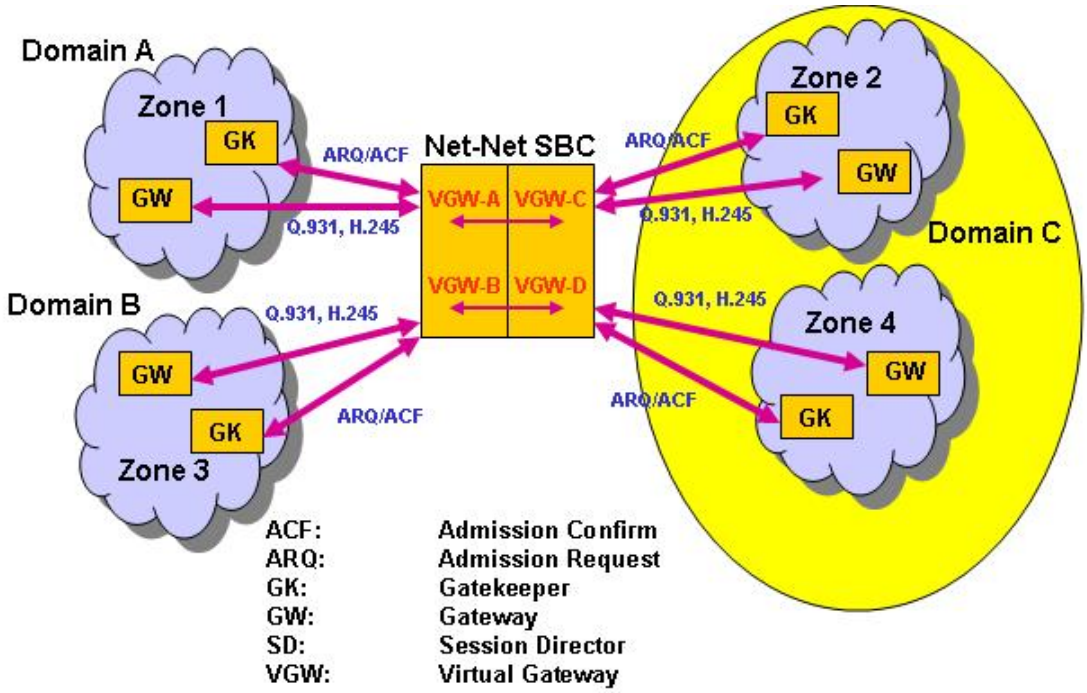
Signaling Modes of Operation

Your Oracle Communications Session Border Controller can operate in different H.323 signaling modes:

- Back-to-back gateway signaling
- Back-to-back gatekeeper proxy and gateway
- Interworking gatekeeper/gateway

Back-to-Back Gateway Signaling

This section explains how signaling takes place when the Oracle Communications Session Border Controller functions as a B2BGW for H.323. The following diagram illustrates the Oracle Communications Session Border Controller acting as a B2BGW.



When configured as a B2BGW, the Oracle Communications Session Border Controller appears as multiple H.323 gateways to multiple networks. You can think of the Oracle Communications Session Border Controller as having virtual gateways, that discovers and registers with a gatekeeper in its respective domain. In this configuration, you need to set the service mode (**isgateway**) parameter for the H.323 interface to enabled for two H.323 interfaces. These interfaces are related either through their outgoing interface (**assoc-stack**) parameters or through routing policies.

If you configure your Oracle Communications Session Border Controller to operate in this mode, it does not issue or respond to LRQs by either confirming them or rejecting them.

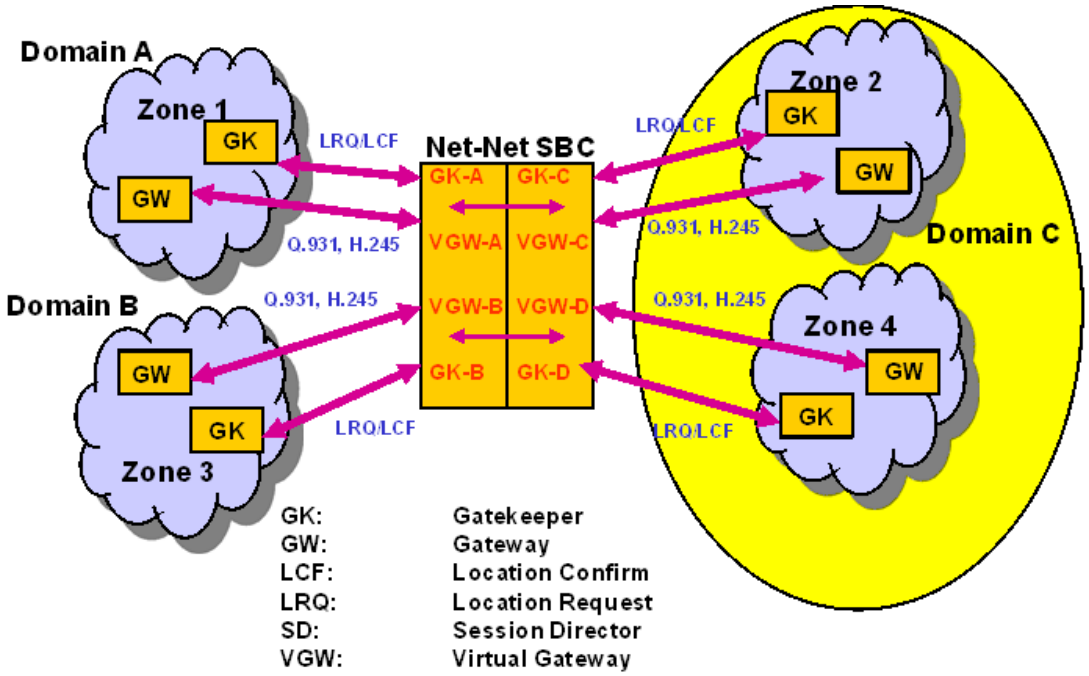
In the diagram above, the Oracle Communications Session Border Controller sends ARQs to the corresponding gatekeeper in its zone when a call is received on the associated interface. In this behavior, the Oracle Communications Session Border Controller acts as a gateway, complying with the H.323 standard, and registers with the configured gatekeeper in its assigned zone. You set all parameters related to the gateway registrations, such as gateway prefix numbers, in the H.323 interface configuration.

In this mode, you can also configure the Oracle Communications Session Border Controller to run like a gateway without a gatekeeper by turning off automatic discovery (auto-gk-discovery) for the remote gatekeeper. When the Oracle Communications Session Border Controller receives a Setup message, it does not send an ARQ and there is no registration for admission requests. Without automatic gateway discovery, the Oracle Communications Session Border Controller uses the local policy to find the appropriate destination for the call. This destination is normally the IPv4 address of the endpoint or gateway, using the well-known port 1720.

If you enable this capability, then the Oracle Communications Session Border Controller finds a gatekeeper.

Back-to-Back Gatekeeper Proxy and Gateway

This section explains how signaling takes place when the Oracle Communications Session Border Controller functions as a back-to-back gatekeeper proxy and gateway for H.323. The following diagram illustrates theOracle Communications Session Border Controller acting as a B2B gatekeeper proxy and gateway.



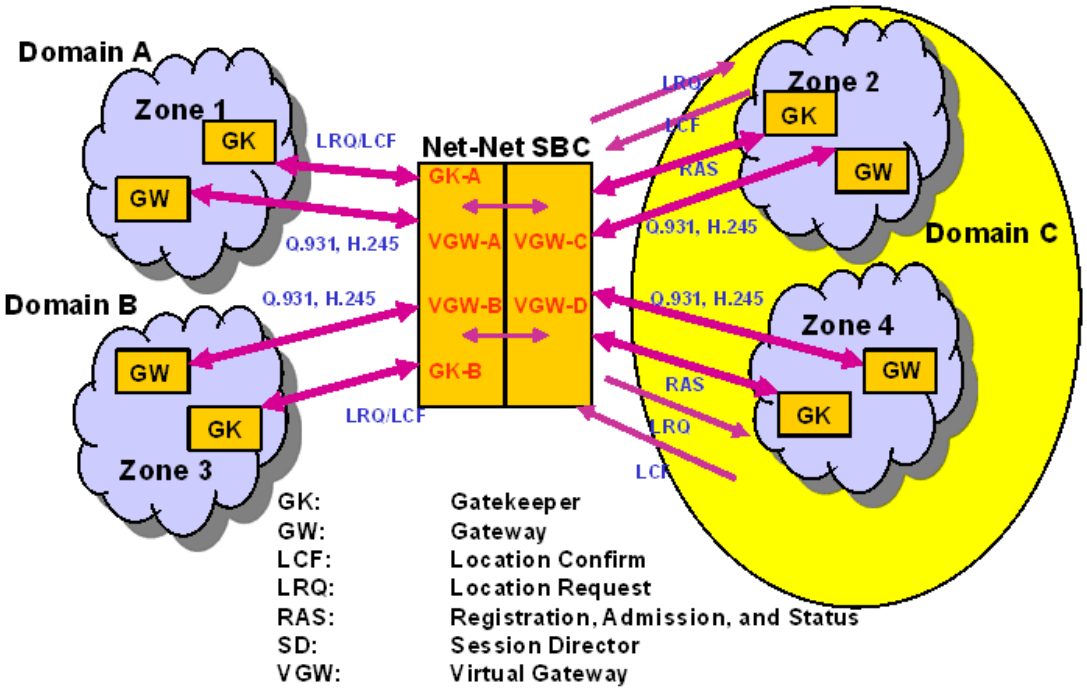
In this application, with the service mode (**isgateway**) parameter set to disabled, the Oracle Communications Session Border Controller responds to LRQs and issues LCFs and LRJs. It sends LRQs and LCFs/LRJs to the local IPv4 address for the H.323 interface. The Oracle Communications Session Border Controller responds to the LRQs by providing a signaling address that performs gateway functions.

When you use it as a back-to-back gatekeeper proxy and gateway, the Oracle Communications Session Border Controller does not issue ARQs. In addition, all parameters related to registration, such as gateway prefix numbers, are ignored.

When you do not configure a gatekeeper, the Oracle Communications Session Border Controller uses the local policy to find the appropriate destination for the call. If there is a matching local policy, the Oracle Communications Session Border Controller returns an LCF to the originating gateway. If no local policy matches, the Oracle Communications Session Border Controller rejects the call by sending an LRJ.

Interworking Gatekeeper-Gateway

This section explains how signaling takes place when the Oracle Communications Session Border Controller functions as an interworking gatekeeper-gateway for H.323. The following diagram shows the Oracle Communications Session Border Controller acting as an interworking gatekeeper-gateway.



When you configure your Oracle Communications Session Border Controller for interworking gatekeeper-gateway mode, one H.323 interface behaves as a B2BGW and its associated interface for the corresponding network behaves like a gatekeeper proxy and gateway. The interface for the gatekeeper proxy and gateway issues and responds to LRQ messages on its network. If the Oracle Communications Session Border Controller knows the gatekeeper in the network of the gateway interface (Zone 2), it sends an LRQ to that gatekeeper. If the gatekeeper responds with an LCF or LRJ, the Oracle Communications Session Border Controller forwards it.

If the gatekeeper (in Zone 2) is unknown, then the Oracle Communications Session Border Controller responds to LRQs on the gatekeeper-gateway network (Zone 1) by using the local policy to determine the appropriate destination for the LRQ. If there is no local policy that matches, then the Oracle Communications Session Border Controller sends an LRJ.

For this configuration, the gateway interface has its service mode (**isgateway**) set to enabled, and the gatekeeper interface has its service mode (**isgateway**) set to disabled.

Realm Bridging with Static and Dynamic Routing

The Oracle Communications Session Border Controller uses static routing and policy-based, dynamic routing to handle H.323 traffic. These types of routing have to do with the way that the outgoing stack is selected.

- Static routing—The incoming H.323 stack always uses the associated H.323 stack that you configure for outgoing traffic; no other stacks are considered.
- Dynamic routing—When there is not an associated stack configured, the Oracle Communications Session Border Controller performs policy-based, dynamic routing known as realm bridging. In this type of realm bridging, the Oracle Communications Session Border Controller checks the configured local policies for address information corresponding to the incoming traffic and finds an address that matches. Next, it checks the next hop in the local policy to determine a realm and uses the first H.323 interface that matches it.

Before You Configure

In order to run H.323 on your Oracle Communications Session Border Controller, you need to configure the basic parameters: physical and network interfaces; global system parameters; SNMP, trap receiver, and accounting support, and any holiday information you might want to set.

You should also decide how you want to set up realms and routing (including the use of session agents and session agent groups) to support H.323 operations.

Global H.323 Settings

When you configure H.323 signaling for your Oracle Communications Session Border Controller, you set global and per-interface parameters. The global parameters govern how the Oracle Communications Session Border Controller carries out general H.323 operations, and these settings are applied to all interfaces you configure for H.323 use. For example, you can turn H.323 support on and off for the entire Oracle Communications Session Border Controller using these settings.

Global H.232 Settings Configuration

For the ACLI, global H.323 parameters are:

```
state          State of the H.323 protocol
log-level      Log level for H.323 stacks
response-tmo   maximum waiting time in sec for response to a SETUP message
connect-tmo    maximum waiting time in sec for establishment of a call
options        optional features/parameters
```

Accessing Global H.323 Parameters

To access the global H.323 configuration parameters in the ACLI:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# h323
   ```

   From this point, you can configure global H.323 parameters. To view all H.323 configuration parameters, enter a **?** at the system prompt. Access to the H.323 interface (**h323-stack**) configuration also appears.

Global H.323 Settings

To configure global H.323 parameters:

1. **state**—Enable or disable the state of H.323 signaling. The default value is **enabled**. Valid values are:
   - enabled | disabled
2. **response-tmo**—Enter the amount of time in seconds that the Oracle Communications Session Border Controller waits between sending a Setup message and tearing it down if there is no response. The default value is **4** and we recommend you leave this parameter set to this value. The valid range is:
   - Minimum—0
   - Maximum—999999999

   A response might be any of the following messages: Call Proceeding, Connect, or Alerting.
3. **connect-tmo**—Enter the amount of time in seconds that the Oracle Communications Session Border Controller waits between sending a Setup message and tearing it down if it does not specifically receive a Connect message from the endpoint. The default is **32** and we recommend that you leave this parameter set to this value. The valid range is:
   - Minimum—0
   - Maximum—999999999

   Receiving a Proceeding or Alert message from the endpoint does not keep this timer from expiring.
4. **options**—Set any options for H.323 features that you want to use. This parameter has a global impact on H.323 behavior, rather that being applied on a per-interface basis.

   If you do not configure options for global H.323 behavior, none appears in the configuration display.
5. **log-level**—Set the process log level for monitoring all H.323 activity on the Oracle Communications Session Border Controller. The default is **INFO** and leaving this parameter set to this value provides an intermediate amount of detail in the logs. Other valid values are:

> **Note:**
>
> Any log level you set here overrides the log level you set in the system configuration's process log level parameter.

Numerical Code	Acme Packet Log Enumeration	Description
1	EMERGENCY	Logs conditions of the utmost severity that require immediate attention.
2	CRITICAL	Logs events of serious condition that require attention as soon as possible.
3	MAJOR	Logs conditions indicating that functionality is seriously compromised.

Numerical Code	Acme Packet Log Enumeration	Description
4	MINOR	Logs conditions indicating that functionality has been impaired in a minor way.
5	WARNING	Logs conditions indicating irregularities in performance.
6	NOTICE	For Acme Packet customer support.
7	INFO	
8	TRACE	
9	DEBUG	

H.323 Interfaces

You need to configure H.323 interfaces for inbound and outbound traffic. When you configure H.323 interfaces, you can set:

- Identity and state
- Realm and H.323 interface associations
- H.323 interface settings for the interface's IPv4 address, RAS and Q. 931 ports, maximum number of Q.931 ports to allow, and any Annex E support you need
- H.323 system resource allocation

H.232 Interfaces Configuration

These are the ACLI parameters that you set:

```
name                 Name of the stack
state                State of the stack
isgateway            Enable the stack to run as a gateway
terminal-alias       List of aliases for terminal
ras-port             Listening port for RAS request
gk-identifier        Gatekeeper's identifier
q931-port            Q.931 call signalling port
alternate-transport  Alternate transport addresses/ports
q931-max-calls       Maximum number of Q.931 calls
max-calls            Stack's maximum number of calls
max-channels         Maximum number of channels per channel
```

To access the H.323 interface (h323-stack) and service mode parameters:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

```
ORACLE(session-router)# h323
```

4. Type **h323-stacks** and press Enter.

```
ORACLE(h323)# h323-stacks
ORACLE(h323-stacks)#
```

From this point, you can configure H.323 interface and service mode parameters. To view all H.323 interface parameters, enter a **?** at the system prompt. The display also includes H.323 service mode parameters.

Identity and State

To set the identity and state of the H.323 interface:

1. **name**—Enter a name for the H.323 interface using any combination of characters entered without spaces. For example: InternalGK1.
2. **state**—Enter the state of this H.323 interface. The default value is **enabled**. Valid values are:
   - enabled | disabled

Realm and Interface Associations

To link this H.323 interface to a realm and to an outgoing H.323 interface:

1. **realm-id**—Enter the identifier for the realm served by this H.323 interface. This parameter must be configured with a valid identifier value from a realm configuration.
2. **assoc-stack**—Enter the name of the outgoing H.323 interface that you want to associate with the H.323 interface you are configuring. To use realm bridging with static routing, you need to set the outgoing H.323 interface. If you do not enter a name, the Oracle Communications Session Border Controller uses dynamic, policy-based selection using the local policy.

H.323 Signaling Interface Settings

You can set the following parameters to define basic settings for your H.323 interface. This is where you set the IPv4 address for opening sockets, the RAS and Q.931 ports, and the maximum number of Q.931 calls that you want to allow.

This is also where you establish Annex E alternate transport. Annex E supports multiplexed call signaling over UDP so that call volume and performance are potentially enhanced. If you do not configure Annex E support, then this H.323 interface does not listen for Annex E requests.

To configure H.323 interface settings:

1. **local-ip**—Enter the IPv4 address that the H.323 interface uses when opening sockets; this is the default H.323 interface IPv4 address. You must use a valid IPv4 address. For example: 192.168.2.5. The default value is **0.0.0.0**.
2. **ras-port**—Enter the number of the port on the local IPv4 address (**local-ip**) on which the Oracle Communications Session Border Controller listens for RAS requests. We

recommend that you set this parameter to its default, the well-known port **1719**. The valid range is:

- Minimum—0
- Maximum—65535

  If you set this parameter to **0**, the Oracle Communications Session Border Controller uses a port assigned by the operating system.

3. **q931-port**—Enter the number for the port on the local IP address for the Q.931 call signaling port. We recommend that you leave this parameter set to its default, **1720**. The valid range is:
   - Minimum—0
   - Maximum—65535
4. **q931-max-calls**—Enter the maximum number of concurrent Q.931 calls you want to allow. The default value is **200**; however, this value should be less than the maximum number of calls you set when configuring H.323 features. The valid range is:
   - Minimum—0
   - Maximum—65535

     If the number of received Q.931 calls exceeds this number, the H.323 interface returns a busy state.
5. **alternate-transport**—Enter a list of one or more Annex E IPv4 address and port combinations for alternate transport. If you do not configure this list, then the Oracle Communications Session Border Controller does not listen for incoming Annex E requests. You must enter the IPv4 address and port combination in the following format, where the two are separated by a colon: **IPv4Address:Port**.

H. 323 System Resource Allocation

You can set the following parameters to determine how many concurrent calls and concurrent channels you want to allow for each H.323 interface.

To allocate H.323 system resources:

1. **max-calls**—Enter the maximum number of concurrent calls allowed on this H.323 interface. The default value is **200**. The valid range is:
   - Minimum—0
   - Maximum—4294967295
2. **max-channels**—Enter the maximum number of concurrent channels allowed for each call associated with this H.323 interface. The default value is **6**. The valid range is:
   - Minimum—0
   - Maximum—4294967295

     The Oracle Communications Session Border Controller checks this parameter on initialization to reserve the appropriate network resources.

H.323 Service Modes

When you set the H.323 service mode, you configure parameters that define what type of service an H.323 interface provides. These parameters govern how the interface functions when you want it to behave as a gatekeeper or as a gateway.

This is also where you set options that support particular H.323 features for a specific interface. These options are different from the ones you set in the global H.323 configuration because they apply only to the interface where you specify them.

H.232 Service Modes Configuration

These are the ACLI parameters that you set:

```
isgateway             Enable the stack to run as a gateway
registration-ttl      Number of seconds before the registration becomes
invalid
terminal-alias        List of aliases for terminal
auto-gk-discovery     Enable automatic gatekeeper discovery
multicast             RAS multicast address
gatekeeper            Gatekeeper's address and port
gk-identifier         Gatekeeper's identifier
h245-tunneling        Enable H.245 Tunneling support
prefixes              List of supported prefixes
process-registration  Enable Registration Request processing
allow-anonymous       allowed requests from H.323 realm
```

To configure the service mode for the H.323 interface:

1. **allow-anonymous**—Enter the admission control of anonymous connections from an H.323 realm accepted and processed by this H.323 stack. The default value is **all**. The valid values are:
   - **all**—Allow all anonymous connections
   - **agents-only**—Allow requests from session agents only
   - **realm-prefix**—Allow session agents and addresses matching the realm prefix
2. **is-gateway**—To use this interface as an H.323 gateway, leave this parameter set to **enabled**, its default value. If you want to use this interface as an H.323 gatekeeper, set this parameter to **disabled**. Valid values are:
   - enabled | disabled
3. **terminal-alias**—Enter a list of one or more aliases that identify the H.323 interface. This value is either the gateway alias or the gatekeeper identifier, depending on the mode you configure for the interface. The aliases are set in the sourceInfo information element of outgoing ARQs.

Configuring Gateway Only Settings

If you are using the H.323 interface as a gateway, you might want to set registration time-out and address prefix parameters.

To configure gateway only settings:

1. **registration-ttl**—Enter the number of seconds before a registration becomes invalid. This value is used during the initial registration process. However, when a registration is confirmed, the time-to-live (TTL) value set by the gatekeeper in the Registration Confirm (RCF) message overrides this value. The default value is **120**. The valid range is:
   - Minimum—0
   - Maximum—4294967295

2. **prefixes**—Enter a list of prefixes for this H.323 interface. Possible prefix types include:

   - H.323 ID | E.164 | URL | IPv4 address

     These prefixes are sent from a gateway interface to a gatekeeper and indicate valid prefixes accepted by that interface for incoming calls. They are used if the interface is configured as a gateway (the **is-gateway** parameter is set to enabled).

     Your entries for this parameter must appear as they do in the following example:

     ```
     e164=17817566800 url=http://www.companyname.com
     h323-ID=xyz email=user@companyname.com
     ipAddress=63.67.143.4:2000
     ```

Gatekeeper Proxy Settings

If you are using the H.323 stack as a gatekeeper proxy, you might want to set:

- Whether registration processing is enabled or disabled
- Whether or not this H.323 interface is signaling-only
- At what H.225 call stage the H.245 procedures should be initiated

To configure gatekeeper proxy settings:

1. **process-registration**—To have the Oracle Communications Session Border Controller drop all RRQs, meaning that it does not acknowledge any requests, leave this parameter set to **disabled**, its default. To have the Oracle Communications Session Border Controller process any RRQs that arrive on this H.323 interface, set this parameter to **enabled**. Valid values are:

   - enabled | disabled

     When registration processing is enabled and the Oracle Communications Session Border Controllerreceives an RRQ on this H.323 interface, it will route the request to the appropriate gatekeeper. After the gatekeeper confirms that registration with an RCF, the Oracle Communications Session Border Controller also confirms it with the endpoint that sent the RRQ. Then the registration becomes part of the Oracle Communications Session Border Controller's registration cache. If this endpoint does not confirm the registration, then the Oracle Communications Session Border Controller will reject the registration with an RRJ and will not cache it.

2. **proxy-mode**—Set this field to the proxy mode that you want to use for the signaling only operation mode. Valid values are:

   - H.225 | H.245

     You can leave this field blank (default) if you are not using a proxy mode.

3. **h245-stage**—Set this field to the stage at which the Oracle Communications Session Border Controller transfers the H.245 address to the remote side of the call, or acts on the H.245 address sent by the remote side. The default value is **connect**. Valid values are:

   - Setup | Alerting | Connect | Proceeding | Early | Facility | noh245 | Dynamic

H.323 Features

This section provides general descriptions of the H.323 features available on the Oracle Communications Session Border Controller and instructs you in how to configure them. Not all of the features described in that chapter require configuration.

Fast Start Slow Start Translations

The Oracle Communications Session Border Controller can translate between Fast Start H.323 endpoints and Slow Start H.323 endpoints. Using this feature, you can reduce delay in establishing media, improve performance, and reduce network congestion caused by a high number of messages being exchanged. Fast Start and Slow Start calls handle information about media for a session in different ways. In a Fast Start call, information about the media is contained in the Setup message. In a Slow Start call, that information is exchanged between endpoints after the session has been established.

When you Fast Start/Slow Start translation, the Oracle Communications Session Border Controller can take a Slow Start call from an H.323 endpoint that does not support Fast Start and re-initiate that call as Fast Start. It also allows an H.323 endpoint that does not support Fast Start to receive a Slow Start call from a Fast Start source because the Oracle Communications Session Border Controller performs all necessary translations.

For the ACLI, the following parameters apply:

```
fs-in-first-msg       Fast Start must be sent in 1st response to Setup message
call-start-fast       Enable outgoing Fast Start call

Fast Start to Slow Start Translation

The Oracle Communications Session Border Controller supports translations from H.323 Fast Start to Slow Start. Using this feature, an H.323 endpoint that only supports Slow Start can call from a Fast Start source when that call goes through the Oracle Communications Session Border Controller.

In a Fast Start call, the originating H.323 endpoint sends a fastStart element in its Setup message. This element contains H.245 OLC messages that allow Fast Start endpoints to establish a media stream when the call is connected. As a result fewer messages are exchanged between the H.323 endpoints than there would be for a Slow Start call (where the fastStart element does not appear). Because media information is sent in the Setup request for the session, there is no need to use the media profiles when converting a Fast Start call to Slow Start.

When you enable the slow start option in the H.323 stack configuration, the Oracle Communications Session Border Controller performs Fast Start to Slow Start conversion. During the translation, the Oracle Communications Session Border Controller retains the media information included in the incoming Fast Start call as it negotiates a connection with the Slow Start endpoint. After a connection with the Slow Start endpoint has been established, the Oracle Communications Session Border Controller negotiates the media capabilities.

Slow Start to Fast Start Translation

When you configure your Oracle Communications Session Border Controller to support H.323 Slow Start to Fast Start translations, you enable an H.323 endpoint that only supports Slow Start to initiate and sustain communication with an H.323 Fast Start endpoint. The Oracle Communications Session Border Controller resolves the Slow Start limitation of exchanging information about media (OLC messages) after the call is connected. The OLC message opens a logical channel, or a unidirectional or bi-directional path used to transmit media packets. Using the Oracle Communications Session Border Controller, you can negotiate the construction of media flows differently, which is described in this section.

When you enable the Fast Start option for calls in the H.323 stack configuration, the Oracle Communications Session Border Controller performs the translation of a Slow Start call into Fast Start. When it receives a Slow Start call, the Oracle Communications Session Border Controller determines its destination and the H.323 stack it uses for the outgoing call.

It is a requirement of this kind of translation that you configure and use media profiles. Since a Slow Start call does not negotiate media until after the call is connected, there needs to be an assumption made about the media to set up a Slow Start to Fast Start call. Media profiles fill this role, and they are assumed to be part of a correct configuration.

The following describes possible scenarios for Slow Start to Fast Start translations.

- When a Slow Start call arrives at the Oracle Communications Session Border Controller and matches one of the session agents that has a media profiles list configured, the outgoing call is set up as a Fast Start call. The session agent's media profiles are used for the logical channels. You must configure the media profiles to reference a codec the endpoint accepts.
  If there are no media profiles configured for the session agent, then the Oracle Communications Session Border Controller uses the media profiles list in the H.323 stack configuration to open the logical channels.
- If a Slow Start calls arrives at the Oracle Communications Session Border Controller and its destination does not match one of the session agents, the Oracle Communications Session Border Controller uses the media profiles list in the H.323 stack configuration for the outgoing call. If there is a list of media profiles, the outgoing call is set up as a Fast Start call with the media profiles list used to open the logical channels.
  If there is no list of media profiles for the outgoing H.323 interface, the Oracle Communications Session Border Controller does not perform Slow Start to Fast Start translation. The Slow Start call exits the Oracle Communications Session Border Controller as it arrived—as a Slow Start call.
- If the egress H.323 interface has the Fast Start option disabled, then the outgoing call uses the Slow Start mode, and the Oracle Communications Session Border Controller does not perform Slow Start to Fast Start translation. In this case, the Slow Start call also exits the Oracle Communications Session Border Controller as it arrived—as a Slow Start call.

Slow Start Fast Start Prerequisites

To perform Fast Start/Slow Start translations, you need to have a standard two-interface configuration already in place.

If you are using the Slow Start to Fast Start translations, you must configure appropriate entries in the media profiles list which is part of the translation parameters. The Fast STart/Slow Start Translations section of the Oracle Communications Session Border Controller Feature chapter describes how the media profiles are used. The list contains the names of media profiles that you configure in the media profile configuration.

Some media profiles are configured by default. If the information you have configured for a media profile does not match up with the defaults, your configuration takes precedence. If there are no configuration overlaps, then the Oracle Communications Session Border Controller loads the configured and default profiles. The default media profiles are:

Type	Payload	Encoding	Bandwidth
audio	0	PCMU	0
audio	2	G726-32	0
audio	4	G723	0
audio	8	PCMA	0

Type	Payload	Encoding	Bandwidth
audio	9	G722	0
audio	15	G728	0
audio	18	G729	0
audio	101	telephone-events	0

Ensure that you use the name of a configured media profile when you enter values in the media profiles list.

Media Profile Configuration

In the ACLI, you can set media profiles that are required for translating H.323 Slow Start to Fast Start. In the ACLI, you set the following:

```
name                encoding name used in sdp rtpmap attribute
media-type          media type used in sdp m lines
payload-type        rtp payload type used in sdp m lines
transport           transport protocol used in sdp rtpmap attribute
req-bandwidth       amount of bandwidth in kilobits required
frames-per-packet   maximum number of frames per packet
parameters          list of <name=value> pairs separated by space
average-rate-limit average rate limit of rtp flow
```

To configure a media profile:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **media-profile** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# media-profile
   ```

   From this point, you can configure media profiles parameters. To view all media profiles configuration parameters, enter a **?** at the system prompt.

4. **name**—Enter the encoding name used in the SDP rtpmap attribute. You must enter a name to uniquely identify the media profile, and you will use this value to make lists of media profiles in H.323 interface configurations.
5. **media-type**—Leave this parameter set to its default, **audio**. Valid values are:
   - audio | video | application | data | image | text
6. **payload-type**—Enter the payload type number that corresponds to the encoding name you entered in Step 4. This value identifies the format in the SDP m lines. There is no default value for this parameter. The About Payload Types section contains a table of standard audio and visual encodings.

> **Note:**
>
> When you use the RTP/AVP transport method, this value must be numeric.

7. **transport**—Enter the type of transport protocol used in the SDP rtpmap attribute. The default is **RTP/AVP**. Valid values are:
   - RTP/AVP | UDP
8. **req-bandwidth**—Enter the total bandwidth in kilobits that the media requires. The default value is **0**. The valid range is:
   - Minimum—0
   - Maximum—4294967295
9. **frames-per-packet**—Enter the maximum number of frames to use per RTP packet. Leaving this parameters set to **0**, its default value means that it is not being used. The valid range is:
   - Minimum—0
   - Maximum—256

     The interpretation of this value varies with codec type and with specific codec.
   - For frame-based codecs, the frame size is specific to each. For example, a G.729 frame contains ten milliseconds of audio, while a G.723.1 codec frame contains thirty milliseconds.
   - For sample-based codecs such as G.711, each frame contains one millisecond of audio.
10. **parameters**—Enter additional codec information. For example, the G.723.1 codec can have an additional silenceSuppression parameter.
11. **average-rate-limit**—Enter the maximum speed in bytes per second for the flow that this media profile applies to. The default value is **0**. The valid range is:
    - Minimum—0
    - Maximum—125000000
12. **peak-rate-limit**—Enter the peak rate for RTP flows in bytes per seconds. The default is **0**. The valid range is:
    - Minimum—0
    - Maximum—125000000
13. **max-burst-size**—Enter the maximum data size at peak rate in bytes. The default is **0**. The valid range is:
    - Minimum—0
    - Maximum—125000000
14. **sdp-bandwidth**—Enable this parameter to use the AS bandwidth modifier in the SDP in the conditions for the application specific bandwidth modifier. The default is **disabled**. Valid values are:
    - enabled | disabled
15. **sdp-rate-limit-headroom**—Specify the percentage of headroom to be added while using the AS bandwidth parameter while calculating the **average-rate-limit** (rate limit for the RTP flow). The default is **0**. The valid range is:

- Minimum—0
- Maximum—100

Fast Start/Slow Start Configurations

When you configure an H.323 interface, you configure it for either Fast Start to Slow Start translation or for Slow Start to Fast Start translation. You cannot configure one H.323 interface for both translation modes.

In the ACLI, you will set the following:

```
fs-in-first-msg       Fast Start must be sent in 1st response to Setup message
call-start-fast       Enable outgoing Fast Start call
call-start-slow       Enable outgoing Slow Start call
media-profiles        list of default media profiles used for outgoing call
```

To configure H.323 interfaces for Fast Start/Slow Start translations:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stacks** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stacks)#
   ```

   From this point, you can configure H.323 interface and service mode parameters. To view all H.323 interface parameters, enter a **?** at the system prompt. The display also includes H.323 service mode parameters.

5. **fs-in-first-msg**—Enable this parameter if you want to include Fast Start fields in the first message that the Oracle Communications Session Border Controller uses to respond to a Setup message. Usually, the first message sent is a Proceeding message If you do not want Fast Start fields included, leave this parameter set to its default value **disabled**. Valid values are:

   - enabled | disabled

6. **call-start-fast**—Enable this parameter if you want Slow Start calls to be translated to Fast Start when this H.323 interface is chosen as the outgoing interface. If this parameter is **enabled**, **call-start-slow** has to remain disabled. The default value is **enabled**. Valid values are:

   - enabled | disabled

     If you set this parameter set to disabled (default), the outgoing call will be set up in the same mode as the incoming call.

7. **call-start-slow**—Enable this parameter if you want Fast Start calls to be translated to Slow Start when this H.323 interface is chosen as the outgoing interface. If this parameter is **enabled**, **call-start-fast** has to remain disabled. The default value is **disabled**. Valid values are:

   - enabled | disabled

     If you leave this parameter set to **disabled**, the outgoing call will be set up in the same mode as the incoming call.

8. **media-profiles**—Enter the list of media profiles that you want to use when translating Slow Start calls to Fast Start. This information is used to open logical channels for the outgoing call.

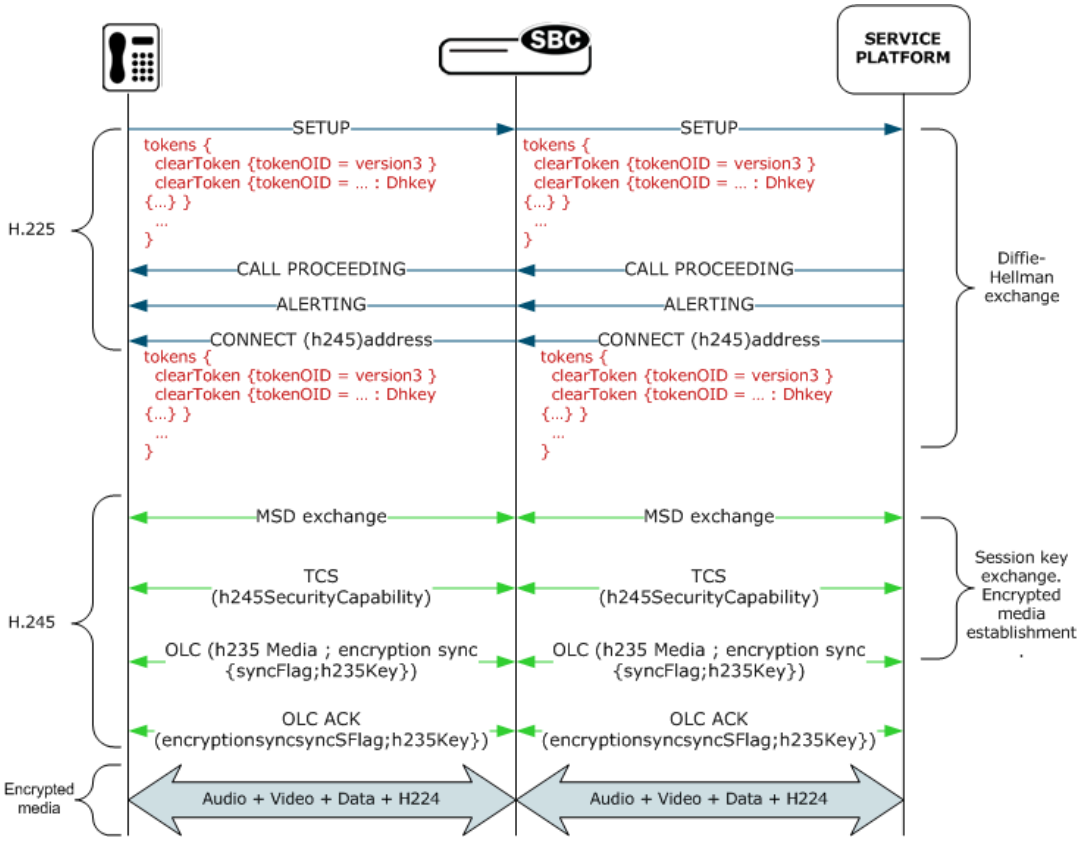
   If you enter the name of a media profile that does not exist, the Oracle Communications Session Border Controller will not perform translation. If you leave this parameter empty, the Oracle Communications Session Border Controller will not perform translation.

H.235 Encryption

Following the ITU-T H.235 encryption standard, the Oracle Communications Session Border Controller allows media (audio, video, and data) media that has already been encrypted by endpoints to pass through it, thereby supporting videoconferencing applications where media confidentiality is key. The ITU-T standard provides a profile with key management using Diffie-Hellman keys and the specification of an encryption algorithm.

Specifically, the Oracle Communications Session Border Controller permits the following:

- H.225 Setup and connect—The tokens parameter and its subfields in H.225 Setup and Connect message to pass transparently through the Oracle Communications Session Border Controller
- H.245Teminal CapabilitySet—The H.245 TerminalCapabilitySet messages to pass transparently through the Oracle Communications Session Border Controller, including:
  - Audio, video, and data capabilities
  - The h235SecurityCapability capability
- H.245 OpenLogicalChannel and OpenLogicalChannelAck—OLC messages with dataType h235Media to pass transparently through the Oracle Communications Session Border Controller; to accomplish this, the Oracle Communications Session Border Controller uses the mediaType subfield instead of the dataType field when the dataType is h235Media. The encryptionSync parameter and its subfields found in OLC and OLCAck messages to pass transparently through the Oracle Communications Session Border Controller.



You do not need to follow special configuration steps to enable this functionality; it works automatically.

RFC 2833 DTMF Interworking

This section explains the Oracle Communications Session Border Controller's support of transporting Dual Tone Multi-Frequency (DTMF) in Real-Time Transport Protocol (RTP) packets (as described in RFC 2833) to H.245 User Input Indication (UII).

Multimedia devices and applications must exchange user-input DTMF information end-to-end over IP networks. The Oracle Communications Session Border Controller provides the interworking capabilities required to interconnect networks that use different signaling protocols. Also, the Oracle Communications Session Border Controller provides DTMF translation to communicate DTMF across network boundaries.

The Oracle Communications Session Border Controller supports RFC 2833 to H.245 UII translation for H.323-to-H.323 calls, when one side is a version 4 H.323 device requiring RFC-2833 DTMF event packets, and the other side is a pre-version 4 H.323 device that only uses H.245 UII.

About RFC 2833

RFC 2833 specifies a way of encoding DTMF signaling in RTP streams. It does not encode the audio of the tone itself, instead a signal indicates the tone is being sent. RFC 2833 defines how to carry DTMF events in RTP packets. It defines a payload format for carrying DTMF digits used when a gateway detects DTMF on the incoming messages and sends the RTP payload instead of regular audio packets.

About H.245 UII

H.245 provides a capability exchange functionality to allow the negotiation of capabilities and to identify a set of features common to both endpoints. The media and data flows are organized in logical channels. H.245 provides logical channel signaling to allow logical channel open/close and parameter exchange operations. The H.245 signaling protocol is reliable, which ensures that the DTMF tones will be delivered.

H.245 User Input Indication (UII) plays a key role in all the services that require user interaction. For video messaging, typical uses of UII include selection of user preferences, message recording and retrieval, and typical mailbox management functions. H.245 UII provides two levels of UII, alphanumeric and signal.

About 2833 to H.245 UII Interworking

The Oracle Communications Session Border Controller provides 2833 to H.245-UII interworking by checking 2833-enabled RTP streams for packets matching the payload type number for 2833. It then sends the captured packet to the host for processing and translation to H.245 UII messages. A H.245 UII message received by the Oracle Communications Session Border Controller is translated to 2833 packets and inserted into the appropriate RTP stream.

About DTMF Transfer

DTMF transfer is the communication of DTMF across network boundaries. It is widely used in applications such as interactive voice response (IVR) and calling card applications.

The multiple ways to convey DTMF information for packet-based communications include:

- In-band audio: DTMF digit waveforms are encoded the same as voice packets. This method is unreliable for compressed codecs such as G.729 and G.723
- Out-of-band signaling events:
  H.245 defines out-of-band signaling events (UII) for transmitting DTMF information. The H.245 signal or H.245 alphanumeric methods separate DTMF digits from the voice stream and send them through the H.245 signaling channel instead of through the RTP channel. The tones are transported in H.245 UII messages.

  All H.323 version 2 compliant systems are required to support the H.245 alphanumeric method, while support of the H.245 signal method is optional.
- RTP named telephony events (NTE): uses NTE to relay DTMF tones, which provides a standardized means of transporting DTMF tones in RTP packets according to section 3 of RFC 2833.

Of the three RTP payload formats available, the Oracle Communications Session Border Controller supports RTP NTE.

RFC 2833 defines the format of NTE RTP packets used to transport DTMF digits, hookflash, and other telephony events between two peer endpoints. With the NTE method, the endpoints perform per-call negotiation of the DTMF transfer method. They also negotiate to determine the payload type value for the NTE RTP packets.

The NTE payload takes the place of codec data in a standard RTP packet. The payload type number field of the RTP packet header identifies the contents as 2833 NTE. The payload type number is negotiated per call. The local device sends the payload type number to use for 2833 telephone event packets using a SDP or H.245 Terminal Capability Set (TCS), which tells the other side what payload type number to use when sending the named event packets to the

local device. Most devices use payload type number 101 for 2833 packets, although no default is specified in the standard.

The 2833 packet's RTP header also makes use of the timestamp field. Because events often last longer than the 2833 packets sending interval, the timestamp of the first 2833 packet an event represents the beginning reference time for subsequent 2833 packets for that same event. For events that span multiple RTP packets, the RTP timestamp identifies the beginning of the event. As a result, several RTP packets might carry the same timestamp.

See RFC 2833 and draft-ietf-avt-rfc2833bis-07.txt for more information.

Preferred and Transparent 2833

To support preferred (signaled) 2833 and transparent 2833, the Oracle Communications Session Border Controller provides 2833 detection and generation (if necessary) when the endpoint signals support for 2833.

- Preferred: the Oracle Communications Session Border Controller only generates and detects 2833 for endpoints if they negotiate support for 2833 through signaling
- Transparent: the Oracle Communications Session Border Controller behaves as it has prior to this release, offering and answering based on end-to-end signaling and transparently relaying 2833

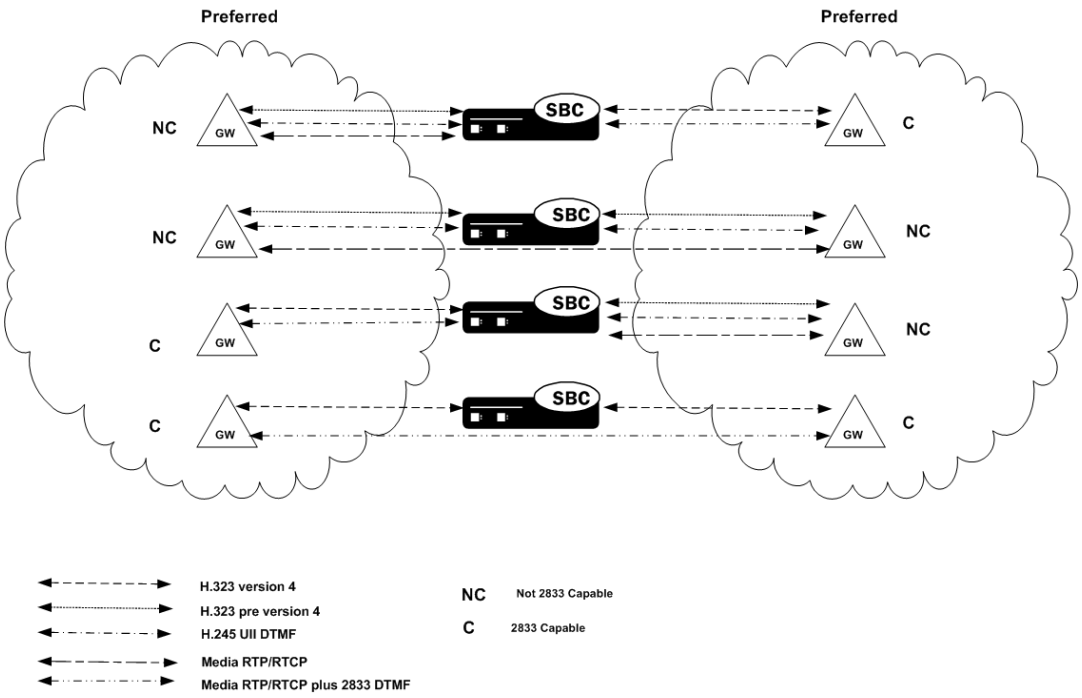
Preferred 2883 Support

If one side of the call, or a session agent, is configured for preferred 2833, the Oracle Communications Session Border Controller only generates and detects 2833 for endpoints if they signal support for 2833. The Oracle Communications Session Border Controller will offer 2833 in the TCS SDP, even if the originating caller did not.

- When the Oracle Communications Session Border Controller manages calls originating from a preferred source going to a preferred target, it:
  Performs 2833 translation for an endpoint when the originating side requests 2833 but the target does not negotiate 2833

  Allows 2833 to pass through if the originating side and target of the call are configured as preferred and negotiate 2833
- When the Oracle Communications Session Border Controller manages calls originating from a preferred source going to a transparent target, it:
  Performs 2833 translation when the originating side requests 2833 but the target is configured as transparent and does not negotiate 2833.

  Allows 2833 to pass through if the originating side and the target of the call are configured as transparent and negotiate 2833. The Oracle Communications Session Border Controller does not perform active translation because both ends support 2833.

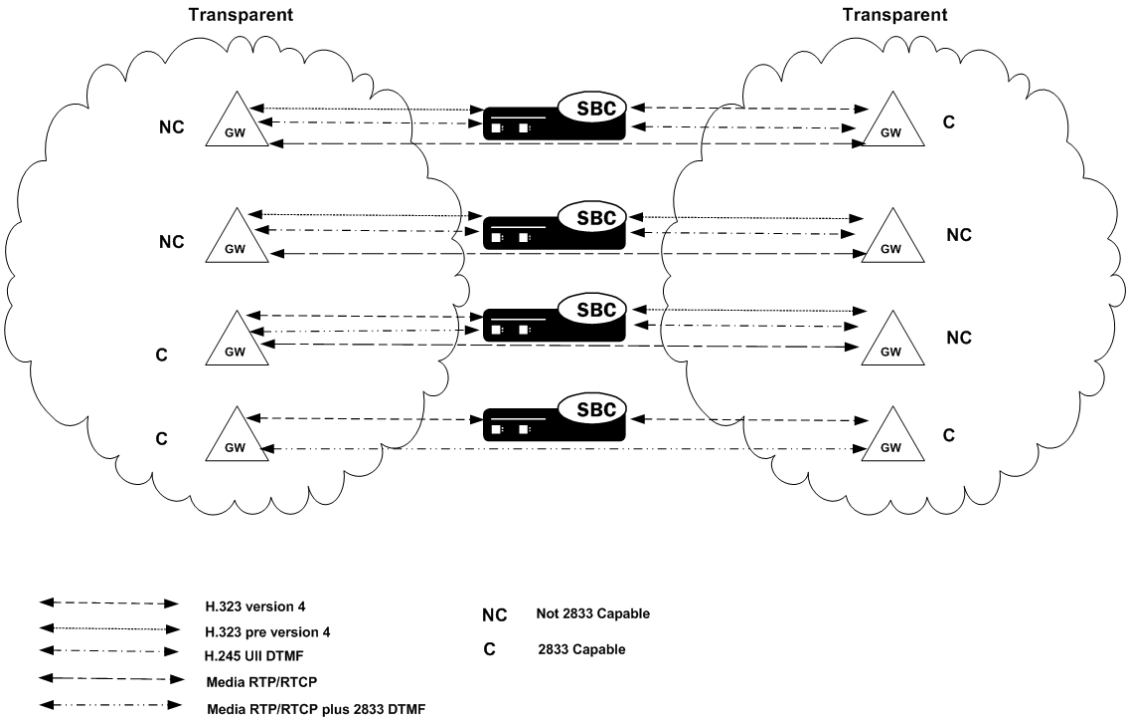


Transparent 2833 Support

The default configuration of the Oracle Communications Session Border Controller for H.323 is transparent 2833. The Oracle Communications Session Border Controller passes on the offered capabilities to the next-hop signaling element. If the next-hop endpoint is for a transparent 2833 target, typical capability negotiation determines the DTMF method. The Oracle Communications Session Border Controller transparently relays the DTMF as it has in previous releases.

With transparent 2833, the Oracle Communications Session Border Controller acts as a typical B2BUA or B2BGW/GK. However when the target of the call is configured as preferred 2833, the Oracle Communications Session Border Controller:

- Relays the 2833 packets if the originating endpoint signals 2833 and the next-hop endpoint for the preferred target signals 2833
- Performs 2833 translation if the originating endpoint does not signal 2833 and the next-hop endpoint for the preferred target does signal 2833
- Does not perform 2833 translation or transparently relay 2833 if the originating endpoint signals 2833 and the next-hop endpoint for the preferred target (or even a transparent 2833 target) does not signal 2833.



Basic RFC 2833 Negotiation Support

If H.323 or session agents on either side of the call are configured for preferred 2833 support, the Oracle Communications Session Border Controller supports end-to-end signaled negotiation of DTMF on a call-by-call basis. If the calling party is not configured for preferred support but sends 2833, the Oracle Communications Session Border Controller sends 2833 to the next-hop called party. If the calling party sends H.245 signals or alphanumeric UII, the Oracle Communications Session Border Controller sends H.245 signals or alphanumeric UII to the next-hop called party (if it is an H.323 next-hop).

The Oracle Communications Session Border Controller also supports hop-by-hop negotiation of DTMF capability on a call-by-call basis, if the signaling protocols or session agents on either side of the call are configured for preferred 2833 support.

H.323 to H.323 Negotiation

The Oracle Communications Session Border Controller serves as the H.323 called gateway. It answers RFC 2833 audio telephony event capability in the version 4 H.323/H.245 TCS when it receives a call from an H.323 endpoint configured for preferred RFC 2833.

If the Oracle Communications Session Border Controller is the answering device, configured for preferred support, and the calling device sends 2833, the Oracle Communications Session Border Controller accepts the 2833 regardless of the next-hop's DTMF capabilities. The received dynamic RTP payload type is used for detecting 2833 packets, while the response dynamic payload type is used for generating 2833 packets.

The Oracle Communications Session Border Controller supports:

- RFC-2833 audio telephony events in the version 4 H.323/H.245 TCS as the H.323 calling gateway, when the Oracle Communications Session Border Controller calls an H.323 endpoint configured for preferred RFC 2833 support. The Oracle Communications Session

Border Controller sends 2833 to the called party regardless of whether the calling party sends it.

- H.245 UII and RFC-2833 packets sent at the same time, to the same endpoint, even if only half of the call is being provided 2833 support by the Oracle Communications Session Border Controller.
  If one half of the call supports H.245 UII, and the other half is being provided 2833 translation by the system, the Oracle Communications Session Border Controller can also forward the H.245 UII it receives to the 2833 endpoint. For example, when the signaling goes through a gatekeeper or third party call control, sending the H.245 UII in the signaling path allows those devices to learn the DTMF digits pressed.

Signal and Alpha Type Support

The Oracle Communications Session Border Controller supports:

- H.245 signal and alpha type UII in the H.323/H.245 TCS as the H.323 calling gateway when the:
  Oracle Communications Session Border Controller calls an H.323 endpoint configured for transparent 2833 support

  calling endpoint's target is configured as preferred

  If the originating preferred side also sends 2833, the Oracle Communications Session Border Controller forwards it to the transparent side. The Oracle Communications Session Border Controller sends signal and alpha UII support to the called party regardless of whether the calling party sends it, if the call originates from a preferred side to a transparent side.
- H.245 alphanumeric UII for DTMF for H.323 endpoints that do not signal 2833 or contain explicit H.245 UII capability, for stacks configured for transparent 2833 support.
  When the other half of the call is an H.323 endpoint of a stack configured for preferred 2833, the Oracle Communications Session Border Controller translates incoming H.245 UII on the transparent side, to 2833 packets on the preferred side, and vice versa. If the other half of the call is an H.323 endpoint of a transparent stack, the Oracle Communications Session Border Controller relays the H.245 UII messages.
- H.245 signal type UII for DTMF for H.323 endpoints that do not signal 2833, but do signal explicit H.245 UII capability, for stacks configured for transparent 2833 support.
  When the other half of the call is an H.323 endpoint of a stack configured for preferred 2833, the Oracle Communications Session Border Controller translates incoming H.245 signaled UII on the transparent side, to 2833 packets on the preferred side, and vice versa. If the other half of the call is an H.323 endpoint of a transparent stack, the Oracle Communications Session Border Controller relays the H.245 UII messages if both sides support it.

H.323 Endpoints

Because there are different H.323 endpoints based on different versions of H.323, the DTMF can be either be transferred out-of-band as UII or in-band using RFC 2833. Most H.323 endpoints:

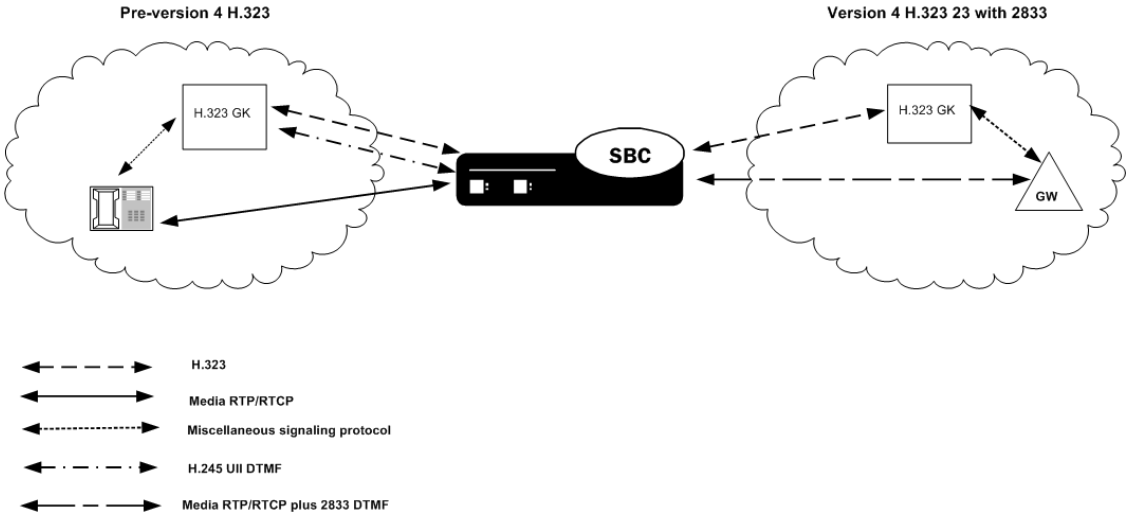
- version 4 and above support RFC 2833
- version 2 and pre-version 4 support UII-Signal
- version 1 and pre-version 2 support UII-Alphanumeric

Translating H.245 UII to 2833 for H.323 Calls

A majority of H.323 endpoints are not version 4 H.323 compliant and do not support RFC 2833 for DTMF transfer. However, some networks include version 4 H.323 devices that require the DTMF events to be signaled in 2833 packets. Network-based version 4 H.323 gateways use RFC 2833 instead of H.245 UII. (Version 4 H.323 devices should support H.245 UII.)

The Oracle Communications Session Border Controller translates 2833 to H.245 UII for H.323-to-H.323 calls when one side is a version 4 H.323 device requiring RFC-2833 DTMF event packets, and the other side is a pre-version 4 H.323 device which only uses H.245 UII.

The Oracle Communications Session Border Controller can translate H.245 UII to RFC2833 and back, based on the admin configuration and H.245 TCS exchanges. This translation enables DTMF to work end-to-end.



RFC 2833 Mode Configuration

To configure RFC 2833 mode:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stacks** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stack)#
   ```

From this point, you can configure H.323 stack parameters. To view all H.323 stack parameters, enter a **?** at the system prompt.

5. **rfc2833-mode**—Set the RFC2833 mode. The default value is **transparent**. The valid values are:
   - **transparent**:—The Oracle Communications Session Border Controller and H.323 stack behave exactly the same way as before and the 2833 or UII negotiation is transparent to the Oracle Communications Session Border Controller.
   - **preferred**—The H323 stack uses 2833 for DTMF transfer, which it signals in its TCS. However, the remote H323 endpoint makes the decision. If the endpoint supports 2833, 2833 is used. If not, the H.323 stack reverts back to using UII. You configure the payload format by configuring the h323-config element.

RFC 2833 Payload Configuration

To configure the RFC 2833 payload in preferred mode:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# h323
   ```

   From this point, you can configure global H.323 parameters. To view all H.323 configuration parameters, enter a **?** at the system prompt.

4. **rfc2833-payload**—Enter a number that indicates the payload type the Oracle Communications Session Border Controller will use for RFC 2833 packets while interworking 2833 and UII. The default value is **101**.The valid range is:
   - Minimum—96
   - Maximum—127

   You configure session agents with:
   - payload type the Oracle Communications Session Border Controller wants to use for RFC 2833 packets while interworking 2833 and UII.
     The default value for this attribute is **0**. When this value is zero, the global rfc2833-payload configured in the h323-configuration element will be used instead. For SIP session agents, the payload defined in the SIP interface is used, if the SIP interface is configured with the preferred RFC 2833 mode.
   - 2833 mode
     A value of transparent or preferred for the session agent's 2833 mode will override any configuration in the h323-stack configuration element.

RFC 2833 SA Configuration

To configure session agents:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

4. **rfc2833-mode**—Set the RFC 2833 mode you want the session agent to use. The default is **none**. The valid values are:
   - **none**—2833 to UII interworking is based on the H.323 stack configuration.
   - **transparent**:—The 2833 or UII negotiation is transparent to the Oracle Communications Session Border Controller. This overrides the H.323 stack configuration, even if the stack is configured for preferred mode.
   - **preferred**:—2833 for DTMF transfer is preferred, which is signaled in the TCS. If the endpoint supports 2833, 2833 is used. If not, the H.323 stack configured as preferred will revert back to using UII. This overrides any configuration in the h323-stack even if the stack is configured for transparent mode.
5. **rfc2833-payload**—Enter a number that indicates the payload type the session agent will use for RFC 2833 packets while interworking 2833 and UII. The default value is **0**. The valid range is:
   - Minimum—0, 96
   - Maximum—127

H.323 Registration Proxy

The Oracle Communications Session Border Controller provides a registration proxy feature that allows a gatekeeper to authenticate a registration before accepting it. This feature is key when two factors are present: authentication is required, and an RRQ from an endpoint includes a token and/or cryptographic token. If authentication for that endpoint is to work, the Oracle Communications Session Border Controller must forward the registration requests received from the endpoint to the gatekeeper separately.When you do not use the H.323 registration proxy, the Oracle Communications Session Border Controller combines all registrations received from H.323 endpoints into a single RRQ and sends it to the gatekeeper. Using the H.323 registration proxy, you can configure the Oracle Communications Session Border Controller to use separate forwarding.

When registration requests are forwarded separately, each RRQ must have a unique CSA. This means that the Oracle Communications Session Border Controller must perform a one-to-one translation of the CSA in the incoming RRQ to a distinct transport address. The translated address replaces the endpoint's CSA in the outgoing RRQ. Then the Oracle Communications Session Border Controller must listen for incoming calls that arrive at this translated transport address for the registered endpoint.

H.235 Authentication Transparency

When operating in this mode, H.235 authentication tokens (cryptotokens) in RAS messages proxied though the Oracle Communications Session Border Controller are passed through transparently.

For applications where Oracle Communications Session Border Controller is between H.323 gateways and a network hosted gatekeeper, the H.235 cryptotokens are passed through unmodified in RAS messages: RRQs, ARQs, and DRQs. This feature allows for secure gateway authentication.

Unique CSA Per Registered Gateway

When operating in this mode, each CSA is mapped to a registered gateway for call routing. The core gatekeeper does not support additive registrations, so a different CSA must be used for each unique registration that goes to the gatekeeper. The gatekeeper does not overwrite previously registered aliases. Also, since the gatekeeper initiates calls to an endpoint on the CSA specified in the RRQ, the Oracle Communications Session Border Controller must listen on the assigned address for incoming calls to that client as long as the client is registered.

Virtual Call Signaling Address

You can configure the Oracle Communications Session Border Controller with:

- A TCP port range for Q.931—Q.931 ports that are frontend ports handled by a real backend socket, and are therefore virtual
- ATCP port range for separate H.245 TCP connections—Actual sockets that the Oracle Communications Session Border Controller handles separately

Virtual call signaling address is an H.323 call signaling address that is registered with a gatekeeper, but does not have a corresponding listening socket in the Oracle Communications Session Border Controller. Using the virtual call signaling address means that numerous network transport addresses do not need to be allocated.

Virtual call signaling addresses work by attaching a range of TCP server ports to a single listening TCP socket. After a connection is accepted, the accepting socket created by the server socket operated normally, as though it were created by the server socket that listens on the same transport address as the destination of the arriving packet.

To use virtual call signaling addresses, you specify a Q.931 port range from which the Oracle Communications Session Border Controller can allocate ports. This port range is associated with the virtual call signal IPv4 address you specify. To bind dynamic TCP connections to aport within a port range, you configure a dynamic H.245 port range. The dynamic H.245 port range refers to the separate TCP connection for H.245 that takes place when tunneling is not being used. This enables the Oracle Communications Session Border Controller to select the port to which the TCP socket is bound. These two port ranges cannot overlap.

When a new RRQ has to be forwarded to the gatekeeper, the Oracle Communications Session Border Controller caches the registration and then forwards a modified copy of the RRQ. The Oracle Communications Session Border Controller allocates a virtual call signal address on the gateway stack and uses it to replace the CSA of the registering endpoint in the forwarded RRQ.

Virtual RAS Address

The Oracle Communications Session Border Controller also allocates a virtual RAS address for each endpoint registration. Before forwarding an RRQ from an endpoint, the Oracle Communications Session Border Controller replaces the RAS address of the registering endpoint with the virtual RAS address on the gateway interface.

RAS Message Proxy

When the Oracle Communications Session Border Controller's registration proxy feature is configured, RAS messages to and from endpoints are forwarded, except for the following: GRQ, GCF, GRJ, IRQ, IRR, IACK, and INACK. If the system receives a valid GRQ on the RAS port of the gatekeeper stack that supports H.323 registration, it responds with a GCF message. Otherwise, it sends a GRJ message.

If the gateway interface receives IRR or IRQ messages, the Oracle Communications Session Border Controller attempts to respond based on the information about the call, and does not forward the messages.

Other RAS messages are forwarded after some modifications:

- Translating the transport address
- Deleting fields that the Oracle Communications Session Border Controller does not support

About Setting Port Ranges

When you configure the H.323 registration proxy feature, you set the Q.931 port range and the dynamic H.245 port range for H.245 connections. If you configure a Q.931 port range, you must also configure a dynamic H.245 port range.

These port ranges cannot overlap because of TCP ports must be unique. The dynamic H.245 port range is used to allocate a real TCP socket, but the Q.931 port range allocates a virtual call signaling address that does not have an associated listening TCP socket.

> **Note:**
>
> You should choose these sockets with future Oracle Communications Session Border Controller features about security in mind because future development will support performing admission control based on these port ranges. You will be able to set up filtering rules to allow only inbound packets to configured port ranges.

The following table shows how the Q.931 and dynamic H.245 port ranges work. If you set the start port of 1024 and the number of ports to 1024, you will have configured a port range that starts at 1024 and ends at 2047. So the final port in the range is the start port number added to the number of points, minus 1. Remember that you cannot overlap the Q.931 and dynamic H.245 port ranges. Notice that the higher the number of the start ports, the fewer ranges of ports you have remaining from which to choose.

Number of Ports	Start Port	n
1024	1024 * n	1-63
2048	2048 * n	1-31

Number of Ports	Start Port	n
4096	4096 * n	1-15
8192	8192 * n	1-7
16384	16384 * n	1-3
32768	32768 * n	1

H.323 Registration Proxy Configuration

In the ACLI, the parameters that apply to this feature are:

```
q931-start-port       Starting port number for port range used for Q.931
call signalling
q931-number-ports     Number of ports in port range used for Q.931 call
signalling
dynamic-start-port    Starting port number for port range used for
dynamic TCP connections
dynamic-number-ports  Number of ports in port range used for dynamic TCP
connections
```

To configure the H.323 registration proxy:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stack** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stack)#
   ```

5. **q931-start-port**—Enter the number where you want the Q.931 port range to start. The default value is **0**. Valid values are:
   - 0 | 1024 | 2048 | 4096 | 8192 | 16384 | 32768
6. **q931-number-ports**—Enter the number of ports to be included in the Q.931 port range to use for the call signalling address forwarded in the RRQ. The default value is **0**. Valid values are:
   - 0 | 1024 | 2048 | 4096 | 8192 | 16384 | 32768

> **Note:**
>
> If you have enabled process registration for this H.323 interface, this value must be set to zero because the interface is a gatekeeper that does not support the virtual call signaling address feature.

7. **dynamic-start-port**—Enter the number where you want the dynamic H.245 port range to start. The default value is **0**. Valid values are:
   - 0 | 1024 | 2048 | 4096 | 8192 | 16384 | 32768
8. **dynamic-number-ports**—Enter the number of ports to be included in the Q.931 port range to use for the call signalling address forwarded in the RRQ. The default value is **0**. Valid values are:
   - 0 | 1024 | 2048 | 4096 | 8192 | 16384 | 32768

H.323 Registration Caching

The Oracle Communications Session Border Controller can cache and proxy an H.225 RRQ between an H.323 endpoint and a gatekeeper. Registration caching has two benefits:

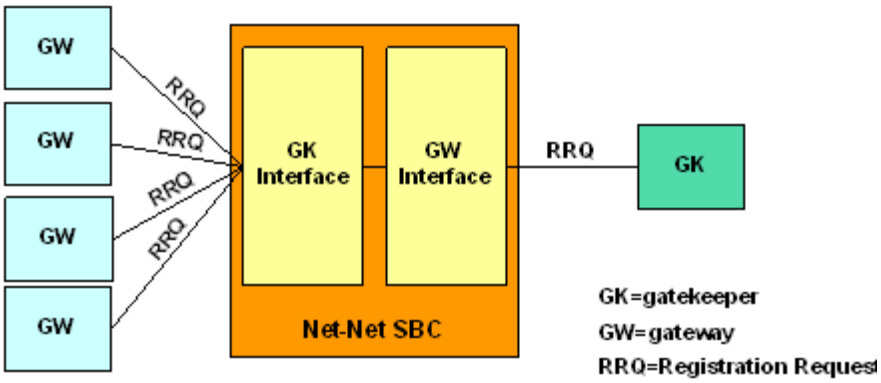
- It allows the aggregation of RRQs sent to a gatekeeper stack and proxies those requests through the gateway stack. If the external gatekeeper associated with the outbound (gateway) interface does not support additive registration, then the Oracle Communications Session Border Controller consolidates the requests by placing them all in the same packet. Otherwise, additive registration is used on the outbound (gateway) interface.
- It allows the gatekeeper stack to use the registration information to route calls from other realms to the endpoints in its realm.

For registration caching, you need to configure at least two H.323 interfaces:

- One gatekeeper interface to receive registrations
- One gateway interface to proxy registrations

The Oracle Communications Session Border Controller caches all successful registrations, using the cache to route calls back to the associated endpoint.

The following diagram shows how RRQs flow during registration caching.



Caveats for Registration Caching

This feature has the following caveats:

- If a gateway stack receives a URQ message from the gatekeeper, it confirms the request with an UCF message. It flushes all registration caching for that stack. However, the Oracle Communications Session Border Controller does not send URQs to the registered endpoints.
- The Oracle Communications Session Border Controller must be rebooted so that the gateway interface can rediscover the gatekeeper under the following circumstances:

Automatic gateway discovery is turned on for the gateway interface by setting the automatic gateway discovery parameter to enabled.

Configuration Requirements

For the Oracle Communications Session Border Controller to determine where to route an RRQ, either the associated stack parameter or the gatekeeper identifier field is used.

First, the Oracle Communications Session Border Controller uses the associated interface (assoc-stack) of the gatekeeper interface to find the interface for the outgoing RRQ. If you do not configure an associated interface and the incoming RRQ has a gatekeeperIdentifier field, the Oracle Communications Session Border Controller finds a configured gateway interface with a matching gk-identifier field and use it as the outgoing interface. If the incoming RRQ does not have a gatekeeperIdentifier field and the gatekeeper interface has a configured gatekeeper identifier, the Oracle Communications Session Border Controller finds a gateway interface with a gatekeeper identifier that matches the one set for the gatekeeper interface and then use it as the outgoing interface. If an outgoing interface cannot be determined, the Oracle Communications Session Border Controller rejects the RRQ with the reason discoveryRequired.

A configured H.323 interface can be the gateway interface for more than one gatekeeper interface. If a call is received on the gateway interface, the registration cache will be queried to find a registration matching the call's destination. If a registration is found, the interface on which the registration was received will be used as the outgoing interface for the call.

Subsequent ARQ or URQ messages coming from a registered endpoint will be proxied to the gatekeeper using the outgoing gateway interface established during registration. If a registration is not found, an ARJ or a URJ will be sent to the endpoint originating the ARQ or URQ.

A gatekeeper interface can respond to a GRQ if the GRQ is received on its RAS interface. The Oracle Communications Session Border Controller supports GRQ on a multicast address.

H.323 Registration Caching Configuration

In the ACLI, the parameters that apply to this feature are:

```
isgateway             Enable the stack to run as a gateway
registration-ttl      Number of seconds before the registration becomes
invalid
terminal-alias        List of aliases for terminal
gatekeeper            Gatekeeper's address and port
gk-identifier         Gatekeeper's identifier
```

To configure the gateway interface parameters for registration caching:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stack** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stack)#
   ```

5. **isgateway**—Enable H.323 stack functionality as a Gateway. Leave this parameter set to its default, **enabled**, so the H.323 stack runs as a Gateway. When this field is set to **disabled**, the H.323 stack runs as a Gatekeeper proxy.Leave this parameter for the service mode set to it's default, **enabled**. Valid values are:

   - enabled | disabled

     Enabling this parameter ensures that registration with the gatekeeper upon startup. It also ensures that all calls will be preceded by an ARQ to the gatekeeper for admission control.

6. **registration-ttl**—Set the registration expiration parameter to the value of the timeToLive field in the RRQ sent to the gatekeeper. The default is **120**. The valid range is:

   - Minimum—0
   - maximum—4294967295

     When the Oracle Communications Session Border Controller receives an RCF from the gatekeeper, it extracts the timeToLive field and uses that value as the time interval for keeping the registration of the gateway interface alive. The Oracle Communications Session Border Controller sends a keep-alive RRQ about ten seconds before the registration expires.

     The registration expiration you set value should not be too low because some gatekeepers simply accept the timeToLive in the RRQ, resulting in a potentially high volume of RRQs.

7. **terminal-alias**—Set this parameter if the gatekeeper requires at least one terminal alias in an RRQ. On startup, the gateway interface registers with the gatekeeper using this terminal alias.

   When the Oracle Communications Session Border Controller forwards an RRQ from an endpoint and if the gatekeeper does not support additive registration, the RRQ has the interface's terminal alias, the aliases of the registering endpoint, and other aliases of all registered endpoints. Otherwise, the RRQ only contains the aliases of the registering endpoint.

8. **gatekeeper** and **gk-identifier**—Configure these parameters if you do not want the Oracle Communications Session Border Controller to perform automatic gatekeeper discovery. If the gatekeeper identifier is empty, then the Oracle Communications Session Border Controller learns the gatekeeper identifier from the gatekeeperIdentifier field in the GCF.

Configuring the Gatekeeper Interface for Registration Caching

In the ACLI, the parameters that apply to this feature are:

```
isgateway             Enable the stack to run as a gateway
gatekeeper            Gatekeeper's address and port
gk-identifier         Gatekeeper's identifier
registration-ttl      Number of seconds before the registration becomes
invalid
```

To configure the gatekeeper interface parameters for registration caching:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stack** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stack)#
   ```

5. **isgateway**—Set this parameter to **disabled** to run the H.323 stack as a Gatekeeper proxy.
6. **gatekeeper**—Leave this parameter empty.
7. **auto-discovery**—Disable the Automatic Gatekeeper discovery feature upon start-up. Set this parameter to **disabled**.
8. **gk-identifier**—Set this parameter to the identification of the gatekeeper to which RRQs received on this interface must be proxied.
9. **registration-ttl**—Enter the number of seconds to set the timeToLive field in the RCF destined for an endpoint. If you do not configure another value, this timer is set to **120** seconds (default).

   This value should not be set too high or too low:

   - Setting a value that is too high causes the registration to be alive too long. If an endpoint reboots during this interval and re-registers with the same terminal aliases (but changes its call signaling address), the registration will be rejected with the reason duplicateAlias.
   - Setting a value that is too low puts an unnecessary load on the Oracle Communications Session Border Controller because it has to handle keep-alive registrations from the endpoint constantly, especially when there are many registered endpoints. If an endpoint does not set the timeToLive field in its RRQ, the registration of that endpoint will not expire.

     If an endpoint registers again without first unregistering itself (e.g., when it crashes and reboots), the Oracle Communications Session Border Controller rejects the registration

using the reason duplicateAlias. The Oracle Communications Session Border Controller uses this reason when the endpoint's call signaling address (IP address and port) is changed but its terminal aliases remain the same.

ACLI Registration Caching Configuration Example

In the following example, the H.323 gatekeeper interface (h323-stack) is private and the gateway interface (h323-stack) is public.

```
h323-config
state                          enabled
log-level                      DEBUG
response-tmo                   4
connect-tmo                    32
h323-stack
name                           private
state                          disabled
realm-id                       private
assoc-stack                    public
local-ip                       192.168.200.99
max-calls                      200
max-channels                   4
registration-ttl               120
terminal-alias
prefixes
ras-port                       1719
auto-gk-discovery              disabled
multicast                      0.0.0.0:0
gatekeeper                     0.0.0.0:0
gk-identifier
q931-port                      1720
alternate-transport
q931-max-calls                 200
h245-tunneling                 disabled
fs-in-first-msg                disabled
call-start-fast                disabled
call-start-slow                disabled

call-start-slow              disabled
media-profiles
process-registration         disabled
anonymous-connection         disabled
proxy-mode
filename
```

H.245 Stage

The Oracle Communications Session Border Controller allows you to set the earliest stage in an H.323 call when the Oracle Communications Session Border Controller initiates the procedure to establish an H.245 channel for the call. If you have enabled H.245 tunneling by setting the h245-tunneling parameter to enabled, then you do not need to configure your system for this feature.

The Oracle Communications Session Border Controller initiates the H.245 procedure by either:

- Sending its H.245 address, or
- Creating a TCP connection to an H.245 address that it has received

You can set this parameter to any of the following stages of an H.323 call: setup, proceeding, alerting, connect, early, facility, noh245, and dynamic. With the exception of early, noh245, and dynamic, these values correspond to types of H.225/Q.931 messages. The dynamic value is described in detail in the next section.

When you configure the early value, your Oracle Communications Session Border Controller begins the H.245 procedure at the time the Setup message is sent or received, or when the Connect message is received.

While these values allows for some flexibility about when the H.245 process is started, they are inherently static. All calls in the H.323 stack configuration use the same value, and it cannot be changed from call to call on that stack.

Dynamic H.245 Stage Support

You can configure your Oracle Communications Session Border Controller for dynamic H.245 support, meaning that the point at which the H.245 process begins can be determined dynamically. To support dynamic H.245, the Oracle Communications Session Border Controller sends its H.245 address in the incoming call when it receives an H.245 address in the outgoing call.

Dynamic H.245 Stage for Incoming Calls

When a call comes in on an H.323 interface that you have configured for dynamic H.245 stage support.

The Oracle Communications Session Border Controller includes its H.245 address in the h245Address field of the first H.225/Q.931 message. The Oracle Communications Session Border Controller does this after it receives the first H.225/Q.931 message with an H.245 address in the outgoing call. Based on the first H.225/Q.931 message received by the Oracle Communications Session Border Controller that has an H.245 address, the Oracle Communications Session Border Controller selects the message in which to include the H.245 address as outlined in the table below.

Message Received with H.245 Address	Message Sent with H.245 Address
Call Proceeding	Call Proceeding, Progress, Alerting, Connect or Facility. The H.245 address is sent in the Call Proceeding message if the system has not sent a Call Proceeding message in the incoming call. This is true only when you enable the Fast Start in first message parameter for the incoming stack; this parameter establishes whether or not Fast Start information must be sent in the first response to a Setup message. Otherwise, the message in which the H.245 address is sent depends on what message is received after the Call Proceeding message. This is because the Oracle Communications Session Border Controller sends its Call Proceeding message directly after receiving the Setup message.
Progress	Progress
Alerting	Alerting
Connect	Connect
Facility	Facility

When it receives the first H.225/Q.931 message with an H.245 address in the outgoing call, the Oracle Communications Session Border Controller creates a listening socket on the incoming interface. It also includes the socket address and port in the H.245 address of the next H.225/Q.931 message that it sends. If there is no pending H.225/Q.931 message for the Oracle Communications Session Border Controller to send, it instead sends a Facility message with the reason startH245. Then the H.245 channel is established when a TCP connection is made to the listening socket.

For the outgoing leg of a call that came in on the H.323 stack configured for H.245 dynamic stage support, the Oracle Communications Session Border Controller starts establishing the H.245 channel when it receives the first H.225/Q.931 message with H.245 address information. It also starts to establish a TCP connection to the address and port specified in the H.245 address information. The H.245 channel for the outgoing call is established while the H.245 address (h245Address) is sent in the incoming call as described above.

Dynamic H.245 Stage for Outgoing Calls

This section describes what happens when a message exits the Oracle Communications Session Border Controller on an H.323 stack that you have configured for dynamic H.245 stage support.

When the Oracle Communications Session Border Controller receives the first H.225/Q.931 message that has H.245 address information, it establishes an H.245 channel. The Oracle Communications Session Border Controller initiates a TCP connection to the address and port specified in the H.245 address information.

If the incoming call for the session is also on an H.323 stack with dynamic H.245 configured, the Oracle Communications Session Border Controller starts the H.245 procedure in the

incoming call. Otherwise, the system sends its H.245 address in the incoming call based on the H.245 stage support that you have configured.

The process is different when the Oracle Communications Session Border Controller receives a TCS message on the outgoing call before the incoming call reaches its H.245 stage. In this instance, the Oracle Communications Session Border Controller sends a Facility message with the reason startH245 with its H.245 address in order to start the H.245 procedure. The reason is needed in order for the Oracle Communications Session Border Controller to exchange TCS messages with the incoming side of the call.

H.245 Stage Configuration

To configure H.245 stage support:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stacks** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stacks)#
   ```

5. **h245-stage**—Set this field to the stage at which the Oracle Communications Session Border Controller transfers the H.245 address to the remote side of the call, or acts on the H.245 address sent by the remote side. The default value is **Connect**. Valid values are:
   - Setup | Alerting | Connect | Proceeding | Early | Facility | noh245 | Dynamic

H.323 HNT

This section explains how H.323 hosted NAT traversal (HNT) works and how to enable this capability on your Oracle Communications Session Border Controller.

The feature enables endpoints behind NATs to originate and terminate calls by resolving the address differences between the NAT and the actual endpoint.

H.323 communication through a NAT becomes an issue when engaging in RAS messaging. While the H.323 standard specifies specific information elements in the RAS messages that indicate the address to which the replies should be sent, these addresses will be behind the NAT and therefore unroutable. The Oracle Communications Session Border Controller solves this problem by sending RAS replies to the layer 3 address from which the associated RAS request was received.

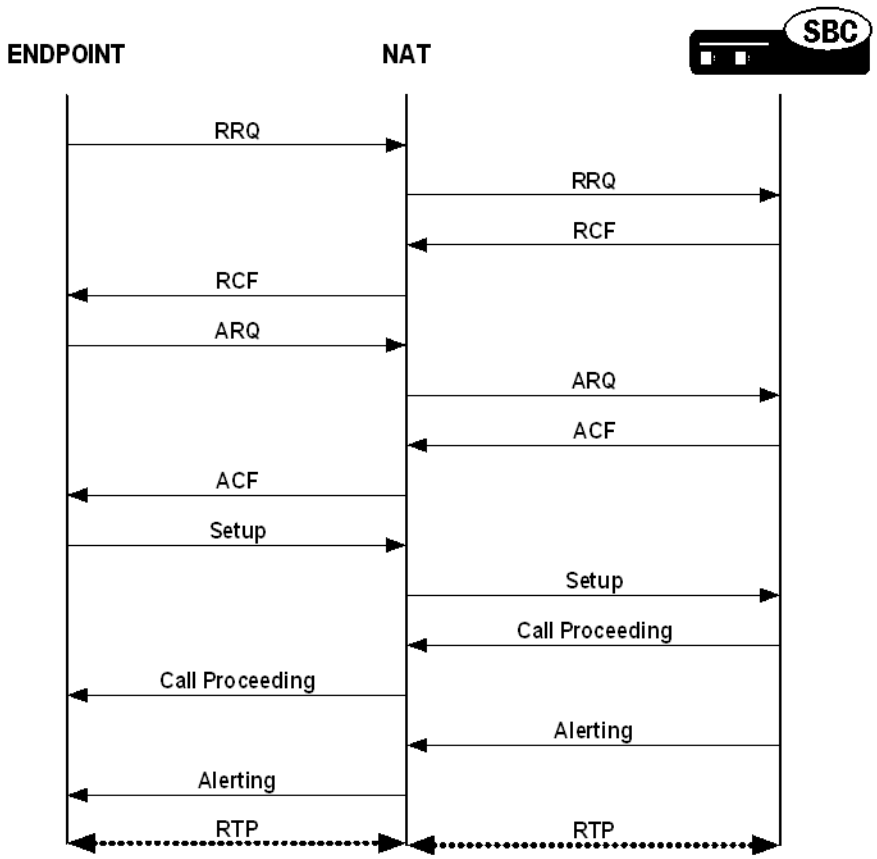
A second issue exists for media channels as the address specified in the H.323 OLC message will be behind the NAT and likewise unroutable. This is resolved by relying on the fact that the forward and reverse channels will utilize the same address and port on the endpoint. By sending media packets to the same address from which the packet are received, media and flow through the NAT.

If you do not use H.323 HNT, the following behavior will occur:

- When an H.323 endpoint is behind a NAT and it registers with a gatekeeper through the Oracle Communications Session Border Controller, the Oracle Communications Session Border Controller tries to send a response back to the endpoint's RAS address rather than to the NAT from which the request was received.
- The same is true for LRQ and IRQ messages because responses without H.323 HNT for outbound sessions, responses were being sent back to the replyAddress or the rasAddress.
- In addition, the Oracle Communications Session Border Controller always induces one-way media because it tries to send the RTP to the media IP address and port it receives in the OLC messages rather than the ephemeral port on the intermediary NAT.

With this ability enabled, however, the Oracle Communications Session Border Controller sends RAS responses back to the address from which the request was received (the NAT). It does not send responses to the endpoint's rasAddress or replyAddress mentioned in the signaling message. The same is true for RTP. With H.323 HNT for outbound sessions enabled, the Oracle Communications Session Border Controller sends RTP to the IP address and port from which it receives the RTP packets (the NAT).

The call flow below illustrates how this feature works:



Caveats

Keep in mind the following caveats when you are enabling H.323 HNT for outbound sessions on your Oracle Communications Session Border Controller:

- This capability does not apply to calls that require IWF translation between SIP and H.323.

H.323 HNT Configuration

You can enable this capability for specific H.323 interfaces.

To enable H.323 HNT:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stack** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters for the H.323 interface.

   ```
   ORACLE(h323)# h323-stack
   ```

5. If you are adding this service to a new H.323 interface that you are creating, type **options hnt** (to enable H.323 HNT), and then press Enter.

   ```
   ORACLE(h323-stack)# options hnt
   ```

6. If you are adding this service to an H.323 interface that already exists, type **select** to select the interface to which you want to add the service. Then use the options command and prepend the option with a plus (+) sign.
   - If you know the same of the interface, you can type the name of the interface at the name: prompt and press Enter.
   - If you do not know the name of the interface, press Enter at the name: prompt. A list of interfaces will appear. Type the number corresponding to the interface you want to modify, and press Enter.
   - **If are adding service to an existing interface and you type options hnt without a plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.**

H.323 Party Number-E.164 Support

Some H.323 gateways cannot handle partyNumber alias addresses in H.225 messages. The system lets you convert this address type to dialedDigits (E.164). This conversion applies to sourceAddress, destinationAddress, and destExtraCallInfo aliases in Setup messages.

To enable this feature, use the convertPNToE164 value in the **options** field of the H.323 stack configuration.

Signaling Only Operation

When you set the Oracle Communications Session Border Controller to operate in signaling-only mode, it acts like a signaling server. It proxies the call signaling messages between two endpoints. Note, however, that the NOracle Communications Session Border Controller does not function as a RAS proxy; it does not proxy RAS messages.

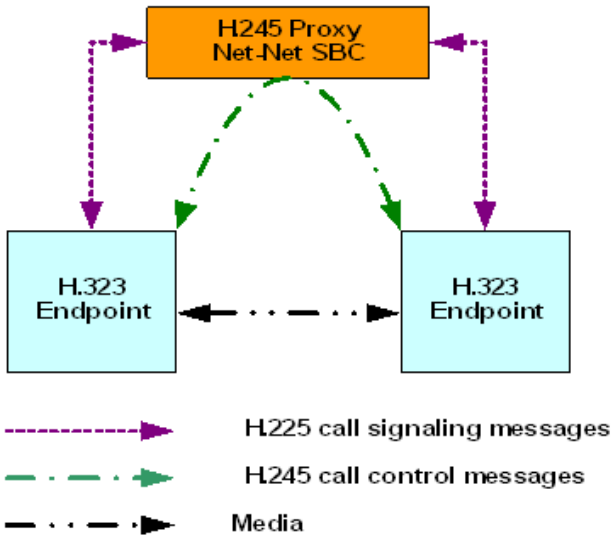
You have two options for the proxy mode:

- H.245 proxy mode—The Oracle Communications Session Border Controller handles call signaling (H.225) and call control (H.245) messages.
- H.225 proxy mode—The Oracle Communications Session Border Controller handles call signaling

To use this feature, you need to set the proxy mode parameter in the H.323 interface configuration to H.225 or H.245.

H.245

When in H.245 proxy mode, the Oracle Communications Session Border Controller proxies or passes through the call signaling (H.225) messages and the call control (H.245) messages. It allows media to flow between the two H.323 endpoints, as shown in the following diagram.



In some deployments, the media might be treated by a NAT device. When the Oracle Communications Session Border Controller is in H.245 proxy mode, any tunneled H.245 message on the ingress side is tunneled in the egress side. However, if the tunneling is refused on the egress side, a separate H.245 session is established.

H.245 proxy mode support is defined in the following table.

Ingress	Egress
Tunneled	Tunneled
Tunneled	Separate H.245 session
Separate H.245 session	Tunneled

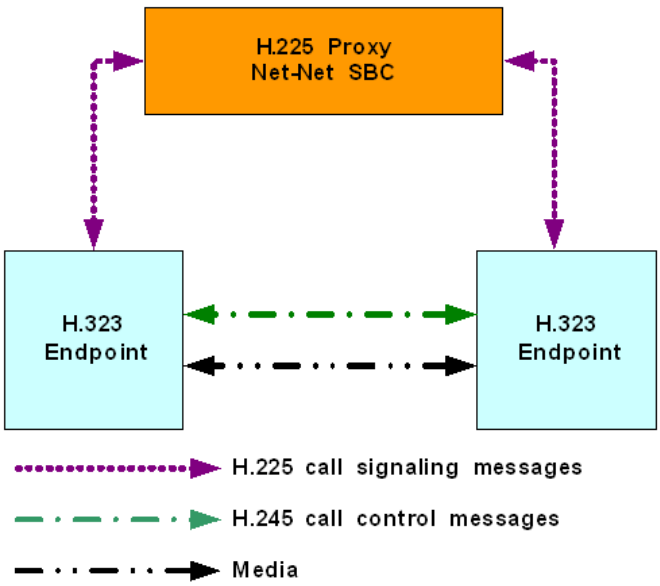
Ingress	Egress
Separate H.245 session	Separate H.245 session

H.225

When in H.225 proxy mode, the Oracle Communications Session Border Controller only proxies call signaling (H.225 messages). The call control (H.245 messages) and the media associated with the session do not go through the Oracle Communications Session Border Controller. Instead, they flow directly between the two H.323 endpoints.

> **Note:**
>
> H.225 proxy mode is only used in specific applications and should not be enabled without consultation from your Acme Packet Systems Engineer.

The following diagram shows the flow.



In certain deployments, the call control message and media are exchanged between the two H.323 endpoints themselves. When the Oracle Communications Session Border Controller is in H.225 proxy mode, any tunneled H.245 message on the ingress side is tunneled in the egress side; this is irrespective of the value configured in the value you set for the **h.245-tunneling** parameter in the H.323 stack configuration.

Maintenance Proxy Function

The Oracle Communications Session Border Controller supports a maintenance proxy function for H.323 and enhances the way the Oracle Communications Session Border Controller creates unique RAS ports. You can register endpoints through the Oracle Communications Session Border Controller with unique RAS port. You can also set the H.323 interface on the enterprise side to represent enterprise-side endpoints and thereby register on the carrier side.

The maintenance proxy creates a many-to-one association between the enterprise and the carrier side. Interfaces on the enterprise side can be associated with the carrier side interface, which also must be configured to for the maintenance proxy feature.

You configure the maintenance proxy feature by simply setting an option in the H.323 interface configuration.

Maintenance Proxy Configuration

To configure the maintenance proxy function, you need to set two values in the options parameters for the H.323 interface (h323-stack):

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stacks** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stacks)#
   ```

5. **options**—Set the options parameter to maintenanceProxy.

Applying TCP Keepalive to the H.323 Interface

To apply these settings individually per H.323 interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **system** and press Enter to access the system-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stack** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stack)# tcp-keepalive
   ```

5. **tcp-keepalive**—Disable this parameter if you do not want the TCP keepalive network parameters to be applied. The default value is **disabled**. Valid values are:
   - enabled | disabled

6. Click OK at the bottom of the window to complete configuring TCP keepalives and the maintenance proxy.

Automatic Gatekeeper Discovery

Available only when the H.323 interface is functioning as a gateway, this feature allows for automatic gatekeeper discovery on start-up.

This feature is based on the Oracle Communications Session Border Controller sending a GRQ to the multicast address of the RAS Multicast Group, which is the device group listening on this address. If you do not configure a multicast address, Oracle Communications Session Border Controller uses the well-known address and port 224.0.1.41:1718 in the address-port combination making up this parameter.

Multicast only functions when the Oracle Communications Session Border Controller is discovering an external gatekeeper. The Oracle Communications Session Border Controller does not respond to multicast gatekeeper queries.

When it receives a GCF message from a gatekeeper, the Oracle Communications Session Border Controller registers with the gatekeeper indicated in the GCF. When it receives an GRJ message that contains optional information about alternative gatekeepers, the Oracle Communications Session Border Controller attempts to register with an alternate.

If you do not use automatic gatekeeper discovery, the Oracle Communications Session Border Controller registers with the gatekeeper you configure in the gatekeeper parameter. In this case, the gatekeeper identifier you configure is included in to the RRQ. No registration a takes place if you do not establish automatic gatekeeper discovery or if you do not configure the gatekeeper and its identifier.

Automatic Gatekeeper Configuration

To configure automatic gatekeeper discovery:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the media-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stacks** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stacks)#
   ```

5. **auto-gk-discovery**—Enable this parameter to use automatic gatekeeper discovery. The default value is **disabled**. Valid values are:
   - enabled | disabled

6. **multicast**—Set this parameter to the address and port where the RAS Multicast Group listens. Your entries in this field will be comprised of an IPv4 address and port values separated by a colon. The default value is **0.0.0.0:0**.

H.323 Alternate Routing

You can configure your Oracle Communications Session Border Controller to try more possible routes within given time constraints and number of retries.

Without Alternate Routing Enabled

If you do not enable H.323 alternate routing, the Oracle Communications Session Border Controller tries one possible next hop gateway when routing H.323 calls even if the applicable local policy has multiple next hops configured. If that next hop gateway fails (either because it is busy or out of service), the Oracle Communications Session Border Controller relays the failure back to the caller, who hears a busy tone.

In addition, the call will only be routed to the other available next hops if the first one is:

- A session agent that has gone out of service because it constraints have been exceeded
- A session agent that has gone out of service because it failed to respond to a Oracle Communications Session Border Controller Setup request
- A session agent group

With Alternate Routing Enabled

When you enable H.323 Alternate Routing on your Oracle Communications Session Border Controller, you enable the use of the other next hops in addition to the first one. The retry, when the other available next hops are used, is transparent to the caller. However, the number of retries is limited by the value you set for the ACLI **connect-tmo** parameter, and this feature works only if there is more than one matching local policy next hop. If there is not more than one match, even if that match is a session agent group, then the call is only attempted once and the caller must retry it.

If the Oracle Communications Session Border Controller receives a Release Complete message before it receives an Alerting message, then it will try the next hop if there are multiple matches. When there is no more than one match, or if the timer or number of retries is exceeded, the Oracle Communications Session Border Controller proxies the most recently received Release Complete message back to the caller.

The following table shows the cause codes and release complete reasons, and either of the two actions the Oracle Communications Session Border Controller takes:

- Recur—Means that the Oracle Communications Session Border Controller performs (or continues to perform) alternate routing
- Proxy—Means that alternate routing stops, and the Oracle Communications Session Border Controller sends a release complete message back to the caller

H.323 Release Complete Reason	Q.850 Cause Code	Action
No Bandwidth	34—No circuit available	Recur
Gatekeeper Resources	47—Resource unavailable	Recur
Unreachable Destination	3—No route to destination	Recur
Destination Rejection	16—Normal call clearing	Proxy
Invalid Revision	88—Incompatible destination	Recur

H.323 Release Complete Reason	Q.850 Cause Code	Action
No Permission	111—Interworking, unspecified	Recur
Unreachable Gatekeeper	38—Network out of order	Recur
Gateway Resources	42—Switching equipment congestion	Recur
Bad Format Address	28—Invalid number format	Recur
Adaptive Busy	41—Temporary Failure	Recur
In Conference	17—User busy	Proxy
Undefined Reason	31—Normal, unspecified	Recur
Facility Call Deflection	16—Normal, call clearing	Proxy
Security Denied	31—Normal, unspecified	Recur
Called Party Not Registered	20—Subscriber absent	Recur
Caller Not Registered	31—Normal, unspecified	Recur
New Connection Needed	47—Resource Unavailable	Recur
Non Standard Reason	127—Interworking, unspecified	Recur
Replace With Conference Invite	31—Normal, unspecified	Recur
Generic Data Reason	31—Normal, unspecified	Recur
Needed Feature Not Supported	31—Normal, unspecified	Recur
Tunnelled Signaling Rejected	127—Interworking, unspecified	Recur

H.323 Alternate Routing Configuration

This section describes how to enable H.323 alternate routing. There is a new parameter, and the behavior of the pre-existing **response-tmo** and **connect-tmo** parameters change when you enable this feature on your system.

To enable this feature, you need to set the new **alternate-routing** parameter in the global H.323 configuration to recur. The other option for this parameter is proxy, which means that the Oracle Communications Session Border Controller performs in the way it did prior to Release 4.1, i.e. try only the first matching local policy next hop that it finds.

You configure H.323 alternate for the global H.323 configuration.

To enable H.323 alternate routing:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. **alternate-routing**—Enable or disable H.323 alternate routing. If you want to keep the pre-4.1 behavior where the Oracle Communications Session Border Controller only tries one matching local policy next hop, leave this parameter set to its default value **proxy**. Valid values are:

   - recur | proxy

5. **response-tmo**—Enter the time in seconds for the response time-out (or T303 timer). This is the amount of time allowed to elapse during which the Oracle Communications Session Border Controller should receive a response to its Setup message. If the first response to the Oracle Communications Session Border Controller's Setup is a callProceeding, then the Oracle Communications Session Border Controller should receive an Alerting or Connect message before this timer (now T303*2) elapses.

   The default for this parameter is **4**. The valid range is:

   - Minimum—0
   - Maximum—999999999

6. **connect-tmo**—Enter the time in seconds for the connect time-out (or T301 timer). This is the amount of time allowed to elapse during which the Oracle Communications Session Border Controller should receive a Connect message.

   For alternate routing, this parameter is also used to limit the number of next hops that are tried and the length of time they are tried in case the first next hop fails. The call needs to be established before this timer expires; the call will fail after maximum of 5 retries.

   The default for this parameter is **32**.

   - Minimum—0
   - Maximum—999999999

H.323 LRQ Alternate Routing

There are networks where the Oracle Communications Session Border Controller is positioned so that it needs to send an H.225 LRQ request to one signaling entity, and then fall back to another signaling entity when there are no resources available on the first. This might be the case when network contain elements that have limited amounts of channels and/or ports.

To handle situations like this one, the Oracle Communications Session Border Controller can be configured for H.323 LRQ alternate routing.

Without this feature enabled, the Oracle Communications Session Border Controller performs H.323 alternate routing for an H.323 call by finding the alternate route for a local policy when the call setup using H.225/Q.931 fails. Some network configurations, however, require that an LRQ message be sent to a gatekeeper prior to call setup in order to request the destination call signaling address—meaning that the Oracle Communications Session Border Controller will release the call if it does not receive an LCF for that LRQ.

With H.323 LRQ alternate routing enabled, the Oracle Communications Session Border Controller can route the call even when it does not receive the LCF.

When the Oracle Communications Session Border Controller routes an H.323 call using a local policy and the applicable route specifies gatekeeper/session agent as the next hop, the Oracle Communications Session Border Controller must send that gatekeeper an LRQ to request the destination for the call signaling address. After it sends the LRQ, the Oracle Communications Session Border Controller might receive either an LCF or an LRJ, or it might receive no response at all. Upon failure—either the receipt of an LRJ or no response within a timeout period—the Oracle Communications Session Border Controller tries alternate routes (additional routing policies) until the call is either set up or the routing list ends. For each alternate route, if the next hop is a gatekeeper/session agent, the Oracle Communications Session Border Controller sends an LRQ to the gatekeeper in order to request the destination call signaling address. Otherwise, the Oracle Communications Session Border Controller simply sets up the call.

For a designated period of time, the Oracle Communications Session Border Controller waits for the a response to the LRQ from the gatekeeper. This timeout period is configured by setting two options in the global H.323 configuration: **ras-tmo** (number of seconds the Oracle Communications Session Border Controller waits before retransmitting a RAS message; default is 4) and **maxRasRetries** (maximum number of times the Oracle Communications Session Border Controller retransmits the RAS; default is 1). The Oracle Communications Session Border Controller calculates the LRQ timeout period by multiplying the **ras-tmo** by the **maxRasRetries** and adding one (**ras-tmo** x **maxRasRetries** +1).

If an out of service session agent is part of a route, the Oracle Communications Session Border Controller skips it when using alternate routing and uses other routes for the policy.

A session agent might go out of service when it exceeds the maximum number of consecutive transaction timeouts to the maximum number of allowable transaction timeouts. Applicable session agent constrain parameter of note are:

- **trans-timeouts**—Maximum number of allowable transaction timeouts (default is 5)
- **ttr-no-response**—Dictates when the SA (Session Agent) should be put back in service after the SA is taken OOS (Out Of Service) because it did not respond to the Oracle Communications Session Border Controller
- **in-service-period**—Amount of time that elapses before a session agent is put back in service after the **ttr-no-response** period has passed

By default, the Oracle Communications Session Border Controller continues to send LRQ messages to a session agent even if the session agent has already sent an LRJ. However, you might want to place a session agent out of service when it has sent a certain number of LRJs; doing so allows alternate routing to take place faster, but this is an optional feature.

To configure an LRJ threshold, you add the **max-lrj** value to an H.323 session agent's **options** parameter; instructions for how to set it and the required syntax appear below. If you do not set this option, then the Oracle Communications Session Border Controller will not put session agents out of service for matters related to LRJs.

If you do set this option (to a non-zero value), then the Oracle Communications Session Border Controller keeps a count of the LRJs received from a session agent. When it receives an LCF from a session agent, the Oracle Communications Session Border Controller resets the counter to zero. This count is used internally only and is not accessible through statistics displays.

If a session agent exceeds the maximum number of LRJs and goes out of service, it remains in that state until the **ttr-no-response** period has passed and it has transitioned through the **in-service-period** time. If the **ttr-no-response** period is zero, then the session agent is never put out of service.

Caveats

The Oracle Communications Session Border Controller does not support H.323 LRQ alternate routing for these scenarios:

- Calls that require translation between SIP and H.323 (IWF calls)
- For pure H.323 calls where the ingress H.323 interface (stack) is associated with another H.323 interface (stack) that has a valid gatekeeper defined; if there is no valid gatekeeper for the egress interface (stack), this feature may apply.

H.323 LRQ RAS Retransmission Configuration

There is no configuration for H.323 LRQ alternate routing; it is enabled by default. You do, however, need to set the ras-tmo and maxRasRetries options to set the timeout period.

If you want to set a maximum number of consecutive LRJs to be received from a session agent, you need to add the **max-lrj** value to an H.323 session agent's **options** parameter.

To configure the number of seconds before the Oracle Communications Session Border Controller retransmits a RAS message:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ACMEPACKET(h323)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **ras-tmo=x** (where X is number of the seconds that the Oracle Communications Session Border Controller waits before retransmitting a RAS message; default is 4) with a plus sign in front of it, and then press Enter.

Set the maxRasRetries option in the same way; here, X is the maximum number of times the Oracle Communications Session Border Controller retransmits the RAS; default is 1).

```
ORACLE(h323-stack)# options +ras-tmo=6
ORACLE(h323-stack)# options +maxRasRetries=2
```

If you type **options** and then the option value for either of these entries without the plus sign, you will overwrite any previously configured options. In order to append the new option to the h323 configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

H.323 LRJ Limit Configuration

To limit the number of LRJs received from an H.323 session agent before putting it out of service:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# session-agent
```

4. Use the ACLI **select** command so that you can work with the session agent configuration to which you want to add this option.

```
ORACLE(session-agent)# select
```

5. **options**—Set the options parameter by typing **options**, a Space, the option name **max-lrj=X** (where X is the maximum number of allowed LRJs) with a plus sign in front of it, and then press Enter.

```
ORACLE(session-agent)# options +max-lrj=3
```

If you type options max-lrj=X (without the plus sign), you will overwrite any previously configured options. In order to append the new option to the session-agent's options list, you must prepend the new option with a plus sign as shown in the previous example.

H.323 CAC Release Mechanism

When an OLC message is sent to the Oracle Communications Session Border Controller and there is insufficient bandwidth available, the Oracle Communications Session Border Controller will reject the incoming OLC. Normally, endpoints decide whether they want to send new OLCs or if they want to release the call. Some endpoints in this situation do neither. When communicating with the last of endpoints, it is desirable for the Oracle Communications Session Border Controller to take action.

The system supports a option in the H.323 interface called olcRejectTimer. When this option is enabled and an OLC is rejected, the stack will:

- If there is another media channel open, the Oracle Communications Session Border Controller will behave as if the release mechanism had not been enabled
- If there are no media channels open, the Oracle Communications Session Border Controller starts a timer for 1 second.
  - If the call is released by the endpoint before the timer expires or another OLC is received from the endpoint before the timer expires, the Oracle Communications Session Border Controller stops the timer and follows expected call handling
  - If the timer expires before either of the above responses from the endpoint occur, the Oracle Communications Session Border Controller releases the call.

H.323 CAC Release Configuration

To enable the H.323 CAC release mechanism:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the media-related configurations.

```
ORACLE(configure)# session-router
```

3. Type **h323** and press Enter.

```
ORACLE(session-router)# h323
```

4. Type **h323-stacks** and press Enter.

```
ORACLE(h323)# h323-stacks
ORACLE(h323-stacks)#
```

5. Use the ACLI **select** command so can add this feature to an existing H.323 interface.

```
ORACLE(h323-stacks)# select
```

6. Set the **options** parameter by typing **options**, a Space, the option name **olcRejectTimer**, and then press Enter.

   ORACLE(h323-stacks)# **options olcRejectTimer**

7. If you are adding this service to an H.323 interface that already exists, type **select** to select the interface to which you want to add the service. Then use the options command and prepend the option with a plus (+) sign.
   - If you know the same of the interface, you can type the name of the interface at the name: prompt and press Enter.
   - If you do not know the name of the interface, press Enter at the name: prompt. A list of interfaces will appear. Type the number corresponding to the interface you want to modify, and press Enter.
   - **If are adding service to an existing interface and type in the option without a plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign: options +olcRejectTimer.**

H.323 Per-Realm CAC

Building on the Oracle Communications Session Border Controller's pre-existing call admission control methods, CAC can be performed based on how many minutes are being used by SIP or H.323 calls per-realm for a calendar month.

In the realm configuration, you can now set a value representing the maximum number of minutes to use for SIP and H.323 session using that realm. Although the value you configure is in minutes, the Oracle Communications Session Border Controller performs CAC based on this value to the second. When you use this feature for configurations with nested realms, the parent realm will have the total minutes for all its child realms (i.e., at least the sum of minutes configured for the child realms).

The Oracle Communications Session Border Controller calculates the number of minutes used when a call completes, and counts both call legs for a call that uses the same realm for ingress and egress. The total time attributed to a call is the amount of time between connection (H.323 Connect) and disconnect (H.323 Release Complete), regardless of whether media is released or not; there is no pause for calls being placed on hold.

If the number of minutes is exhausted, the Oracle Communications Session Border Controller rejects calls with a SIP 503 Service Unavailable message (including additional information “monthly minutes exceeded). In the event that the limit is reached mid-call, the Oracle Communications Session Border Controller continues with the call that pushed the realm over its threshold but does not accept new calls. When the limit is exceeded, the Oracle Communications Session Border Controller issues an alarm and sends out a trap including the name of the realm; a trap is also sent when the alarm condition clears.

> **Note:**
>
> The Oracle Communications Session Border Controller does not reject GETS/NSEP calls based on monthly minutes CAC.

You can change the value for minutes-based CAC in a realm configuration at any time, though revising the value downward might cause limits to be reached. This value resets to zero (0) at the beginning of every month, and is checkpointed across both system in an HA node. Because this data changes so rapidly, however, the value will not persist across and HA node if both systems undergo simultaneous failure or reboot.

You can use the ACLI **show monthly minutes <realm-id>** command (where **<realm-id> is** the realm identifier of the specific realm for which you want data) to see how many minutes are configured for a realm, how many of those are still available, and how many calls have been rejected due to exceeding the limit.

Caveats

> **Note:**
>
> this feature is not supported for HA nodes running H.323.

H.323 Per-Realm CAC Configuration

This section shows you how to configure minutes-based CAC for realms and how to display minutes-based CAC data for a specific realm.

Note that setting the new monthly-minutes parameters to zero (0), or leaving it set to its default of 0, disables this feature.

To configure minutes-based CAC:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **media-manager** and press Enter.

```
Oracle Communications Session Border Controller(configure)# media-manager
Oracle Communications Session Border Controller(media-manager)#
```

3. Type **realm-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(media-manager)# realm-config
ORACLE(realm-config)#
```

4. Select the realm where you want to want to add SIP per user CAC.

```
ORACLE(realm-config)# select
```

5. **monthly-minutes**—Enter the number of minutes allowed during a calendar month in this realm for SIP and H.323 calls. By default, this parameter is set to zero (0), which disabled monthly minutes-based CAC. You can enter a value as high as 71582788.
6. Save and activate your configuration.

Use the ACLI show monthly-minutes command to see the following information:

- How many minutes are configured for a realm
- How many of those are still available
- How many calls have been rejected due to exceeding the limit

To view information about SIP per user CAC using the IP address mode: In either User or Superuser mode, type **show monthly-minutes <realm-id>**, a Space, and the IP address for which you want to view data. Then press Enter. The **<realm-id>** is the realm identifier for the realm identifier of the specific realm for which you want data.

```
ORACLE# show monthly-minutes private_realm
```

H.323 Bearer-Independent Setup

In Release 4.1, the Oracle Communications Session Border Controller supports a new H.323 option that enables H.323 Bearer-Independent Setup (BIS). When enabled, this feature allows exception to slow-start to fast-start conversion on the Oracle Communications Session Border Controller.

H.323 BIS Disabled

Unless you enable this feature, the Oracle Communications Session Border Controller performs slow-start to fast-start conversion when a call entering the system as slow-start was routed to a an outgoing H.323 interface (stack) with **call-fast-start** set to enabled and there is a list of valid media-profiles in the configuration.

H.323 BIS Enabled

There are certain cases in access deployments where the slow-start to fast-start conversion should not be applied. This is the case when the Setup message contains the Bearer Capability information element (IE), which signals BIS.

When you enable this feature and the Oracle Communications Session Border Controller receives an incoming Setup message that does not contain a fastStart field, the Oracle Communications Session Border Controller checks for the BIS in the incoming Setup before it starts to perform the slow-start to fast-start conversion. If it finds the BIS, then it does not perform the conversion.

This feature can be enabled on a global or a per-interface basis, meaning that you can apply it to your system's entire H.323 configuration or you can enable it only for the interfaces where you want it applied.

H.323 BIS Global Configuration

This section explains how to add H.323 BIS support to your global H.323 configuration and to specific H.323 interfaces (stacks).

If you set this option on an H.323 interface (stack), you must set it on the interface (stack) that receives the Setup message with BIS in the Bearer Capability IE.

To enable the H.323 BIS feature globally:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **options +bearerIndSetup** and press Enter.

   ```
   ORACLE(h323-stacks)# options +bearerIndSetup
   ```

   If you type **options bearerIndSetup** without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

H.323 BIS Specific Configuration

To enable the H.323 BIS feature for a specific H.323 interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ```

4. Type **h323-stacks** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stacks)#
   ```

5. Select the H.323 stack to which you want to add H.323 BIS support.

```
ORACLE(h323-stacks)# select
<name>:
```

For a list of configured H.323 interfaces (stacks), press Enter at the <name>: prompt. Then enter the number corresponding to the interface where you want to apply this feature.

6. Type **options +bearerIndSetup** and press Enter.

```
ORACLE(h323-stacks)# options +bearerIndSetup
```

If you type options bearerIndSetup without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

TOS Marking for H.323 Signaling

You can configure your Oracle Communications Session Border Controller to perform TOS/DiffServ marking for H.323 signaling packets. This feature enables you to mark H.323 signaling packets so that they receive specific treatment from upstream devices. This feature assists in routing because you can configure the TOS byte inserted in the H.323 packet to mark the traffic for certain destinations. For example, you can prevent unauthorized video transmission through an audio-only session.

The Oracle Communications Session Border Controller also performs TOS/DiffServ marking for media.

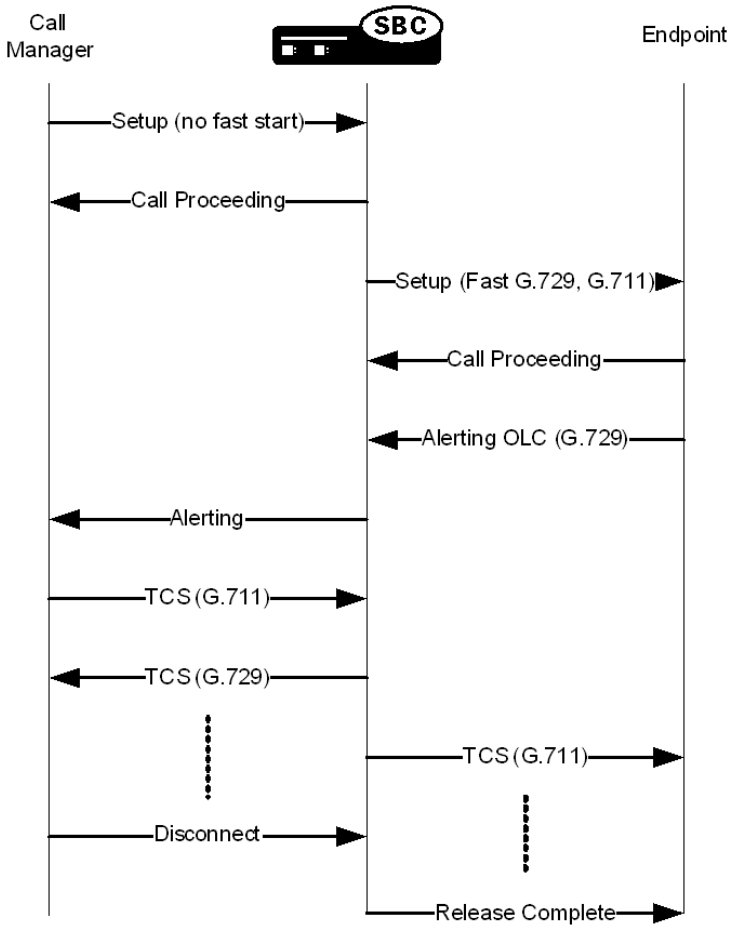
H.323 Codec Fallback

In the global H.323 configuration, you can enable a parameter that allows the Oracle Communications Session Border Controller to renegotiate—or fallback—to the preferred codec used in an incoming terminal capability set (TCS) from the slow-start side of a slow-start to fast-start H.323 call. When enabled, the Oracle Communications Session Border Controller performs this renegotiation when it detects a mismatch between the codec used in the open logical channel (OLC) opened on the fast-start side of the call, and the codec specified by the slow-start side.

Codec Fallback Disabled

With codec fallback disabled, the Oracle Communications Session Border Controller opens a channel using the codec specified by the northbound side. Since the call manager had specified another preferred codec, the result is a codec mismatch leading to a dropped call.

The following diagram shows how codec mismatches end in dropped calls.

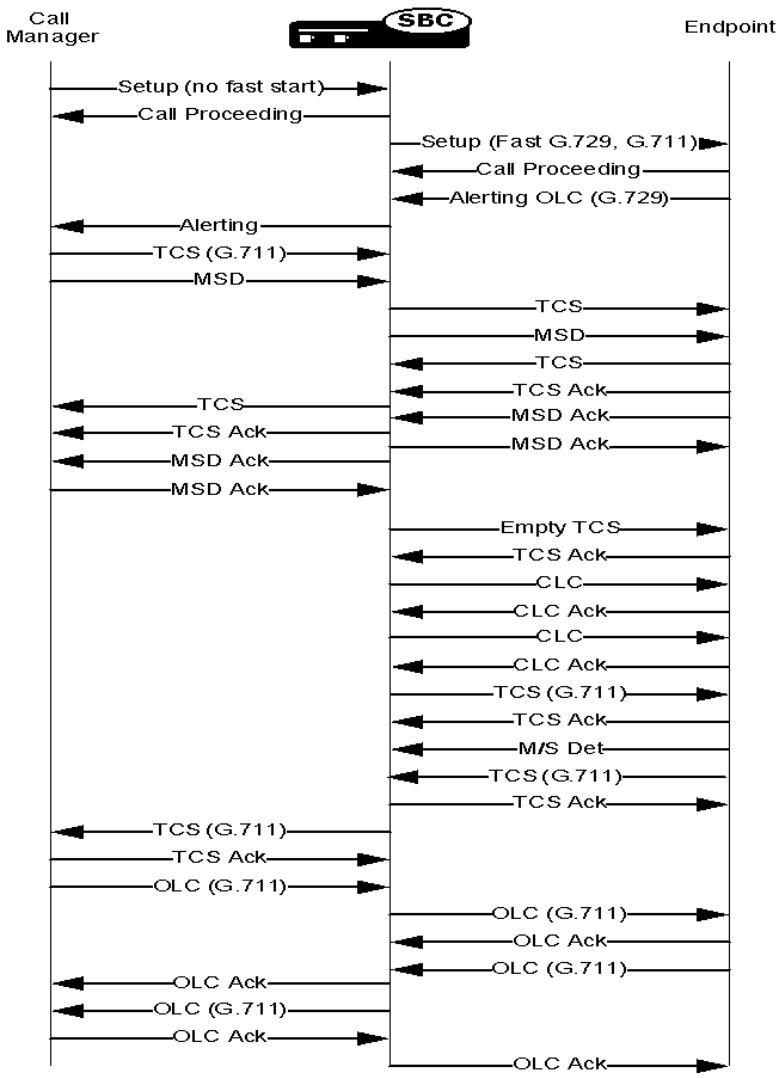


Codec Fallback Enabled

With H.323 codec fall back enabled, the Oracle Communications Session Border Controller attempts to use the preferred codec that the slow-start side of the call specifies. The Oracle Communications Session Border Controller determines matching based on the incoming TCS from the slow-start side and the OLC on the egress side. If the codecs do not match, the Oracle Communications Session Border Controller sends an empty TCS on the egress side and closes the logical channels on the outgoing side of the call.

To trigger a new capabilities exchange, the Oracle Communications Session Border Controller forwards the TCS from the ingress side of the call to the egress endpoint. Then the TCS from the egress endpoint is propagated to the ingress endpoint, and the logical channels are opened.

The following diagram shows a call scenario using the H.323 codec fallback feature.



H.323 Codec Fallback Configuration

Note that you configure this feature for your global H.323 configuration, so it has an impact on all H.323 traffic on your system.

To enable H.323 codec fallback:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter. The system prompt will change to let you know that you can configure individual

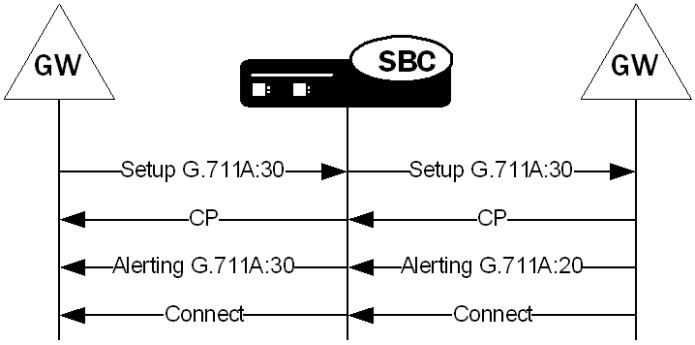
   ```
   ORACLE(session-router)# h323
   ```

4. **codec-fallback**—Enable or disable the H.323 codec fallback feature. The default value is **disabled**. Valid values are:
   - enabled | disabled

H.323 TCS Media Sample Size Preservation

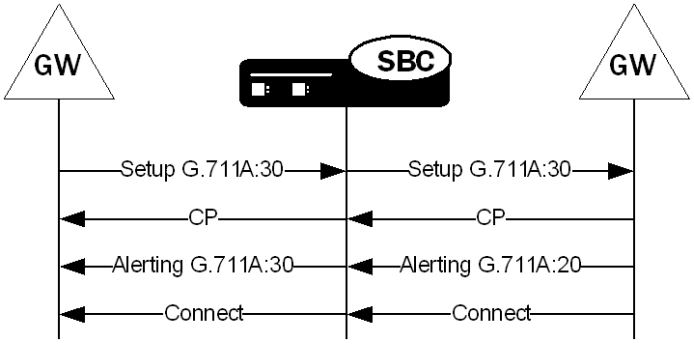
For H.323 fastStart calls, the Oracle Communications Session Border Controller can be configured to preserve the packetization interval from the called gateway if it differs from the one offered in the Setup message the calling gateway sent.

When this feature is disabled and in accordance with the ITU H.323 recommendation, the Oracle Communications Session Border Controller changes the packetization rate to the one used by the calling gateway if the one offered by the called gateway differs. In the following example, this means that the Oracle Communications Session Border Controller replaces the packetization interval of 20 with 30 before it forwards the Alerting message to the calling gateway.



However, not all H.323 elements comply with the ITU recommendation. Since some network elements do modify the packetization rate in the dataType element, this behavior is now configurable.

When you enable media sample size preservation, the Oracle Communications Session Border Controller allows the packetization rate to be modified and forwards on the modified dataType element to the calling gateway. In the following example, you can see that the Oracle Communications Session Border Controller forwards the called gateway's Alerting with the packetization interval of 20 despite the fact that the calling gateway's Setup specified 30.



Note that the calling endpoint might or might not work with the modified dataType.

You can enable this feature for the global H.323 configuration so that it applies to all H.323 fastStart calls, or you can enable it on a per-H.323 interface (stack) basis. When you enable this feature for an individual H.323 interface (stack), the Oracle Communications Session Border Controller performs media sample size preservation for calls egressing on that interface.

Media Sample Size Configuration

This section shows you how to configure media sample size preservation for the global H.323 configuration and for an individual H.323 interface (stack).

To enable media sample size preservation for the global H.323 configuration:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ORACLE(h323)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name **forwardFSAceptedDataType** with a plus sign in front of it. Then press Enter.

   ```
   ORACLE(h323)# options +forwardFSAcceptedDataType
   ```

   If you type options and then the option value for either of these entries **without the plus sign, you will overwrite any previously configured options. In order to append the new option to the h323** configuration's **options list, you must prepend the new option with a plus sign as shown in the previous example.**

5. Save and activate your configuration.

   To enable media sample size preservation for an individual H.323 interface:

6. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

7. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

8. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ORACLE(h323)#
   ```

9. Type **h323-stacks** and press Enter.

   ```
   ORACLE(h323)# h323-stacks
   ORACLE(h323-stack)#
   ```

   If you are adding support for this feature to a pre-existing H.323 interface (stack), then you must select (using the ACLI **select** command) the one you want to edit.

10. **options**—Set the options parameter by typing **options**, a Space, the option name **forwardFSAceptedDataType** with a plus sign in front of it. Then press Enter.

```
ORACLE(h323-stack)# options +forwardFSAcceptedDataType
```

If you type options and then the option value for either of these entries **without the plus sign, you will overwrite any previously configured options. In order to append the new option to the h323-stack** configuration's **options list, you must prepend the new option with a plus sign as shown in the previous example.**

11. Save and activate your configuration.

H.323-TCS H.245 Support for H.264 and G722.1

The Oracle Communications Session Border Controller supports the H.264 video codec and the G722.1 audio codec. Especially useful for customer video product offerings in which the Oracle Communications Session Border Controller is deployed, this support further allows the Oracle Communications Session Border Controller to increase ease of use by supporting private addressing. Without this feature enabled (the Oracle Communications Session Border Controller's previous behavior), the Oracle Communications Session Border Controller required deployment for IANA registered IP addresses—despite the fact that IP VPNs allow for RFC 1918 private addressing.

H.323-TCS Generic Video Configuration

To enable this feature, you need to set up media profile configurations appropriately. Media profiles now allow you to set the configuration either as "generic video" or generic audio.

H.245 provides for defining new capabilities that are described as H.245 generic capabilities (GenericCapability), which the Oracle Communications Session Border Controller now supports using the H.245 GenericCapability structure. H.264 and G.722.1 are the first codecs the Oracle Communications Session Border Controller offers that use this mechanism.

To set a media profile for generic video support:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
```

3. Type **media-profile** and press Enter.

```
ORACLE(session-router)# media-profile
ORACLE(media-profile)#
```

4. **name**—Set the name of the generic video media profile to genericVideo. There is no default for this parameter.
5. **media-type**—Set the media type to use for this media profile; for generic video, set this parameter to video.
6. **payload-type**—Set the payload type to use for the generic video media profile.

7. **transport**—Set the transport type to use for the generic video media profile.
8. Complete the rest of the media profile configuration as needed.
9. Save and activate your configuration.

The following is a sample of a generic video media profile configuration:

```
media-profile
        name                            genericVideo
        media-type                      video
        payload-type                    99
        transport                       RTP/AVP
        req-bandwidth                   0
        frames-per-packet               0
        parameters
        average-rate-limit              0
        sdp-rate-limit-headroom         0
        sdp-bandwidth                   disabled
```

H.323-TCS Generic Audio Configuration

To set a media profile for generic audio support:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **media-profile** and press Enter.

   ```
   ORACLE(session-router)# media-profile
   ORACLE(media-profile)#
   ```

4. **name**—Set the name of the generic audio media profile to genericAudio. There is no default for this parameter.
5. **media-type**—Set the media type to use for this media profile; for generic video, set this parameter to audio.
6. **payload-type**—Enter the format in SDP m lines. No payload type number is assigned for newer, dynamic codecs. For RTP/AVP media-profile elements, this field should only be configured when there is a standard payload type number that corresponds to the encoding name. Otherwise, this field should be left blank. This field is used by the system to determine the encoding type when the SDP included with a session identifies the standard payload type on the em line, but does not include an a-rtpmap entry.
7. **transport**—Set the type of transport protocol to use for the generic audio media profile. The default value is **RTP/AVP**.
   - UPD | RTP/AVP
8. Complete the rest of the media profile configuration as needed.
9. Save and activate your configuration.

The following is a sample of a generic audio media profile configuration:

```
media-profile
        name                            genericAudio
        media-type                      audio
        payload-type                     104
        transport                        RTP/AVP
        req-bandwidth                    0
        frames-per-packet                0
        parameters
        average-rate-limit               0
        sdp-rate-limit-headroom          0
        sdp-bandwidth                    disabled
```

International Peering with IWF and H.323 Calls

When you do not enable this feature, H.323 calls can default to a National Q.931 Number Type and it is not possible to change it to an International number. This feature allows you to override that behavior by configuring the option **cpnType=X**, where X is an integer that maps to various Q.931 Number Types. When this option is set, Q.931 Number Type for both calling party and called party are updated to the configured value for all outing calls on the h323-stack.

The following is a list of possible **cpnType=X** option values for X:

- 0—Unknown public number
- 1—International public number
- 2—National public number
- 3—Specific public network number
- 4—Public subscriber number
- 5—Public abbreviated number
- 6—Private abbreviated number

You configure this feature as an option in the **h323-stack** configuration.

To configure the cpnType=X option for H323-H323 calls:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **h323-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# h323-config
   ORACLE(h323)#
   ```

4. Type **h323-stacks** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(h323)# h323-stack
ORACLE(h323-stack)#
```

5. Set the options parameter by typing **options**, a Space, the option name **cpnType=x** with a plus sign in front of it, and then press Enter.

```
ORACLE(h323-stack)# options +cpnType=x
```

   If you type **options** without the plus sign, you will overwrite any previously configured options. In order to append the new options to the h323-stack's options list, you must prepend the new option with a plus sign as shown in the previous example.

6. Save and activate your configuration.

Default OLC Behavior Changed in Upgrade

You can configure the Oracle Communications Session Border Controller to force media profiles in OLC messages when negotiating H.323 calls. This is the default behavior prior to Release S-C6.1.0.

In Release 6.1.0 and forward the default behavior of OLC is to inherit the values recieved in the signaling message from the remote endpoint.

To enable forced media profiles in OLC:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
ORACLE(configure)#
```

2. Type **session-router** and press Enter.

```
ORACLE(configure)# session-router
ORACLE(session-router)#
```

3. Type **h323-config** and press Enter.

```
ORACLE(session-router)# h323-config
ORACLE(h323-config)#
```

4. **options**—Set the options parameter by typing **options**, a Space, the option-name **forceMediaProfileInOLC** with a plus sign in front of it, and then press Enter.

```
ORACLE(h323-config)# options +forceMediaProfileInOLC
```

   If you type the option without the plus sign, you will overwrite any previously configured options. In order to append the new options to the SIP interface configuration's options list, you must prepend the new option with a plus sign as shown in the previous example.

5. Save and activate your configuration.

Options

The options parameter in the global H.323 and H.323 interface configurations allows you to establish the use of specific features; most of those features are customer specific.

You should exercise caution when you apply options because of the fact that many of them are for customer-specific applications. Consult with your Acme Packet systems engineering to find out if using a particular option would be an advantage to you.

Under no circumstance do we recommend that you configure options without Oracle consultation. There is the chance that you could set an option that might harm an otherwise sound configuration.

Some of the options described below are only applicable to IWF calls. However, you need to establish them in your H.323 configuration.

Global H.323 Options

The following table lists and describes global H.323 options for the Oracle Communications Session Border Controller (SBC).

> **Note:**
>
> Oracle recommends you contact your Oracle account representative before configuring these options.

Options	Description
NoDynamicMSD	SBC forcefully assumes the “primary” role for an outgoing call, and the "secondary" role for an incoming call.
AllowOLCWoMSD	SBC sends OLC before primary - secondary determination is complete. Causes the SBC to be noncompliant with the H.323 recommendation, which does not permit an OLC to be sent prior to MSD completion.
ModifyMediaInAck	SBC accepts and propagates changes to media presented in an OLC Ack. Applies only to Fast Start OLC/OLC Ack messages embedded in H.225 and Q.931 messages during call setup. Causes SBC to be noncompliant with the H.323 recommendation, which does not permit media characteristic to be specified in an OLC to be changed in an OLCAck.
MapG729	SBC maps H.245 G.729 to SDP G.729 with Annex B and vice versa. Applicable only to IWF calls.
ColonG729	SBC uses the : (colon) instead of the = (equal sign) in the media attribute line a=fmtp:18 annexb=yes/no when mapping H.245 G.729 or SDP G.729 with Annex B. Applicable only to IWF calls.
IwfLRQ	SBC sends an INVITE (with no SDP) to a redirect server in response to an incoming LRQ received on an H.323 interface. If a 3xx message with a redirected contact header is returned, the SBC will send an LCF in response to the LRQ. Otherwise, it will send an LRJ.
NoG729AnnexB	SDP received by the IWF with H.729 and no FMTP will be mapped to G.729 on the H.323 side of the call. Can also be set in the session agent options parameter.
sameT38Port	SBC does not allocates separate ports for audio and T.38. SBC will send the same audio port in the OLCAck that it sees in a request mode for T.38 and a new OLC for T.38.

Options	Description
pvtStats	SBC includes program value tree (PVT) statistics in the show h323d display that are a sum of the PVT statistics for all H.323 interfaces. Used for debugging purposes.
strayARQTimer	Required the syntax "strayARQTimer=x," where x is the number of seconds the system waits before tearing down an unsuccessful call in the case of stray ARQs.
forceMediaProfileInOLC	Reverts to older OLC Behavior.

H.323 Interface Options

The following table lists and describes the H.323 interface options.

> **Note:**
>
> Oracle recommends that you contact your Oracle account representative before configuring these options.

Option	Description
stackAliasWins	Oracle Communications Session Border Controller will replace the sourceAddress of the incoming Setup message with the terminal alias of the egress interface when copying the incoming sourceAddress to the outgoing Setup message.
uniqueRRQRASAddress	Oracle Communications Session Border Controller will generate unique rasAddress for each RRQ that it sends to a gatekeeper in response to an incoming RRQ received on an H.323 interface configured for process registration. The IP address will be the local-ip of the outgoing interface, so the port is the unique portion of the rasAddress.
nonV4AdditiveRRQ	Gatekeeper associated with the H.323 interface support additive registration even though it does not set the additiveRegistration field in the RRQ message. When sending in the additive mode, the H.323 interface only sends with the RRQ new terminal aliases that need to be registered. In non-additive mode, the interface sense all the terminal aliases that have been registered, plus the new aliases.
cachedTerimnalAlias	Oracle Communications Session Border Controller copies the terminal alias(es) of the registered endpoint to the asourceAddress field of the Setup message. Terminal alias(es) are changed after the system successfully processes an RRQ from the endpoint.
proxySrcInfo	Oracle Communications Session Border Controller copies the sourceInfo from the incoming Setup message to the outgoing Setup message. Otherwise, Oracle Communications Session Border Controller uses its own endpointType for the sourceInfo field.
noAliasinRCF	Oracle Communications Session Border Controller does not include any terminal alias in the RCF.
forceH245	Oracle Communications Session Border Controllerinitiates an H.245 connection after the call is connected. Otherwise, Oracle Communications Session Border Controller listens for an H.245 connection to be initiated by a remote endpoint.
useCPNInRAS	Oracle Communications Session Border Controller uses the calling party number (CPN) IE of the incoming call as the srcInfo of a RAS message sent in the outgoing call (such as an ARQ).

Option	Description
maintenanceProxy	Oracle Communications Session Border Controller registers interfaces on the enterprise side with a gatekeeper on the carrier side, and registers endpoints through the Oracle Communications Session Border Controller with a unique rasAddress. Interfaces on the enterprise side are associated with the carrier interfaces; you set this option on the carrier side.
convertPNToE164	Oracle Communications Session Border Controller converts the address type partyNumber to dialedDigits (E.164). Conversion applies to sourceAddress, destinationAddress, and destExtraCallInfo aliases in Setup messages.
useCalledPNAsDestInfo	Oracle Communications Session Border Controller uses the H.225 called party number IE as the destinationInfo in ARQ and LRQ requests. Since translation rules can be applied to the Called Party Number, the option enables digit normalization for RAS requests. When not used, Oracle Communications Session Border Controller derives the destinationInfo field in RAS requests from the DestnationAddress field of the incoming Setup.
waitForIncomingH245	On the incoming leg, the Oracle Communications Session Border Controller does not send out its h245Address, but waits for the calling endpoint to send its H245Address.Applies to the outgoing call led as well: The Oracle Communications Session Border Controller does not send out a Facility with startH245 reason and waits for the called endpoint to send its H245Address.
uniqueRRQSrcPort	Enables H.323 RAS Port Mapping. The Oracle Communications Session Border Controller uses the RAS port that it assigned in the rasAddress parameters of an RRQ message as the UDP source port of the outgoing RRQ. Because this feature is linked to the unique RRQ functionality, be aware of the following before you enable the feature: • Enabling H.323 RAS Port Mapping automatically enables the Oracle Communications Session Border Controller's unique RRQ functionality, eliminating the need for you to configure the latter as a separate option. • Enabling the unique RRQ functionality (by setting the uniqueRRQRASAddress option) does not automatically enable H.323 RAS Port Mapping.
srcCallSignallingPort	Enables use of the Q.931 port value for the port field in the sourceCallSignalAddress parameter in an H.225 Setup message. Useful for customers who configure a separate H.323 interface (stack) on the core side for each external IP-PBX.

H.323 Stack Monitoring

In releases prior to S-C6.2.0, the Oracle Communications Session Border Controller provides SNMP monitoring of H.323 session agents but not of the H.323 stacks themselves. The H.323 stack/interface configuration now provides a way for you to set alarm thresholds on a per-stack basis. When enabled, this alarm system ties into the max-calls value to send critical, major, or minor alarms when the number of calls approaches the threshold.

Each H.323 stack now has a threshold crossing alert (TCA) where you can set up three severity levels: critical, major, and minor. You can define one severity level or all three for each stack. To prevent the alarm from firing continuously as call volume through the stack varies, each severity level has an has a reset value below the TCA you set. In addition, each threshold value resets when:

- An alarm with a higher severity is triggered, or
- The built-in reset value for the threshold level is 1% less than the parameter value

RTN 1477

H.323 Stack Monitoring Configuration

This section shows you how to configure H.323 stack monitoring for one H.323 stack configuration. This example shows one instance of the alarm-threshold sub-configuration being established; remember that you can set three—critical, major, and minor. Simply repeat the configuration steps to add more severity levels.

To set up H.323 stack monitoring:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ORACLE(configure)#
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **h323** and press Enter to access the global H.323 configuration.

   ```
   ORACLE(session-router)# h323
   ORACLE(h323)#
   ```

4. **Type h323-stack and press Enter. If you are adding H.323 stack monitoring to an existing H.323 stack configuration, then remember you must select the stack you want to edit.**

   ```
   ORACLE(h323)# h323-stack
   ORACLE(h323-stack)#
   ```

5. Type **alarm-threshold** and press Enter to configure this feature.

   ```
   ORACLE(h323-stack)# alarm-threshold
   ORACLE(alarm-threshold)#
   ```

6. **severity**—Enter the type of severity level for the alarm you want to define. Choose from: **critical**, **major**, or **minor**. This value is required, and defaults to **minor**.
7. **value**—Enter the percentage of the number of calls defined in the **max-calls** parameter that triggers the alarm. For example, if you want to set a minor alarm to fire when the call rate through the stack reaches half the **max-calls** value, enter **50** (meaning 50%). The default value for this parameter is 0, which disables the alarm.

   Remember that if the number of calls falls to below 1% of the max-calls threshold you set, the clear trap fires.
8. Save your work. You can see the data related to this feature using the ACLI **display-alarms** and **show h323 stack stack-alarms** commands.

H.323 Automatic Features

This section describes H.323 features that are automatically enabled on your Oracle Communications Session Border Controller. You do not have to configure special parameters

to turn them on. Even though you do not have to turn these features on, this section describes what they do and how they work.

Alias Mapping

Alias mapping permits destination addresses to be modified by a gatekeeper.

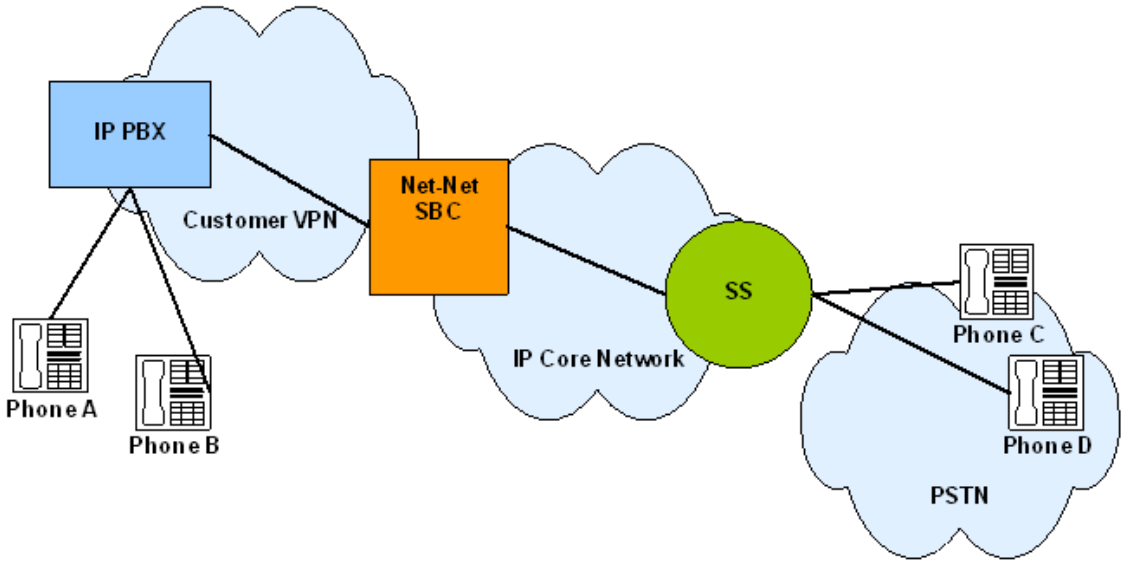
When sending an ARQ or an LRQ message to a gatekeeper, the Oracle Communications Session Border Controller sets the canMapAlias field in that message to true. This setting indicates that the Oracle Communications Session Border Controller accepts modified destination information from the gatekeeper. If the resulting ACF or LCF contains destinationInfo and/or destExtraCallInfo fields, then the Oracle Communications Session Border Controller copies that information respectively to the destinationAddress and destExtraCallInfo fields of the Setup message. In addition, if the destinationInfo is either type e164 or type partyNumber, the Oracle Communications Session Border Controller copies the information into the calledPartyNumber information element (IE) of the Setup message, replacing the existing calledPartyNumber IE.

You do not need to configure special parameters for this feature; it is enabled automatically.

Call Hold and Transfer

The Oracle Communications Session Border Controller's H.323 call hold and transfer feature supports consultation in addition to call holder and transfer. This feature uses signaling procedures based on the ITU-T recommendations/H.323 specification for what it calls third party initiated pause and rerouting.

The following diagram shows how the Oracle Communications Session Border Controller is positioned to provide call hold and transfer support for H.323.



Call Hold and Transfer Basic Call

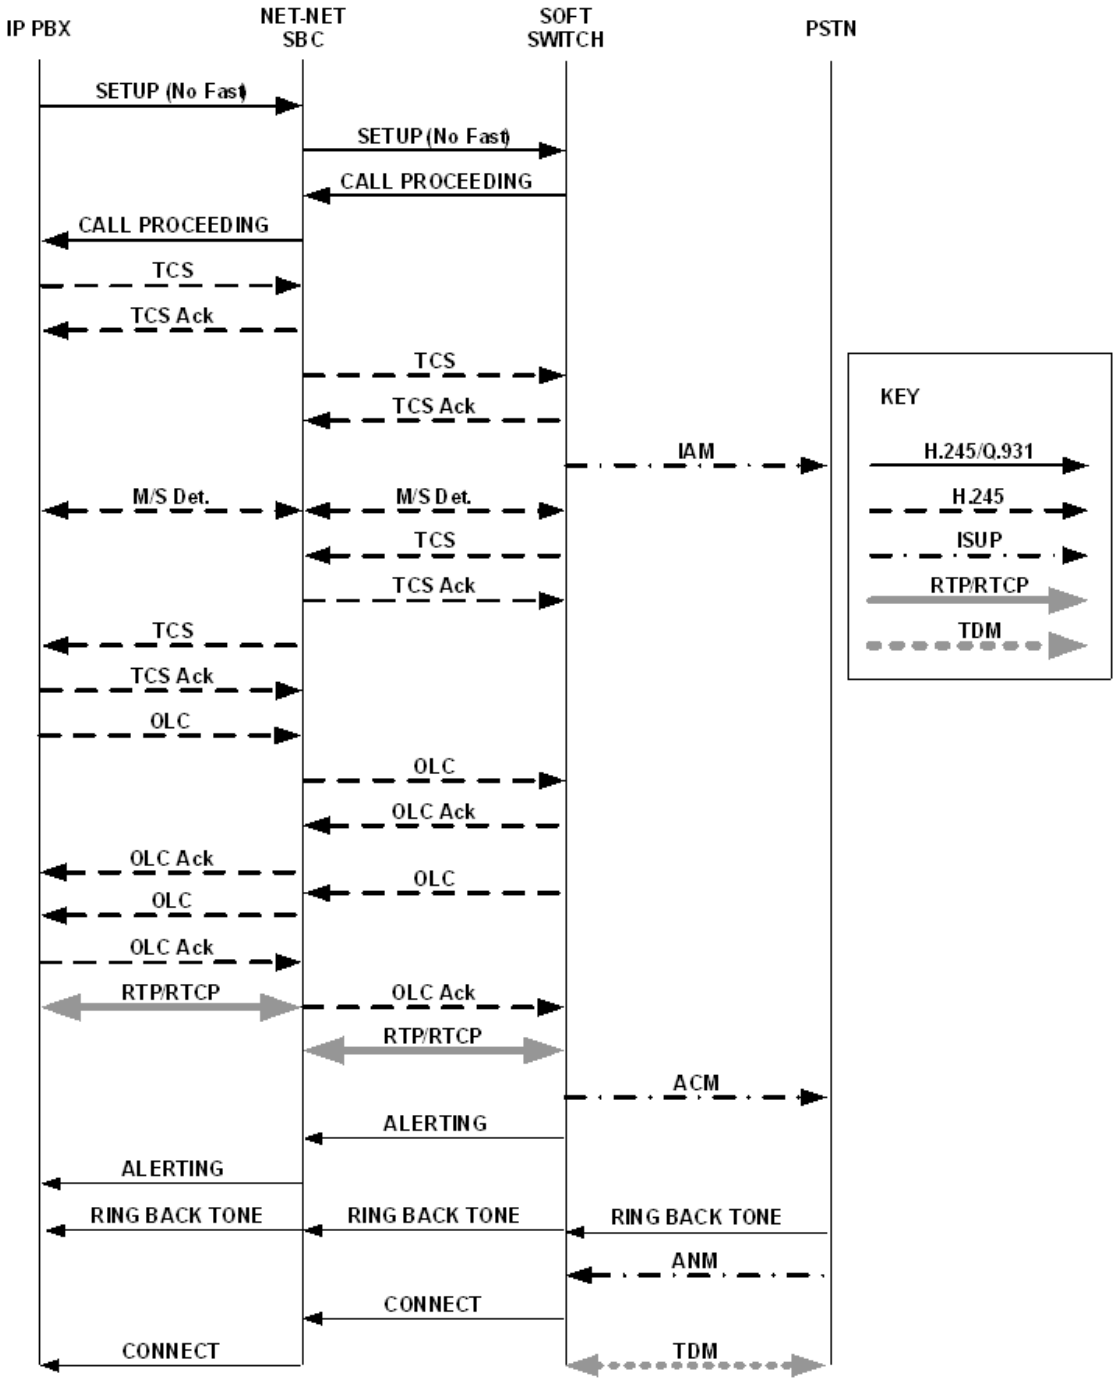
The following diagram show the signaling and media flows between the IP PBX and a softswitch. Note how the Oracle Communications Session Border Controller is position to mediate flows between the two devices.

In the Call Proceeding messages forwarded to the IP PBX, the Oracle Communications Session Border Controller uses a non-zero value to ensure that the IP PBX initiates an H.245 session. A progress indicator does not need to be included if the H.245 address is present in any of the following message types: Alerting, Progress, or Connect.

After the Oracle Communications Session Border Controller receives a Call Proceeding message from the softswitch that contains the H.245 address, the Oracle Communications Session Border Controller sends another Call Proceeding with its own H.245 address.

In the following call flow, the softswitch generates message to the gateway. These messages are:

- Initial Address Message (IAM)
- Address Complete Message (ACM)
- Answer Message (ANM)

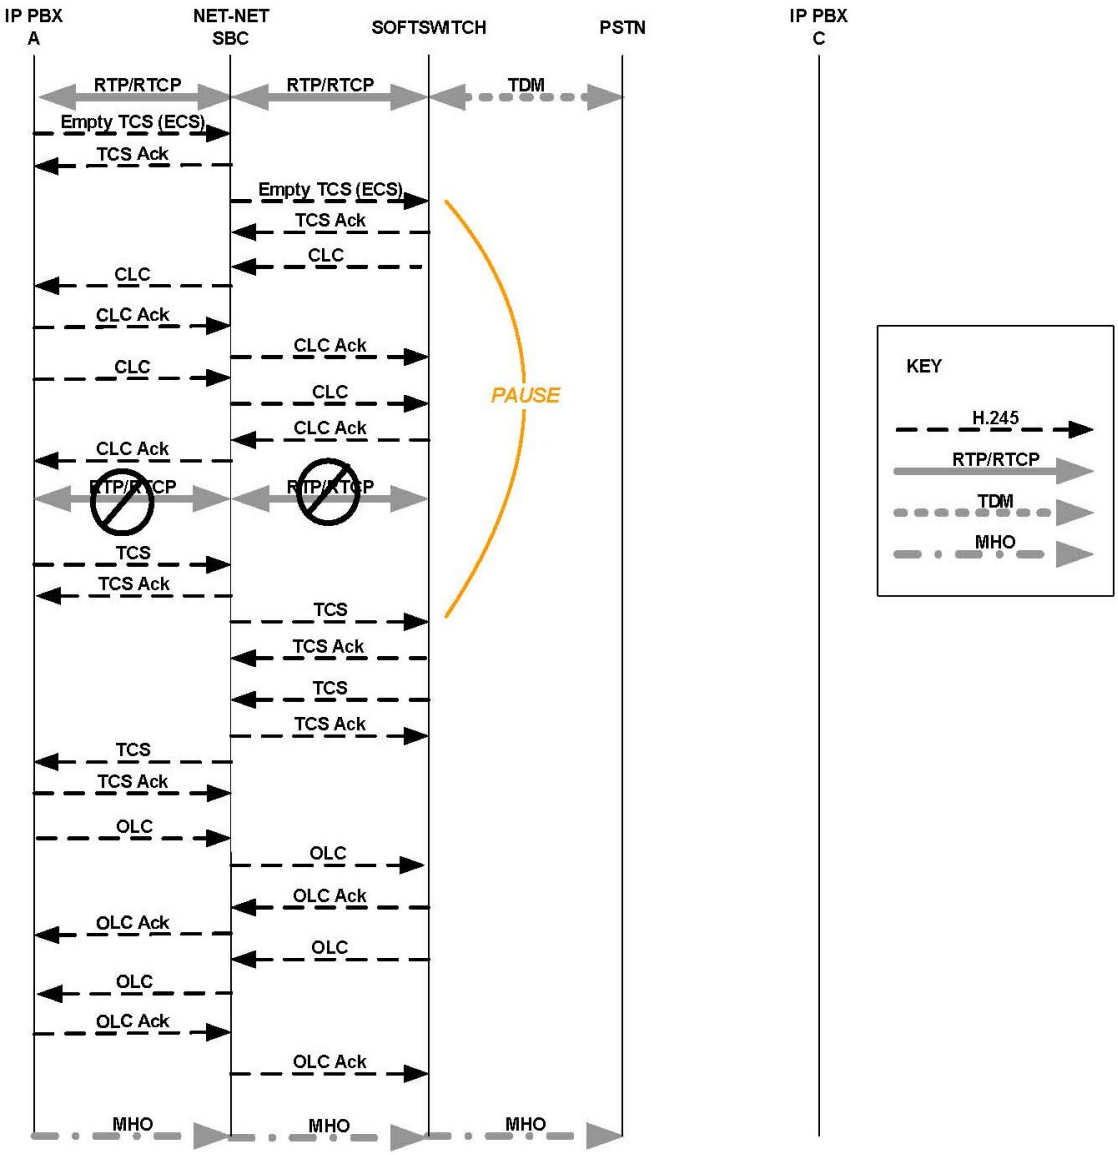


Call Hold and Transfer Music on Hold

The following diagram begins with the condition that IP PBX A is already connected with a gateway, with the Oracle Communications Session Border Controller and the softswitch positioned between the two.

You can see in the call flow where the channels for transporting media are closed, and where the RTP/RTCP is stopped. This creates a pause for the call. With the Oracle Communications Session Border Controller mediating the process, IP PBX A and the softswitch exchange TCS

and OLC messages that allow music on hold (MHO) to flow between IP PBX A and the gateway.



Call Hold and Transfer

The following diagram shows how call transfer works on the Oracle Communications Session Border Controller for H.323. In this diagram, you can see:

- Where local ringback occurs
- Where the pause begins and ends
- Where users and gateways are awakened
- Where logical channels are opened and closed

Media Release for SS-FS Calls

When the Oracle Communications Session Border Controller routes a slow-start to fast-start call, it is possible for the same fast-start call to be routed back through the Oracle Communications Session Border Controller making for a hairpin flow. If it does becomes a hairpin flow, then the Oracle Communications Session Border Controller routes it to its destination as a fast-start to fast-start call. This can result in one-way media if:

- The destination of the hairpin call is in the same realm as the originating slow-start to fast-start call
- The realm reference in the first bullet item is configured to disable in-realm media management
- The called endpoint accepts the proposed fast-start logical channels

The enhancements to the Oracle Communications Session Border Controller's behavior described in this section show how the Oracle Communications Session Border Controller follows additional procedures when setting up a hairpin flow to avoid one-way media when media release occurs.

For H.323 calls, the Oracle Communications Session Border Controllerestablishes media using the H.245 procedures described in the H.245 ITU-T recommendation: control protocol for multimedia communication. It also uses the Fast Connect procedure defined in the H.323 ITU-T recommendation: packet-based multimedia communication systems.

The latter ITU-T recommendation allows a calling endpoint to send a Setup message that contains a fastStart element, a sequence of OLC structures that describe the calling endpoint's proposed forward/reverse logical channels. If the called endpoint accepts this proposal, then logical channels are established.

When the Oracle Communications Session Border Controller translates a call originating in slow-start to fast-start, it uses a Fast Connect procedure in the outgoing leg by sending an outgoing Setup that includes a fastStart element with one or more OLC structures. But when the Oracle Communications Session Border Controller constructs this message, it is unaware of whether the call will become hairpinned or if media release will occur. Because it does not yet have this information, the Oracle Communications Session Border Controller sets the Network Address and the TSAP identifier in the OLC structures to the ingress IP address and port of a corresponding media flow allocated for media traveling between the calling and called endpoints. So if the called endpoint accepts the fastStart the Oracle Communications Session Border Controller proposes, the called endpoint would send its media to the Oracle Communications Session Border Controller. After acceptance, the system starts H.245 procedures on the slow-start side of the call to set up logical channels on that side. Then the Oracle Communications Session Border Controller updates the IP address and port of the media flows using OLC and OLCAck messages received from the calling endpoint.

This procedure works well for endpoints that are not in the same realm, or that are in the same realm for which media management is disabled, because each endpoint must send its media through the Oracle Communications Session Border Controller. When the endpoints are in the same realm and when media management is enabled, however, the Oracle Communications Session Border Controller must perform additional steps for media release in slow-start to fast-start calls.

To support media release in slow-start to fast-start calls, the Oracle Communications Session Border Controller performs a hold-and-resume procedure on the fast-start side. After it establishes channels on the slow-start side and if it detects media release being enabled, the Oracle Communications Session Border Controller sends and empty TCS to the fast-start side to put that side on hold. Then the called endpoint closes all the logical channels it previously opened in the Fast Connect procedure and stops transmitting to them. And the Oracle Communications Session Border Controller also closes it logical channels. Once the channels are closed, the Oracle Communications Session Border Controller resumes the call by sending a new, restricted TCS to the fast-start side. The restricted TCS only contains the receive and transmit capabilities of the codecs types that the called endpoint accepted in the Fast Connect procedure, and it forces the called endpoint to re-open logical channels of the same codec types accepted in the Fast Connect procedure. Once it receives and OLC from the called endpoint, the Oracle Communications Session Border Controller sends on OLCAck with the Network Address and TSAP identifier for the logical channel from the calling endpoint. Then the Oracle Communications Session Border Controller re-opens logical channels (of the same codec types that it open in the Fast Connect procedure). If the called endpoint has not changed its Network Address and TSAP identifier for its logical channels, media is re-established after the Oracle Communications Session Border Controller and the called endpoint exit the hold state. The last steps is for the Oracle Communications Session Border Controller to re-sends the full TCS message from the calling to the called endpoint to inform the called endpoint of the full capabilities of the calling endpoint.

Dependencies

This feature depends on the following assumptions:

- The H.323 endpoint supports the third-party-initiated pause and re-routing feature.
- The H.323 endpoint does not change its Network Address and TSAP identifier when it re-opens the logical channels.
- The H.323 endpoint does not immediately tear down the call when there is not established logical channel in the call.

Hold-and-Resume Procedure

The hold-and-resume procedure has three states:

- Media Hold—Starts when the Oracle Communications Session Border Controller (SBC) sends the empty TCS to the called endpoint to put it on hold.
  When the SBC detects media release, it puts the called endpoint on hold. It can only do so if it has exchanged the TCS and TCSAck messages and completed primary-secondary determination with the calling endpoint.

  When the SBC receives a TCSAck in response to the empty TCS that it sent to the called endpoint, it closes the logical channels it opened as part of the Fast Connect procedure; the called endpoint likewise closes its logical channels. The two then exchange CLC and CLCAck messages, which signals the start of the Media Resume state.
- Media Resume—Starts when the SBC sends a restricted TCS to resume the call.
  The restricted TCS the SBC sends contains only the receive and transmit capabilities of the codec types previously accepted by the called endpoint in the Fast Connect procedure. This forces the called endpoint to re-open logical channels of the same codec type that were previously accepted in the Fast Connect procedure.

  After sending this TCS, the system is ready (as specified in the ITU-T recommendations) to take part on the primary-secondary determination (MSD) process. However, the called party and not the SBC initiates the MSD if it is required. The MSD is completed if necessary. Alternately, the called endpoint can start to re-open its logical channels. When it receives the first OLC from the called endpoint, the SBC also starts to re-open its logical channels.
- Media Complete—Starts when all the logical channels that the SBC re-opens are acknowledged by the called endpoint.

When it enters the Media Complete state, the SBC updates the called endpoint with the full capabilities of the calling endpoint by sending the full TCS.

H.323 and IWF Call Forwarding

This section describes the Oracle Communications Session Border Controller's H.323 and IWF Call Forwarding feature, which is supported for H.323 calls and for calls initiated in SIP that require interworking to H.323.

Previous Behavior

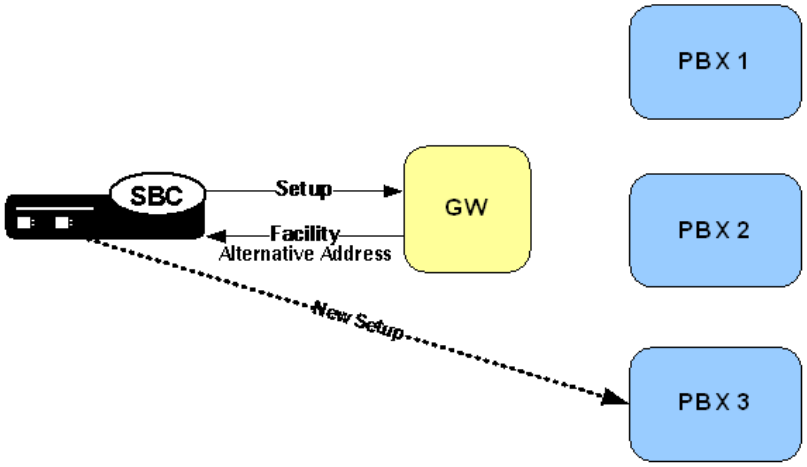
Prior to Release 4.1, the Oracle Communications Session Border Controller did not forward calls when the remote H.323 endpoint sent a Facility message with Call deflection as the reason and an alternate address for forwarding. Instead, it would either:

- Fail to release the initial call and initiate the forwarded call
- Drop the entire call when the remote endpoint for the call tore down the session

New Behavior

In the diagram below, you can see that the Oracle Communications Session Border Controller sends the initial Setup message to the gateway, and the gateway returns the Facility message with an alternate address for forwarding. Rather than engaging in its former behavior, the Oracle Communications Session Border Controller now releases the call with the gateway and sends a new Setup to the alternate address from the Facility message.

This new Setup up has no effect on the first call leg, which remains connected.

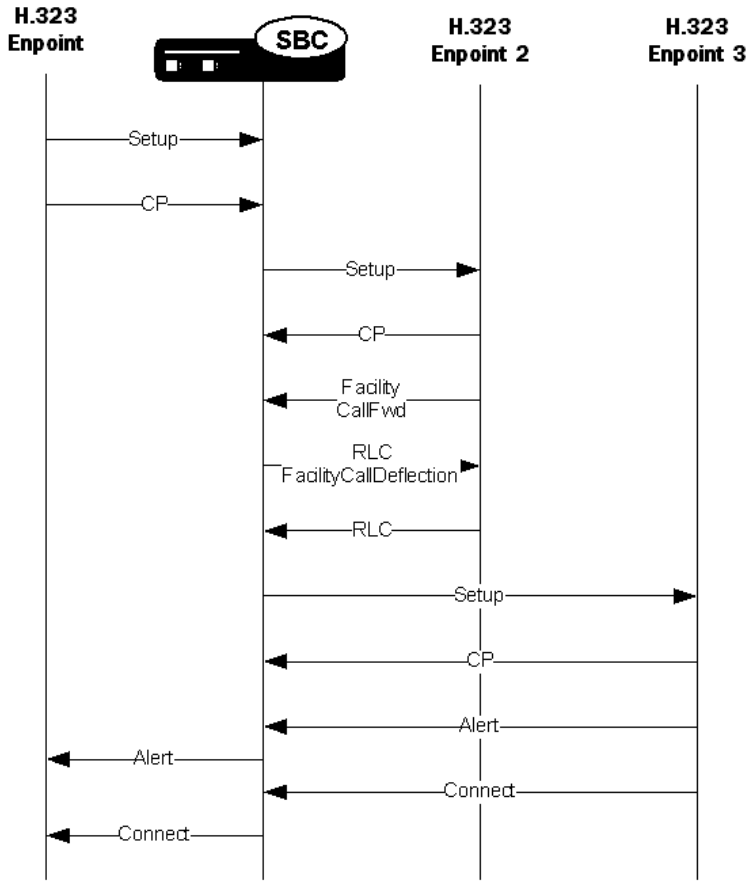


When it receives a Facility message with the reason CallForwarded, the Oracle Communications Session Border Controller looks for an alternate transport address in the Facility's alternativeAddress or alternativeAliasAddress element. The Oracle Communications Session Border Controller releases the egress call with the reason facilityCallDeflection. Then it takes one of two courses of action:

- If it does not find an alternative address, the Oracle Communications Session Border Controller releases the ingress call (with the reason facilityCallDeflection).
- If it finds an alternative address and the egress call has not been alerted or answered, the Oracle Communications Session Border Controller at this point tries to initiate a new egress call. The Oracle Communications Session Border Controller uses the alternative alias address to populate the calledPartyNumber information element (IE) and the destination address of the new Setup.

H.323 Sample Call Flow

The following diagram shows how the H.323 Call Forwarding feature works in a purely H.323 environment.



H.323 NOTIFY Support

To inform another call party of a certain event or communicate information to it, and H.323 entity might send a NOTIFY message. For example, a gateway might send a NOTIFY message to inform the calling party of a display name for a transferee. in previous releases, the Oracle Communications Session Border Controller did not process such a NOTIFY message, blocking the message from reaching its intended destination.

The Oracle Communications Session Border Controller supports the NOTIFY message so that it can pass through and reach its intended destination.

Caveats

The Oracle Communications Session Border Controller does not support interworking the NOTIFY message to a SIP message for calls that require interworking between H.323 and SIP; this support is for pure H.323 calls only.

H.323 H.239 Support for Video+Content

The Oracle Communications Session Border Controller supports multiple media streams for the same payload, generic capabilities, and H.239 generic messages. As a result, these additions broaden the Oracle Communications Session Border Controller's support for videoconferencing, and free you from have to configure media profiles for H.323 support.

> **Note:**
>
> These additions are supported for H.323-H.323 traffic only. These additions do not support SIP-H.323 interworking (IWF), so you still need to configure media profiles for that application.

Multiple Media Streams with the Same Payload

In releases prior to S-C6.2.0, the Oracle Communications Session Border Controller supports multiple audio-video-data streams only if those streams use different payload types. The Oracle Communications Session Border Controller's behavior is extended to provide this support as of Release S-C6.2.0. The Oracle Communications Session Border Controller identifies extendedVideoCapability used to establish an additional channel for H.239-compliant endpoints, an OLC that was formerly not supported.

Support for Generic Capabilities

This feature identifies the OIDs, shown in the table below, and uses the dynamicPayload type from the incoming OLC to generate its own OLC. You no longer need media profiles for genericAudio, genericVideo, and genericData.

Capability Name	Capability Class	Capability Identifier
H.283	Data protocol	{itu-t (0) recommendation (0) h (8) 283 generic-capabilities (1) 0}
G.722.1	Audio protocol	{itu-t (0) recommendation (0) g (7) 7221 generic-capabilities (1) 0}
G.722.1 Extension	Audio protocol	{itu-t (0) recommendation (0) g (7) 7221 generic-capabilities (1) extension (1) 0}
H.324	Data protocol	{itu-t (0) recommendation (0) h (8) 324 generic-capabilities (1) http (0)}
H.263	Video protocol	{itu-t (0) recommendation (0) h (8) 263 generic-capabilities (1) 0} Note: Use of this capability to signal H.263 "Profiles and Levels" per Annex X/ H.263 should always be accompanied in parallel by the signalling of the same modes in H263VideoCapability. This is necessary to ensure that systems which do not recognize the H.263 generic capabilities continue to interwork with newer systems.
H.224	Data protocol	{itu-t (0) recommendation (0) h (8) 224 generic-capabilities (1) 0}
G.722.2	Audio protocol	{itu-t (0) recommendation (0) g (7) 7222 generic-capabilities (1) 0}
G.726	Audio protocol	{itu-t (0) recommendation (0) g (7) 726 generic-capabilities (1) version2003 (0)}
H.241/H.264	Video protocol	{itu-t (0) recommendation (0) h (8) 241 specificVideoCodecCapabilities (0) h264 (0) generic-capabilities (1)}

Capability Name	Capability Class	Capability Identifier
H.241/H.264	Video protocol	{itu-t(0) recommendation(0) h(8) 241 specificVideoCodecCapabilities(0) h264(0) iPpacketization(0) RFC3984NonInterleaved(1)}
H.241/H.264	Video protocol	{itu-t(0) recommendation(0) h(8) 241 specificVideoCodecCapabilities(0) h264(0) iPpacketization(0) RFC3984Interleaved(2)}

Support for H.239 Generic Messages

This section describes the Oracle Communications Session Border Controller's support for H.239 Generic Messages.

Generic Message	Description
Generic Request	• flowControlReleaseRequest—Used when a device wants to add a channel toward an MCU that has sent multipointConference, or if the device wants to increase a channel bit rate when the channel is flow-controlled. The message has the channelId, which is the logicalChannelNumber of the channel. The Oracle Communications Session Border Controller proxies this message, replacing the channelId with the logicalChannelNumber of its channel. • presentationTokenRequest—Request by the sender to acquire the indicated token. The message has the channelId, which is the logicalChannelNumber of the channel. The Oracle Communications Session Border Controller proxies this message, replacing the channelId with the logicalChannelNumber of its channel.
Generic Response	• flowControlReleaseResponse—Sent in response to the flowControlReleaseRequest, either acknowledging or rejecting the request. The "acknowledge" response indicates the far-end device intends to make a best-effort attempt to comply with the request. The exact bit rate requested may not be allocated. The reject response indicates that the far-end device does not intend to comply with the request. The response contains the channelId that was sent in the request. While proxying the response, the Oracle Communications Session Border Controller will replace the channelId with the channelId it received in the request. • presentationTokenResponse—Sent in response to the presentationTokenRequest. The response will either confirm or reject the assignment of the indicated token to the sender of the presentationTokenRequest. The response contains the channelId that was received in the request. While proxying the response, the Oracle Communications Session Border Controller will replace the channelId with the channelId it received in the request.
Generic Command	• presentationTokenRelease—Sent by the device holding the token in order to relinquish the token. The message has the channelId, which is the logicalChannelNumber of the channel. The Oracle Communications Session Border Controller proxies this message, replacing the channelId with the logicalChannelNumber of its channel.

Generic Message	Description
Generic Indication	• presentationTokenIndicateOwner—Indicates who owns the token. The message has the channelId, which is the logicalChannelNumber of the channel. The Oracle Communications Session Border Controller proxies this message, replacing the channelId with the logicalChannelNumber of its channel.

Support for Miscellaneous Indication

An endpoint sends a miscellaneous indication to send (logicalChannelActive) or stop (logicalChannelInactive) live video streams. The message has a channelId, which is the channel's logicalChannelNumber. The Oracle Communications Session Border Controller proxies this message, replacing the channelId with the logicalChannelNumber of its own channel.

Video Conferencing Support for Polycom Terminals

The Oracle Communications Session Border Controller includes support for Polycom video conferencing that implements messaging properly and presents proper addressing information for session billing, as described below.

The Oracle Communications Session Border Controller supports operations in a video conferencing environment with Polycom H323 terminals and a Polycom MCU (Multipoint Conferencing Unit) by relaying H.239/H.245. The Oracle Communications Session Border Controller implements the following messages appropriately:

- Miscellaneous command message with subtype such as multiPointModeCommand, cancelMultipointModeCommand
- Conference Indication message with subtype such as terminalNumberAssign, terminalYouAreSeeing

The Oracle Communications Session Border Controller can also resolve a video conference billing issue caused by a NAT device. NAT devices change the sourceCallSignalAddress in a Setup message to the IP address of the NAT device. Deployments that rely on this address in CDRs to bill for the service need this address to be that of the original station behind the NAT. The user sets the **addSrcCallSignalAddr** option in the **h323-stack** that receives the incoming Setup to cause the Oracle Communications Session Border Controller to present the desired address.

The srcCallSignalAddress field in the admissionRequest message received by the Oracle Communications Session Border Controller often contains the transportAddress of the calling endpoint. This field is optional for the admissionRequest message. If configured with the option and presented with this field, the Oracle Communications Session Border Controller saves the address for later use in outgoing Setup messages. If the srcCallSignalAddress field in the admissionRequest message is not present, or is equal to 0.0.0.0, the Oracle Communications Session Border Controller does not save it.

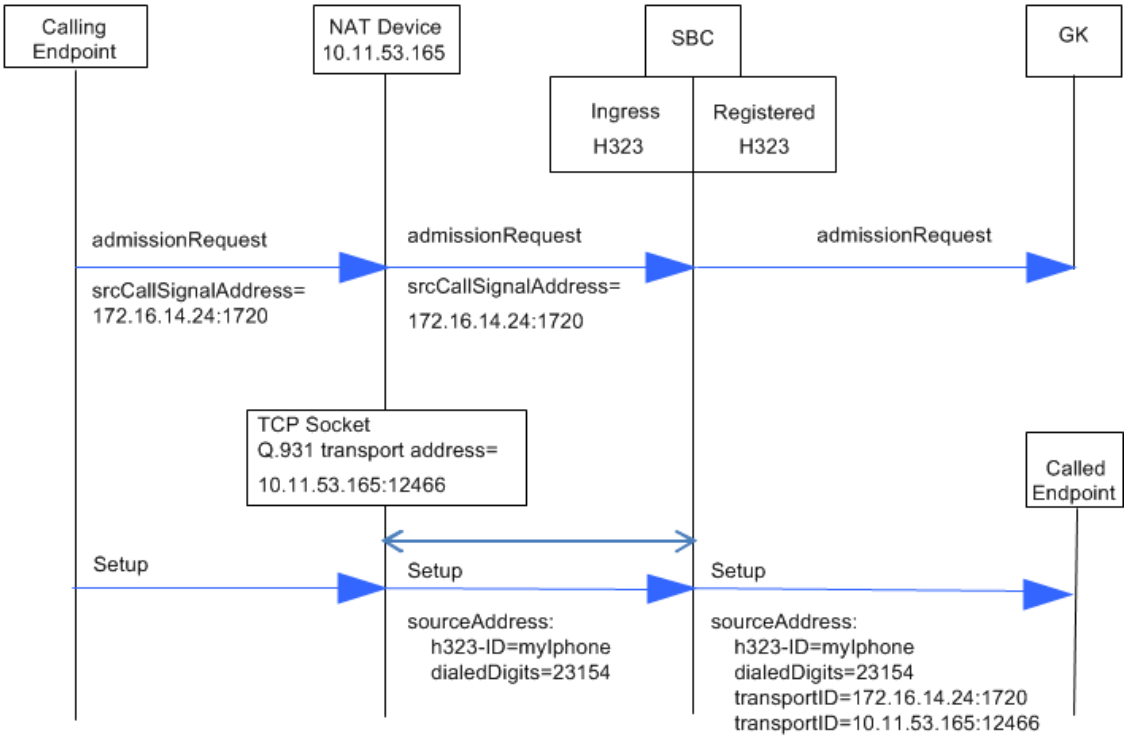
Having stored this address, the Oracle Communications Session Border Controller uses it following the steps below. Note that the Setup message in this scenario is preceded by the admission request and confirmation messages from the gatekeeper for the call.

1. Add the srcCallSignalAddress, saved from the admissionRequest message, into the sourceAddress field of the outgoing Setup message. The Oracle Communications Session Border Controller adds this address in the format of an AliasAddress of type transportID

after any other AliasAddresses that are normally included from the incoming Setup sourceAddress field.

2. Add the remote transport address of the incoming Q.931 TCP connection, into the sourceAddress field of the outgoing Setup message. The Oracle Communications Session Border Controller adds this address in the format of an AliasAddress of type transportID, after the alias that was added in step 1.

The call flow diagram below depicts the Oracle Communications Session Border Controller adding addresses in accordance with this feature.



Use the syntax below to set this option on the h323-stack receiving the incoming Setup.

```
(h323-stack)# options +addSrcCallSignalAddr
```

The user can find this process confirmed in the log.h232d log file.

ACLI Signaling Mode Configuration Examples

The following ACLI displays provide examples of the Signaling Modes of Operation described earlier in this chapter.

Configuration Fields and Values for B2BGW Signaling

This example provides is a sample for the Back-to-Back Gateway Signaling mode of operation.

```
h323-config
        state                           enabled
        log-level                       INFO
        response-tmo                    4
```

```
        connect-tmo                     32
h323-stack
        name                            zone1
        state                           enabled
        isgateway                       enabled
        realm-id                        zone1realm
        assoc-stack                     zone2
        local-ip                        x.x.x.x (IP address of VGW-A)
        max-calls                       200
        max-channels                    10
        registration-ttl                0
        terminal-alias
                                        h323-ID=private
        ras-port                        1719
        auto-gk-discovery               enabled

Additional Information

This section contains detailed tables to use as a reference when you are learning about H.323 features or when you are configuring them.

About Payload Types

You set the payload type when you are configuring a media profile to support Slow Start to Fast Start Translation.

When you configure media profiles, you might need set the payload type to identify the format in the SDP m lines. For RTP/AVP, the default transport method of a media profile configuration, this will be the RTP payload type number. Newer codecs have dynamic payload types, which means that they do not have an assigned payload type number.

When you use RTP/AVP as the transport method, you should only set the payload type when there is a standard payload type number for the encoding name; otherwise, leave the payload type blank.

The Oracle Communications Session Border Controller uses the payload type value to determine the encoding type when SDP identifies the standard payload type in the m line, but does not include an a=rtpmap entry. These are two equivalent SDPs:

c=IN IP4 192.0.2.4

```
m=audio 0 RTP/AVP 0
```

c=IN IP4 192.0.2.4

```
m=audio 0 RTP/AVP 0
a=rtpmap:0 PCMU/8000
```

The first does not include the RTP map entry, but uses the standard payload type of 0. If the Oracle Communications Session Border Controller receives an SDP like the first, it uses the payload type 0 to locate the corresponding media profiles configuration. When an a=rtpmap is present, the Oracle Communications Session Border Controller uses the encoding name in the a=rtpmap line to find the media profile configuration and does not consider the payload type number.

Payload Types for Standard Audio and Visual Encodings

The following is a table of standard audio and visual payload encodings defined in H. Schulzrinne, GND Fokus, RTP Profile for Audio and Visual Conferences with Minimal Control, RFC 1890, and in the *RTP Parameters* document in IANA's Directory of Generally Assigned Numbers.

Payload Type	Encoding Name	Audio (A)/Visual (V)	Clock Rate (Hz)
0	PCMU	A	8000

About RAS Message Treatment

When you enabled the H.323 Registration Proxy, the Oracle Communications Session Border Controller modifies and deletes certain fields as outlined in the table below. The Oracle Communications Session Border Controller forwards any fields that are not listed in this table without modifying or deleting them.

> **Note:**
>
> Although the Oracle Communications Session Border Controller forwards a field, it does not always support the feature related to that field.

Field Name	Message	Deleted	Modified	Value Used in Modification
alternateEndpoints	RRQ, URQ, ACF	X	N/A	N/A
alternateGatekeeper	RCF, URQ	X	N/A	N/A
altGKInfo	RRJ, URJ, DRJ	X	N/A	N/A

IWF Services

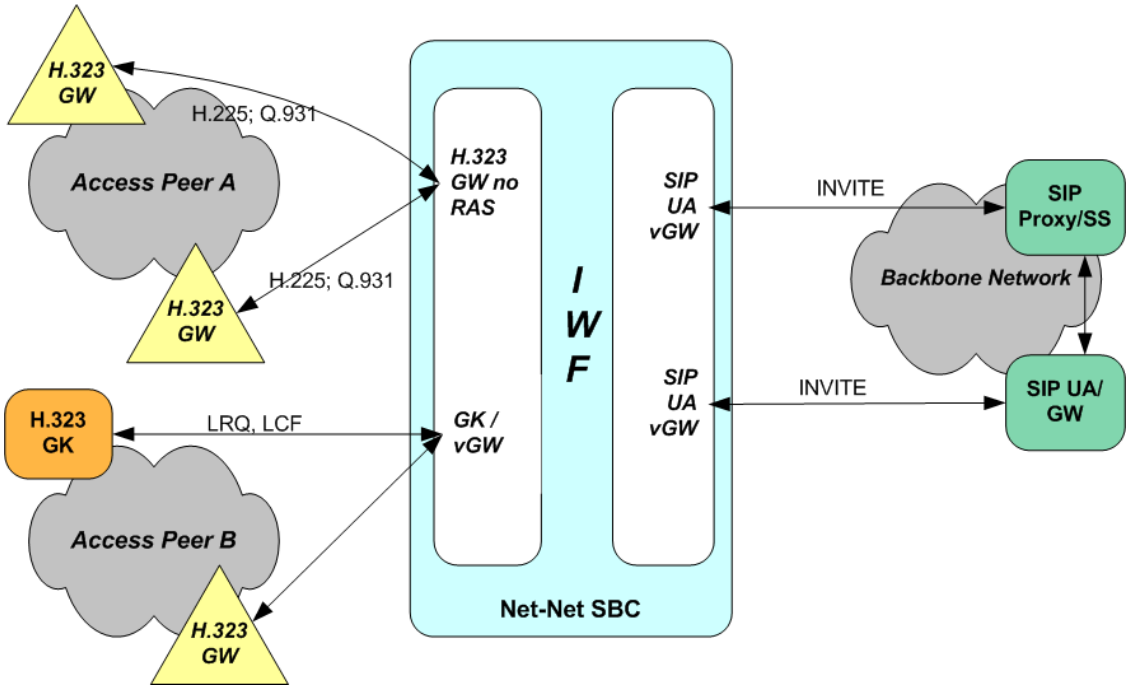
Using the Oracle Communications Session Border Controller's interworking function (IWF), you can interconnect SIP networks with H.323 networks. Considering the large amount of H.323 deployments already in place and the continuing emergence of SIP in new VoIP deployments, the IWF provides a much-needed solution. SIP providers can maintain a single-protocol backbone while exchanging VoIP sessions with H.323 providers.

The H.323 Signaling Services section contains information about the H.323 signaling modes of operation that the Oracle Communications Session Border Controller supports. The following H.323 signaling modes of operation can be used when you use the Oracle Communications Session Border Controller's IWF in an access or a peering solution.

- Back-to-back gateway signaling
- Interworking gatekeeper/gateway

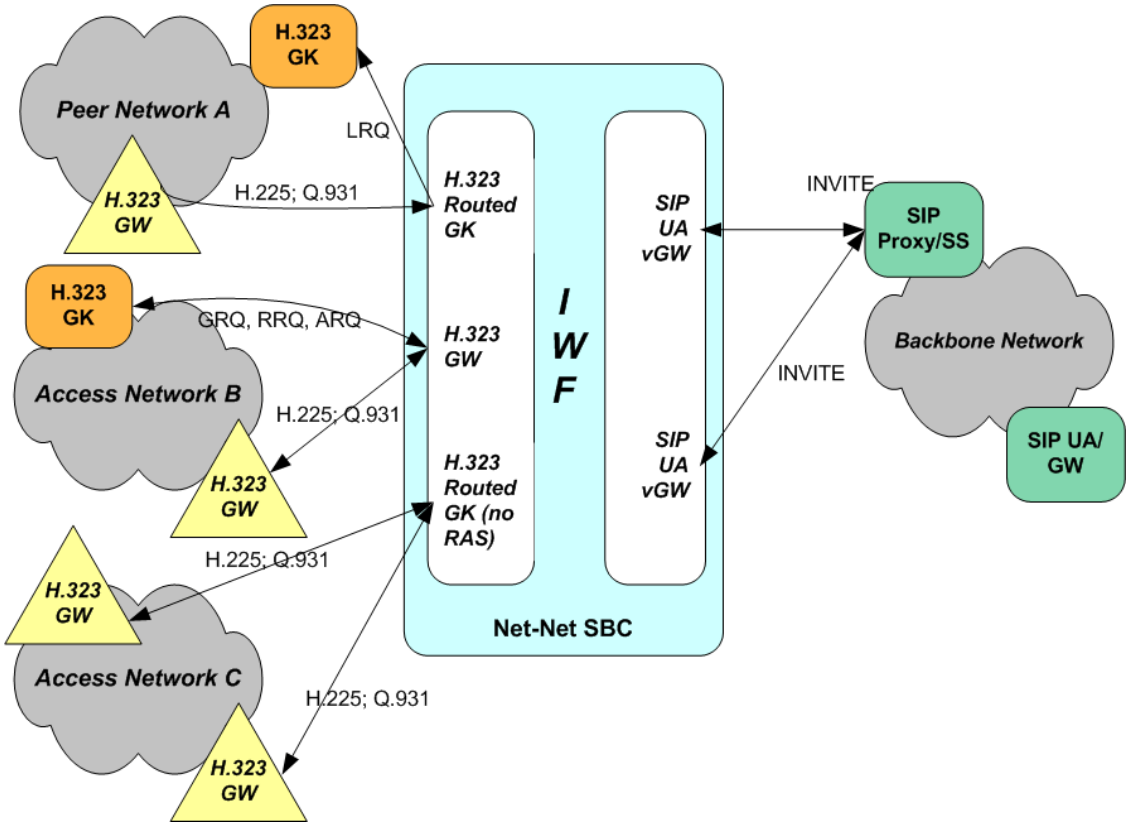
Access Network Application

You can configure your Oracle Communications Session Border Controller so that it provides an access solution for your network. The access solution allows SIP-based hosted communications platforms to be extended to enterprise-based H.323 systems. In the figure below, you can see different types of H.323 signaling modes being interworked with SIP. On the H.323 side, the Oracle Communications Session Border Controller can appear to be a gatekeeper or a gateway, depending on how you configure the H.323 interface. On the SIP side, the Oracle Communications Session Border Controller can appear to be a SIP UA or behave as a virtual gateway.



Networking Peering Application

In the IWF network peering solution, you can see the same network elements at work. However, the H.323 side of this IWF application shows the use of a gatekeeper controlled gateway for Peer Network B. Because this is a peering solution, the SIP side of the Oracle Communications Session Border Controller communicates with the SIP proxy or softswitch in the backbone network rather than with the SIP UA or SIP gateway.



SIP and H.323

The Oracle Communications Session Border Controller supports interworking between SIP and H.323 for H.323 Slow Start and Fast Start calls. In addition to describing IWF sessions when initiated from the H.323 side and from the SIP side (with sample call flows), this section provides information you will need when you configure SIP and H.323.

SIP H.323 Negotiation H.323 Fast Start

The Oracle Communications Session Border Controller can perform protocol translations for SIP and H.323 Fast Start, where media capabilities are sent with the Setup request for an H.323 session.

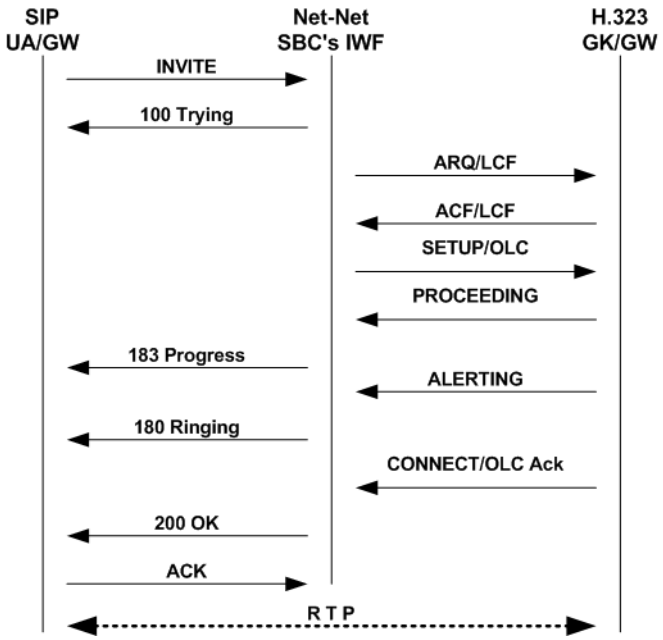
This section's call flow diagrams show how SIP and H.323 messages flow between SIP and H.323 devices, with the Oracle Communications Session Border Controller positioned between the two entities so it can perform translations. The following two sample scenarios with Fast Start appear in the diagrams below, although other scenarios are possible:

- Calls originating in SIP being translated to H.323 Fast Start
- Calls originating in H.323 Fast Start translated to SIP

SIP to Fast Start H.323

In the following diagram below, a SIP endpoint (such as a UA or a SIP Gateway) initiates a session by sending an INVITE message destined for an H.323 endpoint (a GK or GW). Between these entities, the system is positioned to perform interworking. The Oracle Communications Session Border Controller recognizes that the INVITE message is destined for an H.323 device, and returns a 100 Trying message to the SIP endpoint as it attempts to negotiate the H.323 side of the session. This negotiation starts when the Oracle Communications Session Border Controller initiates the RAS process with the H.323 endpoint by sending either an ARQ or an LRQ, allowing the Oracle Communications Session Border Controller to determine if the H.323 endpoint will accept the session.

Once the H.323 endpoint responds with an ACF or LCF, the Oracle Communications Session Border Controller reissues the SIP INVITE on the H.323 side as an H.225 Setup, which is sent with the OLC. Then the H.323 endpoint responds with Proceeding and Alerting messages (which correspond respectively to SIP 183 Progress and 180 Ringing messages). At that point, the H.323 endpoint sends a Connect message that includes the OpenLogicalChannel message (OLC), announcing the logical channel for media flows has been set up. The Oracle Communications Session Border Controller converts the H.323 OLC to a SIP 200 OK. After receiving the 200 OK, the SIP endpoint sends an ACK, confirming that the session has been established. Because there is no H.323 equivalent for the SIP ACK, the Oracle Communications Session Border Controller does not generate a corresponding message on the H.323 side. At this point, the session is fully established and RTP flows between the endpoints.

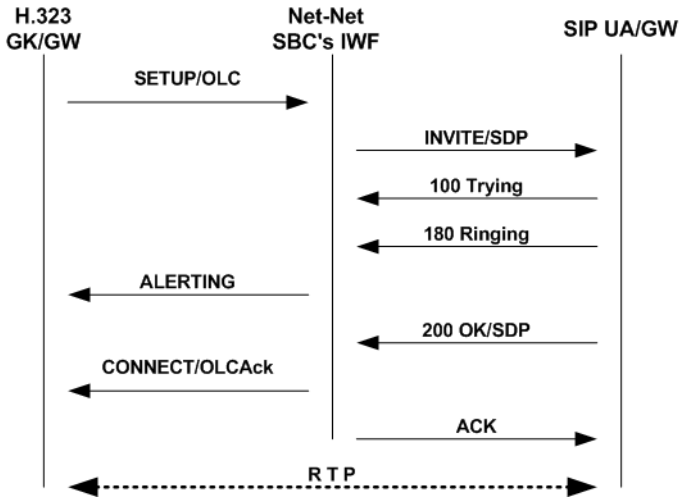


H.323 Fast Start to SIP

In the diagram below, an H.323 endpoint (a GK or GW) initiates a session by sending a Setup request destined for a SIP endpoint (such as a UA or a SIP Gateway). Between these entities,

the Oracle Communications Session Border Controller is positioned to perform interworking. The H.323 endpoint has completed the RAS process prior to sending the SETUP message.

The Oracle Communications Session Border Controller receives the Setup message and then sends a SIP INVITE on the SIP side. The SIP endpoint responds with a 100 Trying; the Oracle Communications Session Border Controller does not resend this message on the H.323 side. Next, the SIP endpoint issues a 180 Ringing message, which the Oracle Communications Session Border Controller reissues to the H.323 endpoint as an Alerting message. The SIP endpoint then sends a 200 OK, retransmitted by the Oracle Communications Session Border Controller as a Connect message that includes an OLC. Once the Oracle Communications Session Border Controller sends an ACK to the SIP endpoint, RTP flows between the endpoints.



SIP H.323 Negotiation H.323 Slow Start

The Oracle Communications Session Border Controller can also perform protocol translations for SIP and H.323 Slow Start, where—unlike the cases with Fast Start described above—media information is not sent with the Setup request for an H.323 session. For H.323 Slow Start, media is negotiated after the session is established.

This section's call flow diagrams show how SIP and H.323 messages flow between SIP UA/GW and an H.323 GK/GW, with the Oracle Communications Session Border Controller positioned between the two entities so it can perform translations. Two sample scenarios with Slow Start appear in the diagrams below:

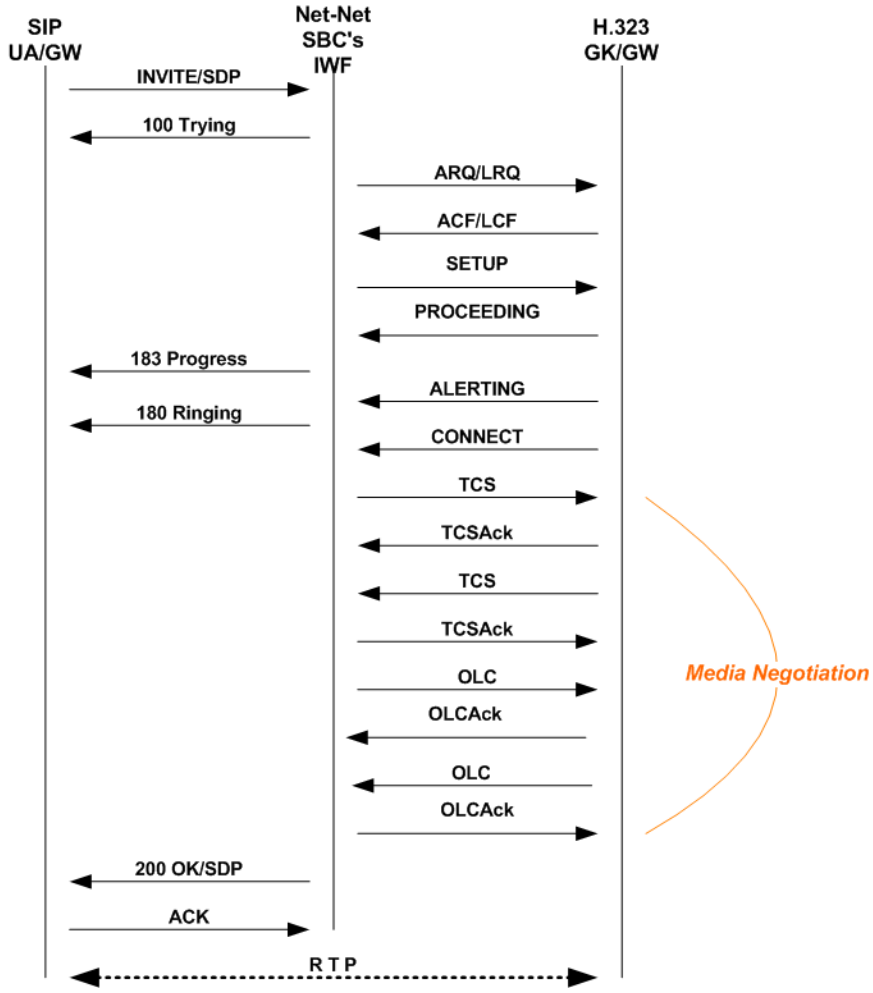
- SIP being interworked to Slow Start H.323
- Slow Start H.323 being interworked to SIP

H.323 SIP to Slow Start

In the following diagram below, a SIP endpoint (such as a UA or a SIP Gateway) initiates a session by sending an INVITE request destined for an H.323 Slow Start endpoint (a GK or GW). Between these entities, the Oracle Communications Session Border Controller is positioned to perform interworking.

The call flow for this type of translation works fundamentally the same way that the translation does for SIP to Fast Start H.323, with the exception of how the media is established. Media is negotiated through the exchange of TCS and OLC messages after the H.323 Connect and SIP

180 Ringing messages have been sent. The first TCS message is sent from the Oracle Communications Session Border Controller to the H.323 endpoint, and it contains information about media capabilities in SDP. The H.323 endpoint accepts and acknowledges this information with a TCS Ack message. Then the H.323 endpoint sends a second TCS, carrying information about the Gateway's capabilities, that the Oracle Communications Session Border Controller accepts and acknowledges. The H.323 endpoint and the Oracle Communications Session Border Controller then exchange OLC and OLC Ack messages that establish the operating mode and Gateway capability. Finally, the Oracle Communications Session Border Controller completes the 200 OK/ACK sequence on the SIP side, and RTP flows between the two endpoints.



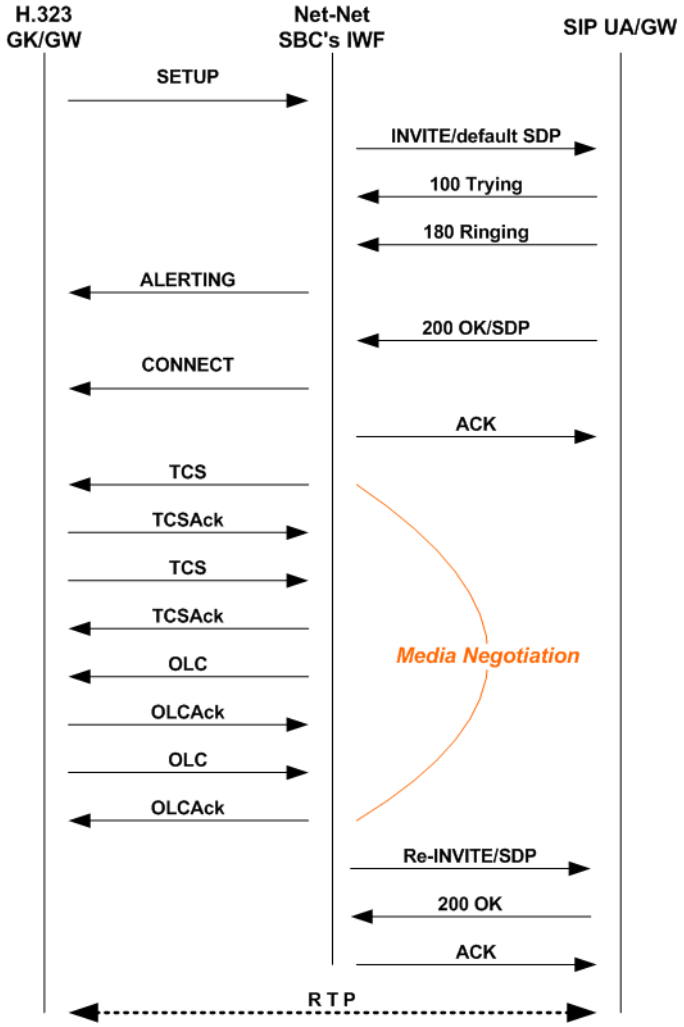
H.323 Slow Start to SIP

In the following diagram below, an H.323 endpoint (GW or GK) initiates a session by sending a Setup request destined for a SIP endpoint (such as a UA or a SIP Gateway). Between these entities, the Oracle Communications Session Border Controller is positioned to perform interworking. The H.323 endpoint has completed the RAS process prior to sending the SETUP message.

The call flow for this type of translation works fundamentally the same way that the translation does for H.323 Fast Start to SIP, with the exception of how the media is established. When the Oracle Communications Session Border Controller receives an H.323 message destined for a SIP endpoint, it sends a SIP INVITE message that includes default SDP to that SIP endpoint. The default SDP is constructed using information in the media profiles listed for the IWF

configuration; if necessary, this media information is amended later in the sequence. Once the call is set up, the Oracle Communications Session Border Controller negotiates media with the H.323 endpoint through a series of TCS/TCS Ack and OLC/OLC Ack messages that establish the operating mode and Gateway capability.

When the Oracle Communications Session Border Controller completes media negotiation with the H.323 endpoint, it issues a re-INVITE to the SIP endpoint that contains the updated information needed for media transmission. In response, the SIP endpoint sends a 200 OK message that the Oracle Communications Session Border Controller answers with an ACK. Then RTP can flow between the two endpoints.



Status and Codec Mapping

The Oracle Communications Session Border Controller maps SIP and H.323 status codes as described in this section. Status and codec mapping do not require configuration; they occur transparently.

IWF Termination from H.323

When a call that requires the IWF terminates from the H.323 side, the Oracle Communications Session Border Controller uses the mapping scheme in the following table to determine the appropriate SIP status.

H.323 Disconnect Reason	SIP Status
No Bandwidth	480 Temporarily Unavailable
Gatekeeper Resource	404 Not Found
Unreachable Destination	404 Not Found
Destination Rejection	603 Decline
Invalid Revision	505 Version Not Supported
No Permission	401 Unauthorized
Unreachable Gatekeeper	503 Service Unavailable
Gateway Resource	480 Temporarily Unavailable
Bad Format Request	400 Bad Request
Adaptive Busy	486 Busy Here
In Conference	486 Busy Here
Undefined Reason	500 Internal Server Error
Facility Call Deflection	486 Busy Here
Security Denied	401 Unauthorized
Called Party Not Registered	404 Not Found
Caller Not Registered	401 Unauthorized

IWF Termination During H.323 RAS

When a call that requires the IWF terminates from the H.323 side during RAS and generates an error, the Oracle Communications Session Border Controller uses the mapping scheme in the following table to determine the appropriate SIP status.

H.323 RAS Error	SIP Status
Called Party Not Registered	404 Not Found
Invalid Permission	401 Unauthorized
Request Denied	503 Service Unavailable
Undefined	500 Internal Server Error
Caller Not Registered	401 Unauthorized
Route Call To Gatekeeper	305 User Proxy
Invalid Endpoint ID	500 Internal Server Error
Resource Unavailable	503 Service Unavailable
Security Denial	401 Unauthorized
QoS Control Not Supported	501 Not Implemented
Incomplete Address	484 Address Incomplete
Route Call to SCN	302 Moved Temporarily
Aliases Inconsistent	485 Ambiguous
Not Currently Registered	401 Unauthorized

IWF RAS Registration Failure Code Mapping

For calls that require interworking between H.323 and SIP, the Oracle Communications Session Border Controller supports IWF response code mapping. This feature enables the Oracle Communications Session Border Controller to support configurable SIP response codes for IWF calls that fail during RAS, when the Oracle Communications Session Border Controller has been unable to register with a gatekeeper; this allows a wider range of more accurate response codes to be communicated.

When this feature is not enabled, the Oracle Communications Session Border Controller generates a 404 Not Found when a SIP-to-H.323 call fails as a result of the stack's failure to register with a gatekeeper.

When the condition noted above takes place, the response code can be any of the ones listed in this table. The code values listed in the table are used to specify the code to which you want to map.

Code	Description
403	Forbidden
406	Not Acceptable
408	Request Timeout
410	Gone
420	Bad Extension
480	Temporarily Unavailable
486	Busy Here
487	Request Terminated
500	Server Internal Error
503	Service Unavailable
504	Server Time-out
600	Busy Everywhere
603	Decline

To enable IWF RAS registration failure code mapping:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **h323** and press Enter.

   ```
   ORACLE(session-router)# h323
   ORACLE(h323)#
   ```

4. **options**—Set the options parameter by typing **options**, a Space, the option name preceded by a plus sign (+) (**iwfRegFailCode=X**), and then press Enter. X is the SIP response code that you want to use; the table above lists the supported response codes that are supported.

   ```
   ORACLE(h323)# options +iwfRegFailCode=503
   ```

   If you type **options iwfRegFailCode=X**, you will overwrite any previously configured options. In order to append the option to the options list, you must prepend the new option with a plus sign as shown in the previous example.

IWF Termination from SIP

When a call that requires the IWF terminates from the SIP side, the Oracle Communications Session Border Controller uses the mapping scheme in the following table to determine the appropriate H.323 Release Complete Reason code.

SIP Status	H.323 Release Complete Reason
300 Multiple Choices	Undefined Reason
401 Unauthorized	Security Denied
402 Payment Required	Undefined Reason
403 Forbidden	No Permission
404 Not Found	Unreachable Destination
405 Method Not Allowed	Undefined Reason
406 Not Acceptable	Undefined Reason
407 Proxy Authentication Required	Security Denied
408 Request Timeout	Adaptive Busy
409 Conflict	Undefined Reason
410 Gone	Unreachable Destination
411 Length Required	Undefined Reason
414 Request-URI Too Large	Bad Format Address
415 Unsupported Media Type	Undefined Reason
420 Bad Extension	Bad Format Address
480 Temporarily Unavailable	Adaptive Busy
481 Call/Transaction Does Not Exist	Undefined Reason
482 Loop Detected	Undefined Reason
483 Too Many Hops	Undefined Reason
484 Address Incomplete	Bad Format Address
485 Ambiguous	Undefined Reason
486 Busy Here	In Conference
487 Request Terminated	Undefined Reason
488 Not Acceptable Here	Undefined Reason
500 Internal Server Error	Undefined Reason
501 Not Implemented	Undefined Reason
502 Bad Gateway	Gateway Resource
503 Service Unavailable	Gateway Resource
504 Gateway Timeout	Adaptive Busy
505 Version Not Supported	Invalid Revision
600 Busy Everywhere	Adaptive Busy
603 Decline	Destination Rejection
604 Does Not Exist Anywhere	Unreachable Destination
606 Not Acceptable	Undefined Reason

Q.850 Cause to H.323 Release Complete Reason

When a call that requires the IWF terminates from the H.323 side and no H.323 Release Complete Reason is specified, the Oracle Communications Session Border Controller maps the Q.850 cause to an H.323 Release Complete Reason using the mapping scheme in the following table. This new H.323 status is then mapped to a SIP status as described in the IWF Termination from SIP table.

Q.850 Cause	H.323 Release Complete Reason
No Route To Destination	Unreachable Destination
Normal Call Clearing	Destination Rejection
User Busy	In Conference
Subscriber Absent	Called Party Not Registered
Invalid Number Format	Bad Format Address
Normal Unspecified	Undefined Reason
No Circuit/Channel Available	No Bandwidth
Network Out Of Order	Unreachable Gatekeeper
Temporary Failure	Adaptive Busy
Switching Equipment Congestion	Gateway Resource
Resource Unavailable	Gatekeeper Resource
Incompatible Destination	Invalid Revision
Interworking Unspecified	No Permission

Codec Mapping

The Oracle Communications Session Border Controller uses the following mapping scheme when converting media specifications between H.245 (used in H.323) and SDP (used in SIP).

Media coming into the Oracle Communications Session Border Controller one way exits the system in the corresponding way as specified in the following table. For example, media coming into the Oracle Communications Session Border Controller as H.245 type g711Ulaw64k exits the system as media type PCMU.

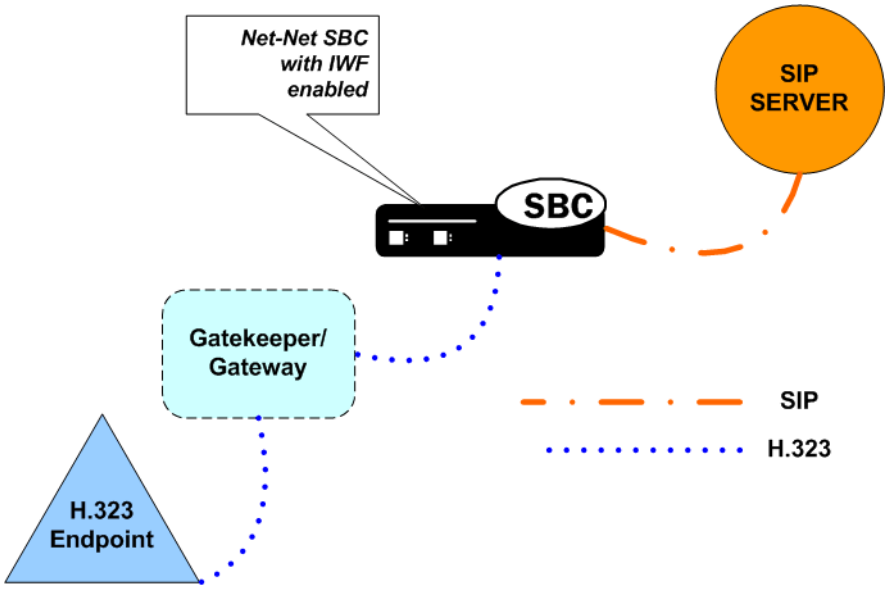
H.245 Type	SDP Media Type
g711Ulaw64k	PCMU
g711Ulaw56k	PCMU
g711Alaw64k	PCMA
g711Alaw56k	PCMA
g726	G726-32
g7231	G723
g722	G722
g728	G728
g729wAnnexB	G729
g729	G729 fmtp:18 annexb=no
h261VideoCapability	H261
h263VideoCapability	H263

IWF Service Enhancements

This section describes the Oracle Communications Session Border Controller features that are supported for when the Oracle Communications Session Border Controller performs interworking between SIP and H.323. Enabling these enhancements only requires that you set up a fully functional SIP configuration, a fully functional H.323 configuration, and that you enable IWF on your Oracle Communications Session Border Controller . You do not have to set any special configuration because these enhancements happen automatically.

SIP Redirect—H.323 LRQ Management

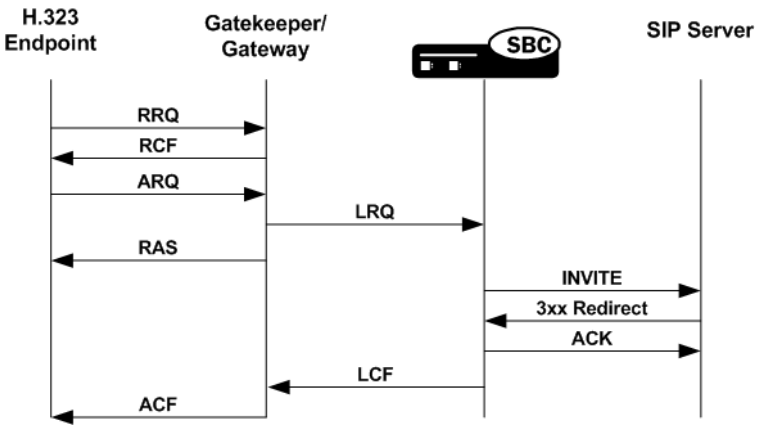
When it needs to interact with a SIP Redirect server, the Oracle Communications Session Border Controller can interpret the SIP messages and manage them on the H.323 side of the session. For IWF sessions, the Oracle Communications Session Border Controller handles SIP Redirect and H.323 LRQ messages.



Redirect—LRQ Management Sample 1

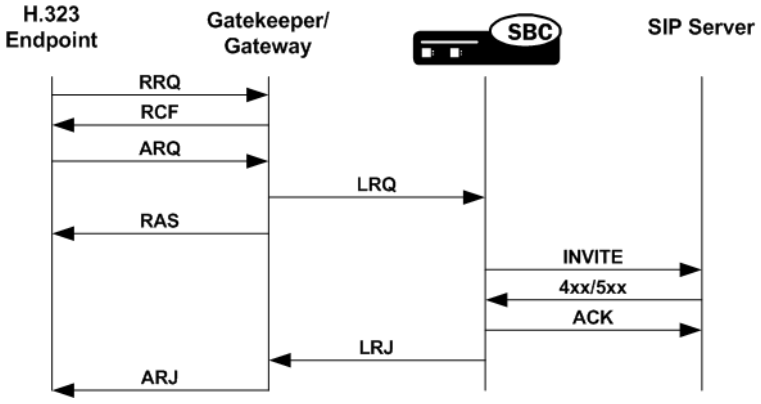
This section presents three possible scenarios for SIP Redirect-H.323 LRQ management.

The following diagram shows an established session that uses SIP Redirect—H.323 LRQ management. Here, the Oracle Communications Session Border Controller sends an INVITE to a SIP Redirect Server that responds with a 3xx Redirection message. The Oracle Communications Session Border Controller then sends the gatekeeper/gateway an LCF message that causes an ACF message to be sent to the H.323 endpoint.



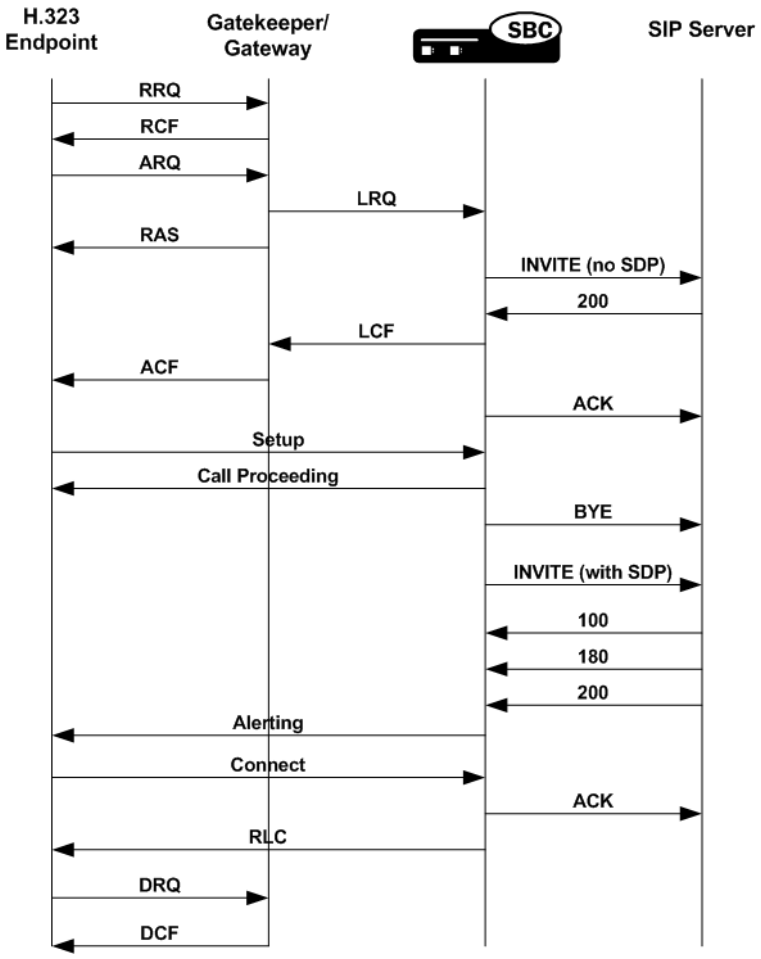
Redirect—LRQ Management Sample 2

The following diagram shows how the Oracle Communications Session Border Controller handles the exchange when the SIP Redirect server declares either that there is an error or that there is no such user. These SIP messages come from either the 4xx Request Failure or 5xx Server Failure series. In the example below, the SIP Redirect server returns a 401 Unauthorized message, which the Oracle Communications Session Border Controller interworks and communicates to the H.323 gatekeeper as an LRJ. Then the H.323 gatekeeper/ gateway issues an ARJ to the H.323 endpoint.



Redirect—LRQ Management Sample 3

In this call flow, the SIP server issues a 2xx Successful message that is not supposed to be sent (because a 3xx, 4xx, or 5xx message should be sent in response to the Oracle Communications Session Border Controller 's INVITE). The Oracle Communications Session Border Controller sends a BYE message to the SIP Redirect Server, but it tries to initiate the session again, this time successfully. The final sample call flow shown rarely occurs.



SIP INFO and DTMF UII Management

The Oracle Communications Session Border Controller supports DTMF for that require the IWF, enabling features such as keypress, alphanumeric, and hookflash. Because tones are not transmitted as audio, they must pass as out-of-band signaling information, meaning that the Oracle Communications Session Border Controller needs to convert an H.245 UII (User Input Indication) into SIP.

Depending on the capability of the H.323 endpoint, the Oracle Communications Session Border Controller sends either an alphanumeric or DTMF signal in the H.245 UII. The Oracle Communications Session Border Controller sends nothing if the endpoint does not support an alphanumeric or DTMF signal. The SIP INFO message will have a content type of application/ dtmf-relay, and the message body will be in the form Signal=*\r\nDuration=250\r\n. If the duration is absent in the SIP INFO or the UII received on the H.323 side is alphanumeric, the Oracle Communications Session Border Controller uses the a 250 millisecond default value.

Mid-Session Media Change

Mid-session media change happens during a call that requires the IWF when the type of media being sent while a session is in progress changes. For example, a fax transmission might require mid-session media change; besides fax, other applications of this feature are possible. To support the transmission of a T.38 fax sent over an IWF session, some media channels must be opened and others closed. In addition, the Oracle Communications Session Border

Controller can accommodate a request for media change from, for example, audio to an image type for T.38 fax.

Because the media requirements are driven by endpoints and Gateways, you do not have to configure the Oracle Communications Session Border Controller s mid-session media change support.

Enhanced Support for FAX Calls

The Oracle Communications Session Border Controller now supports T.38 fax calls in networks containing elements that do not comply with the ITU-T H.323 Annex D recommendation for how to replace an existing audio stream with a T.38 fax stream. This support applies to signaling that requires interworking between SIP and H.323.

In the standard call model following the ITU-T recommendation, the endpoint detecting the fax tone sends an H.245 RequestMode message to its peer with a T.38 data mode. The receiving endpoint returns a RequestMode Ack by way of acknowledgement, triggering the sending endpoint to close its audio channel and open a T.38 fax channel. The receiving endpoint closes and opens the same channels on its end. T.38 fax streams flow upon the acknowledgement of all relevant channels.

However, certain endpoints close their logical channel before sending the H.245 RequestMode message for T.38, leaving the Oracle Communications Session Border Controller with its audio channel still open and without having attempted to open a T.38 fax channel. To overcome this issue, the Oracle Communications Session Border Controller now checks whether or not audio channels have been closed whenever it receives an H.245 RequestMode message for T.38. If it finds a closed audio channel, the Oracle Communications Session Border Controller checks for the presence of a matching outgoing audio channel. A match causes the Oracle Communications Session Border Controller to close the audio channel and continue with the procedure for converting to T.38 fax.

Removing the T.38 Codec from an H.245 TCS

For SIP-H.323 IWF sessions, H.323 automatically inserts the T.38 FAX codec in the H.246 TCS message. You can stop this insertion using the **remove-t38** parameter in the H.323 global configuration.

Early Media

For call that require the IWF, the Oracle Communications Session Border Controller supports a cut-through for early media for calls that originate in SIP or H.323.

For a session originating in SIP, the provisional message will contain the SDP information if a Fast Start OLC was received in the Call Proceeding, Alerting, or Progress messages. The same SDP will be sent in the SIP 200 OK.

For a session that starts in H.323, the Oracle Communications Session Border Controller translates the SDP it receives in SIP messages (either a 180 or a 183) into the appropriate H.323 Fast Start elements: Alerting or Progress. If the Alerting or Progress messages contain Fast Start elements, the Progress Indicator Q.931 information element (IE) will also be included in the message with Progress Descriptor 8, indicating that in-band information or an appropriate pattern is now available. This causes the call party to enable end-to-end early media in the reverse direction in accordance with H.323 v4.

In addition, the Oracle Communications Session Border Controller allows early media to flow in the forward direction for a call that requires the IWF starting in H.323 that is being translated to SIP. This happens after the Oracle Communications Session Border Controller has received

provisional response with SDP and has sent Alerting or Progress message with Fast Start to the calling party. Similarly, early media in the forward direction is enabled for a call that requires the IWF starting in SIP and being translated to H.323. This happens after the Oracle Communications Session Border Controller received Alerting or Progress messages with Fast Start and maps the Alerting or Progress to SIP 180 or 183 provisional response with the SDP answer.

Display Name Mapping

The Oracle Communications Session Border Controller displays the full name and number of the calling party (for features such as Caller ID) when it handles calls that require the IWF. The Oracle Communications Session Border Controller takes the display name in the From field of the SIP INVITE and maps it to the display IE so that it can show the full name of the calling party.

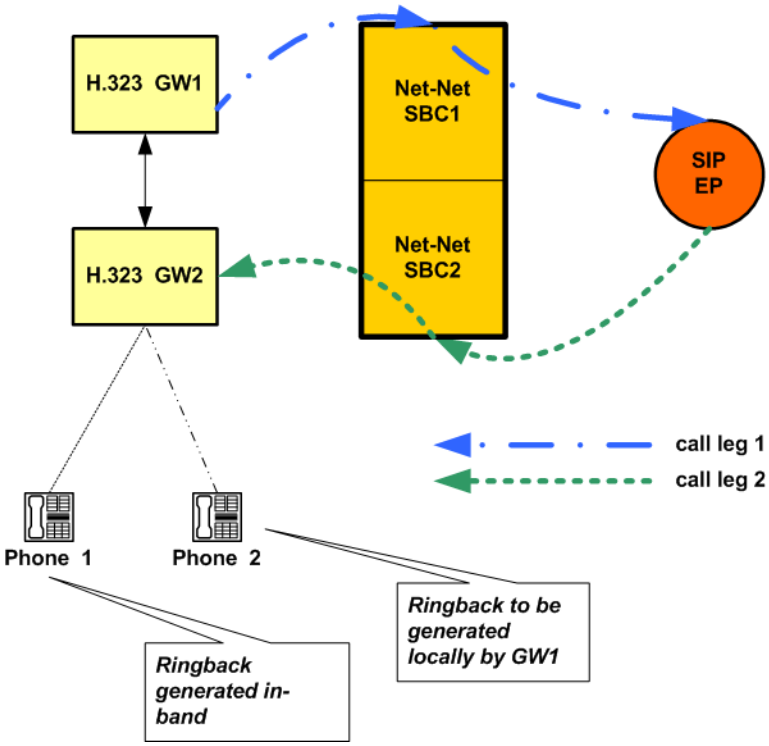
IWF Ringback Support

When interworking SIP and H.323 to a gateway, PSTN gateway, or other endpoint, the Oracle Communications Session Border Controller uses the mappings shown in the table below. The absence or presence of SDP in the SIP provisional message determines whether the tones are generated in-band or locally.

For each of the mappings listed in the following table, this section provides a sample call flow.

SIP Message	H.323 Message
No Message	CallProceeding
No Message	Progress without PI
183 with SDP	Progress with PI
180 w/o SDP	Alert without PI
180 with SDP	Alert with PI

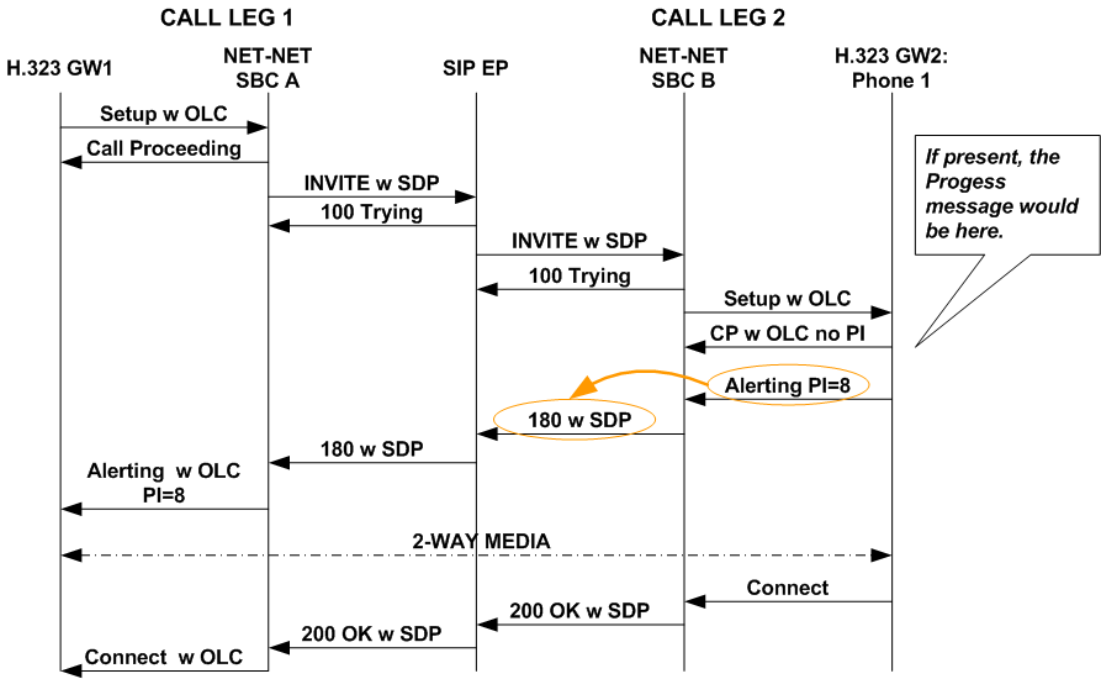
In the following diagram, a call that requires the IWF passes through the Oracle Communications Session Border Controller twice, creating two call legs. The call originates from H.323 GW1 and terminates in Phone 1 or Phone 2.



Sample 1 In-band Ringback without Progress Message

This sample flow shows how the Oracle Communications Session Border Controller handles a call that requires the IWF where there is no progress message. In this call flow, there is a progress indicator of eight (8), meaning that ringback is in-band.

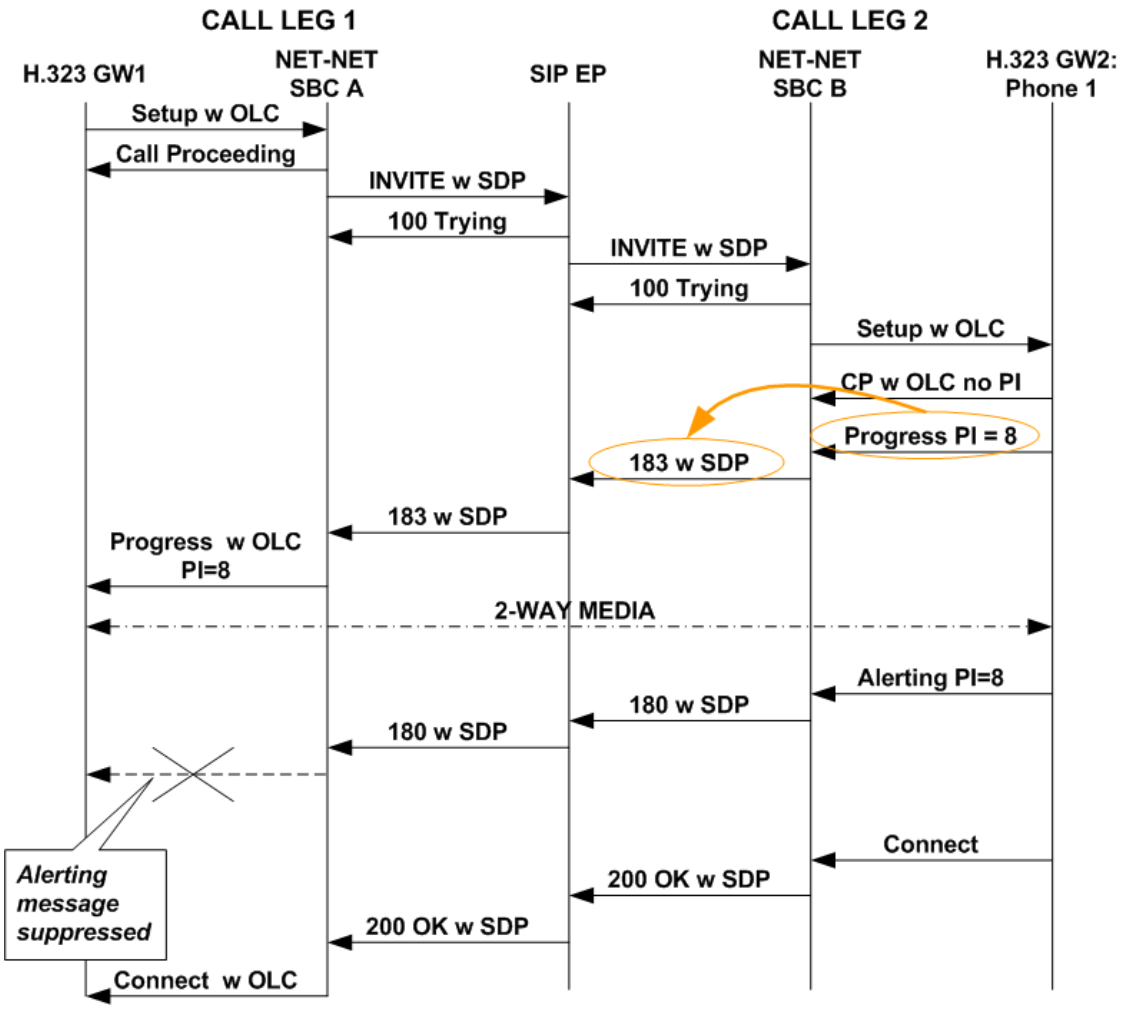
In this diagram, you can see that the Oracle Communications Session Border Controller maps the progress indicator included in the Alerting message sent from Phone 1 through H.323 GW2 to a SIP 180 message with SDP. When the Progress message appears, it contains the progress indicator rather than the Alerting message containing it.



Sample 2 In-band Ringback with Progress Message

This sample flow shows how the Oracle Communications Session Border Controller handles a call that requires the IWF where there is a progress message. In this call flow, there is a progress indicator of eight (8), meaning that ringback is in-band.

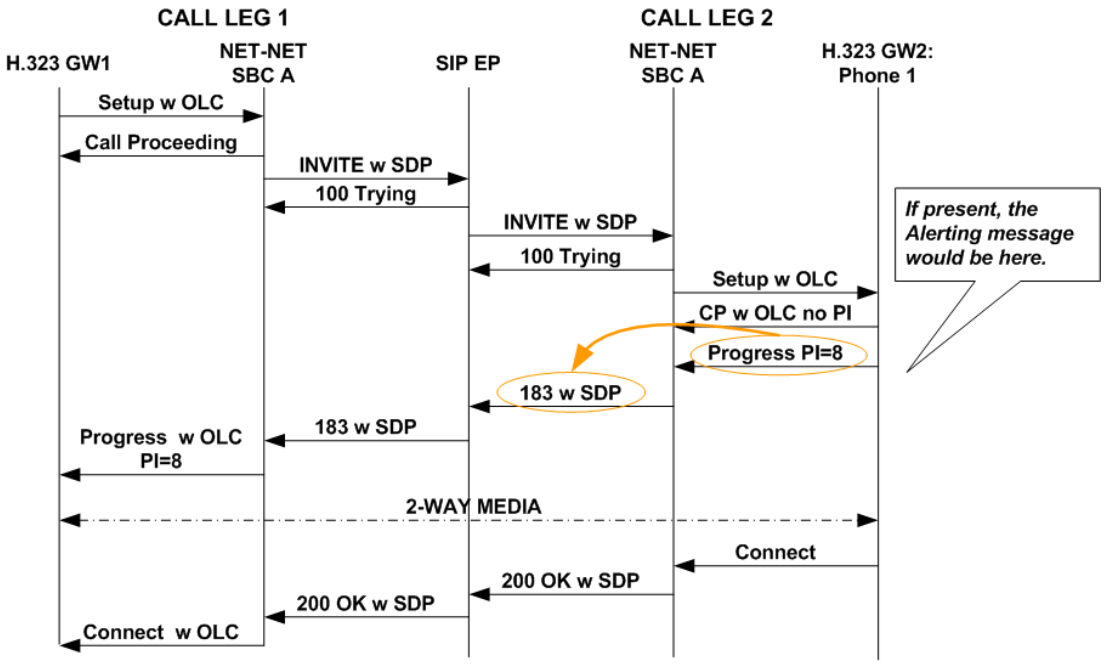
For this call flow, you can see again that the Oracle Communications Session Border Controller maps the progress indicator included in the alerting message sent from Phone 1 through H.323 GW2 to a SIP 180 message with SDP. Note that now the Progress message contains the progress indicator.



Sample 3 In-band Ringback without Alerting Message

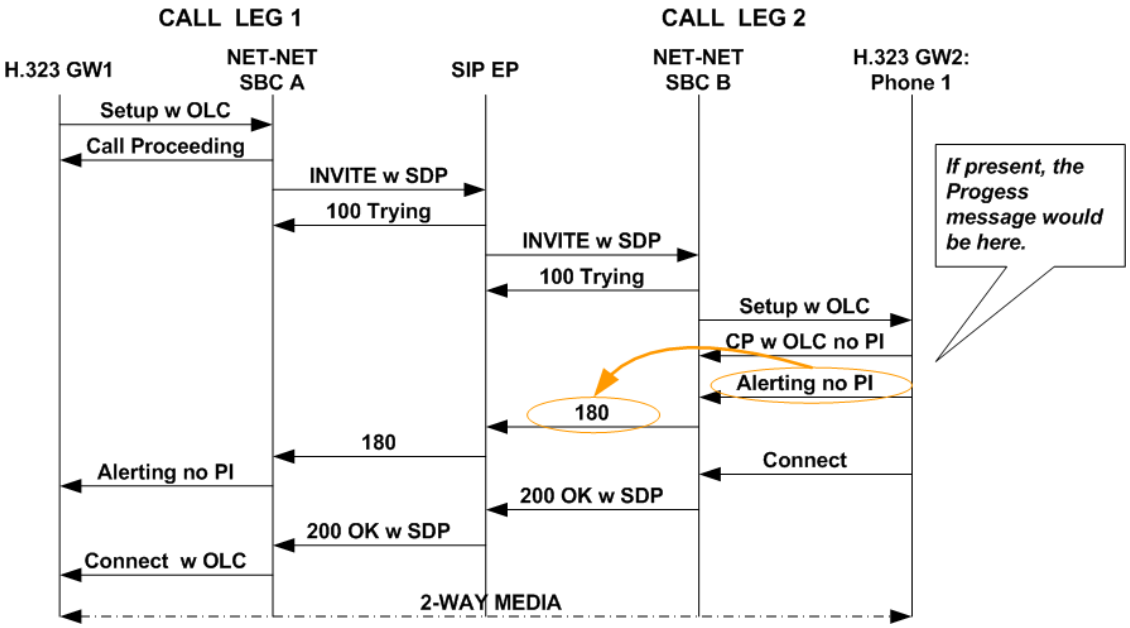
This sample flow shows how the Oracle Communications Session Border Controller handles a call that requires the IWF where there is no progress message. In this call flow, there is a progress indicator of eight (8), meaning that ringback is in-band.

In this diagram, you can see that the Oracle Communications Session Border Controller maps the progress indicator included in the Progress message sent from Phone 1 through H.323 GW2 to a SIP 180 message with SDP. When the Alerting message appears, it contains the progress indicator rather than the Progress message containing it.



Sample 4 Out-of-band Ringback without Progress Message

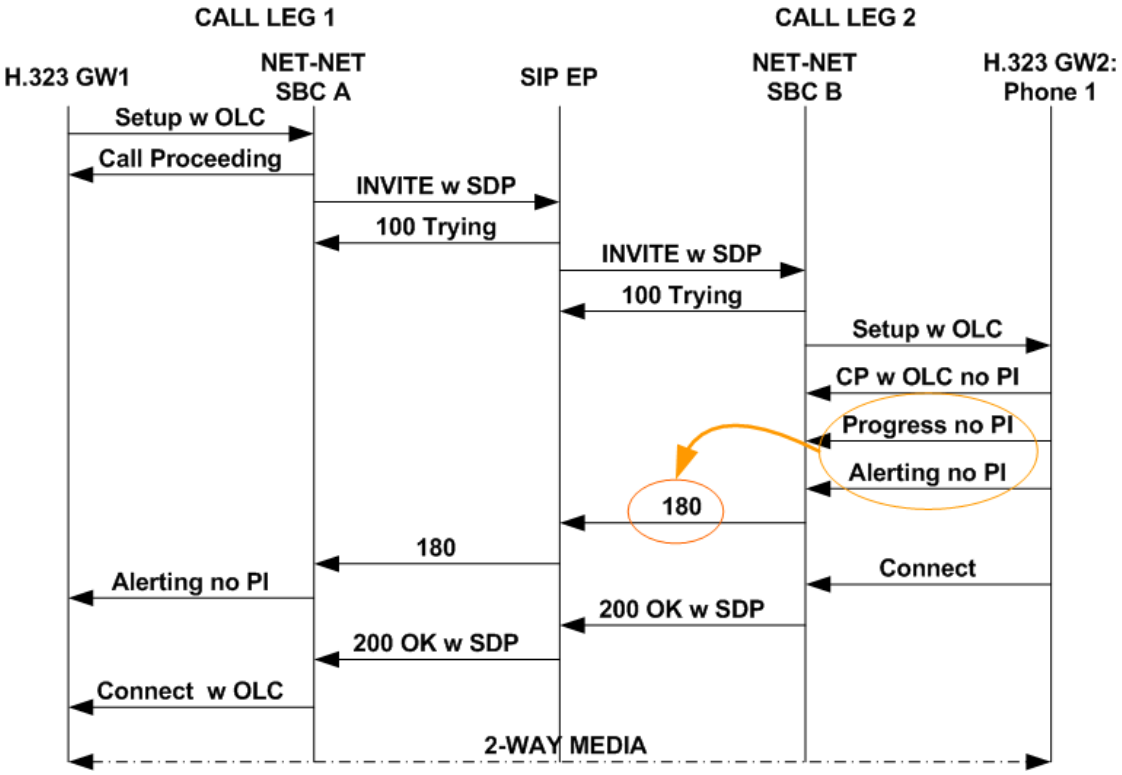
When there is no progress indicator included in the Alerting message, then there is out-of-band ringback. The system maps the Alerting message to a SIP 180, but it it does not include SDP in the SIP 180. This call flow shows that there is no Progress message and that media cannot be set up until after H.323 Connect and SIP messages are sent.



Sample Flow 5 Out-of-band Ringback with Progress Message

When there is no progress indicator included in either the Alerting or Progress messages, then there is out-of-band ringback. The system maps the Alerting message to a SIP 180, but it does

not include SDP in the SIP 180. This call flow shows includes the Progress message; still, media cannot be set up until after H.323 Connect and SIP messages are sent.

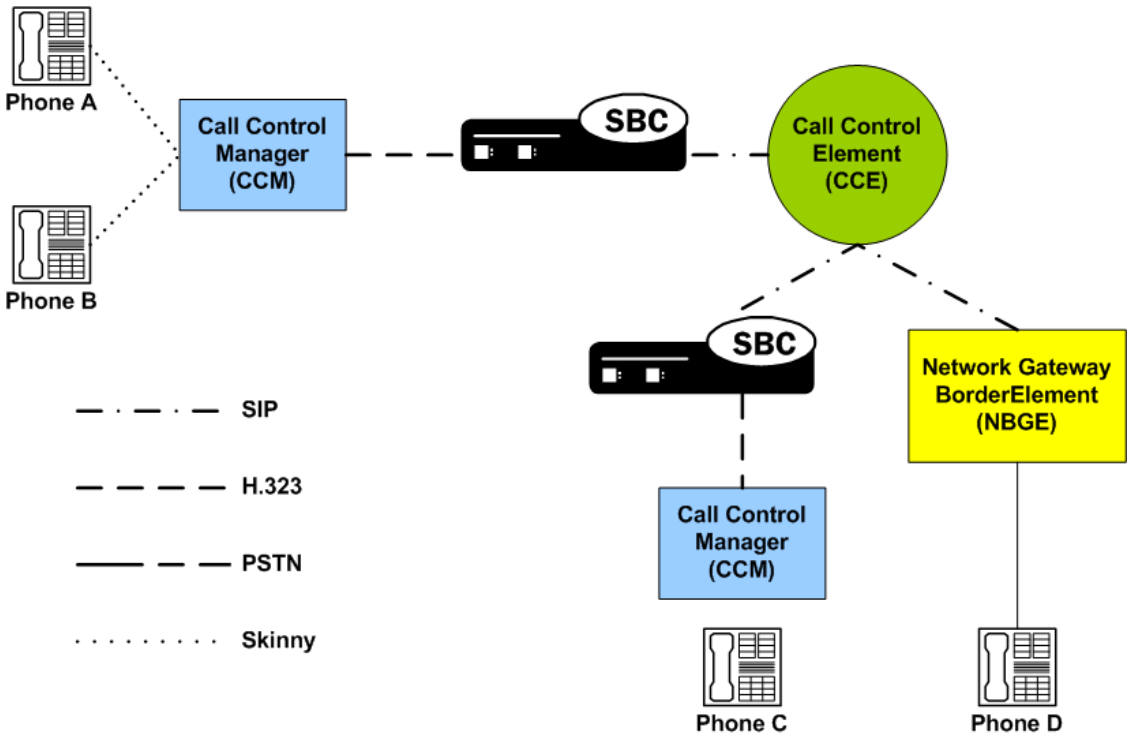


H.323 Endpoint-Originated Call Hold and Transfer

When calls that require the IWF originating in H.323, the Oracle Communications Session Border Controller supports call hold, transfer, and conference for the H.323 call leg. The call hold and transfer feature uses signaling procedures based on the ITU-T recommendations/ H.323 specification for third party initiated pause and rerouting.

You do not have to configure the Oracle Communications Session Border Controller 's call hold and transfer feature.

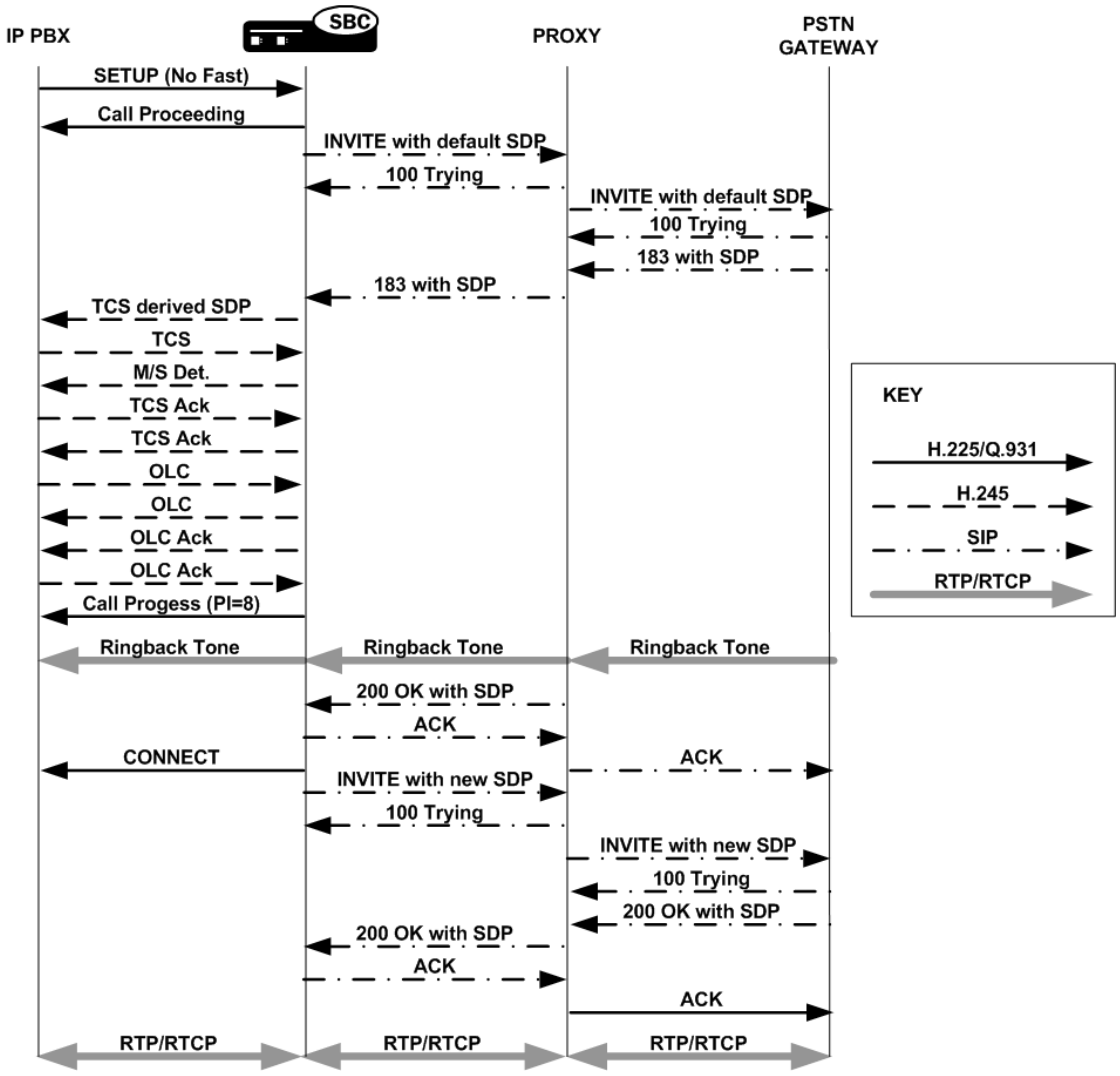
The following diagram shows how the Oracle Communications Session Border Controller provides call hold and transfer support for IWF sessions that originate in H.323. As you review this section's call flow diagrams, you might want to refer back to the following logical diagram directly below to review the network elements involved, and what protocols they use.



Basic Call

In the following sample basic call, IP PBX A sends an H.323 Slow Starts message ultimately destined for the PSTN through the Oracle Communications Session Border Controller . The Oracle Communications Session Border Controller performs translation to SIP and inserts default information about media. Once the PSTN gateway responds with a 183 containing SDP, the Oracle Communications Session Border Controller sends that information to IP PBX A. Then the Oracle Communications Session Border Controller and the IP PBX exchange TCS- and OLC-related messages, and they negotiate primary-secondary determination. The Oracle Communications Session Border Controller also sends IP PBX A a Call Progress message with a progress indicator of 8.

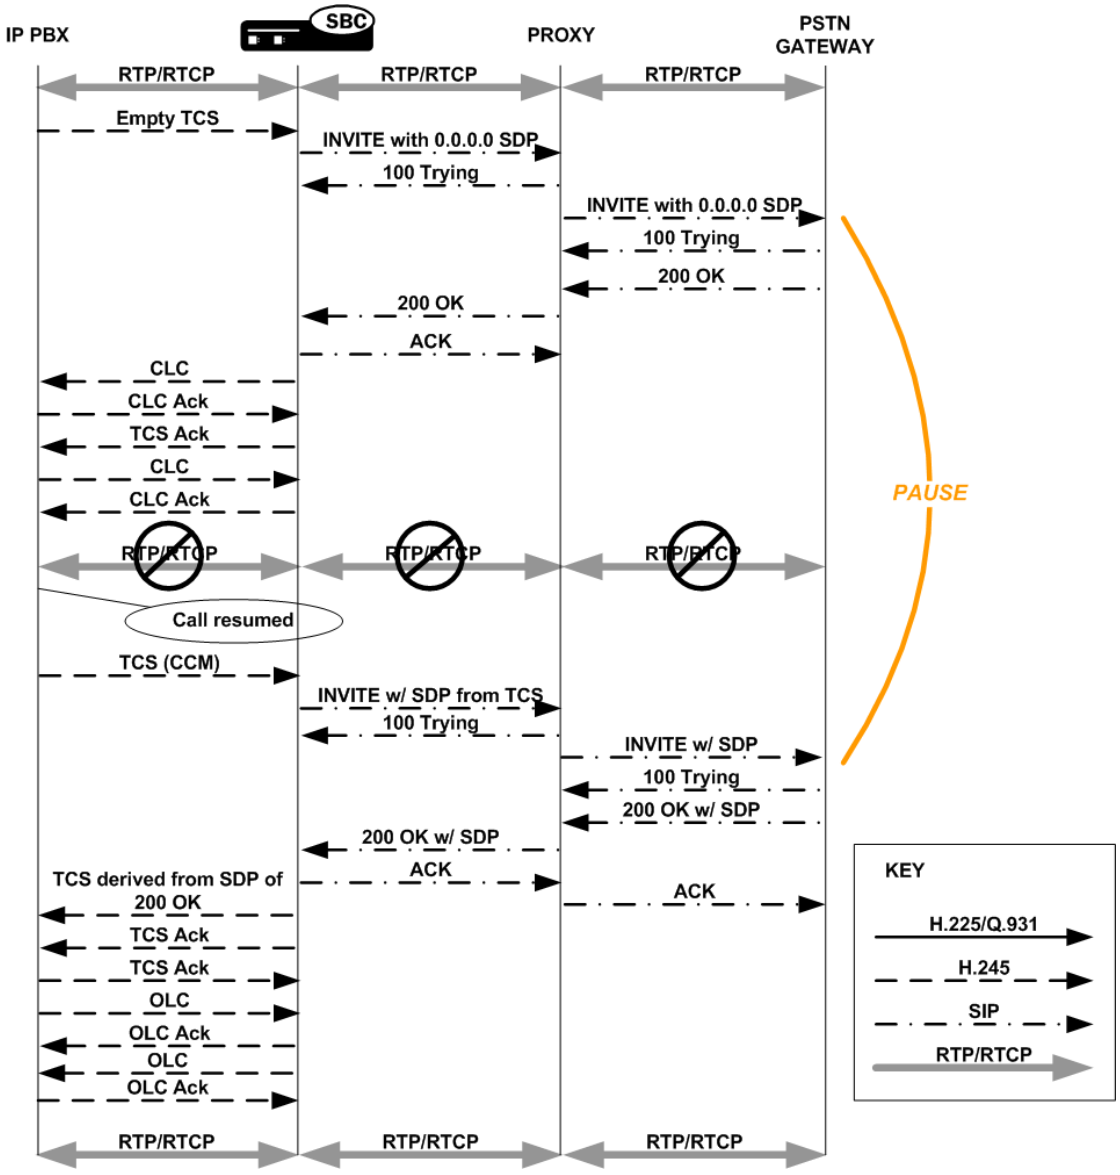
After the ring-back tone, the proxy sends a 200 OK message with SDP to the system. The Oracle Communications Session Border Controller sends a Connect message to the IP PBX A, and then it sends another SIP INVITE to the proxy that contains amended SDP (if that information about media is different from the default). After 200 OK and ACK messages are exchanged, media (RTP/RTCP) flow takes place.



Hold

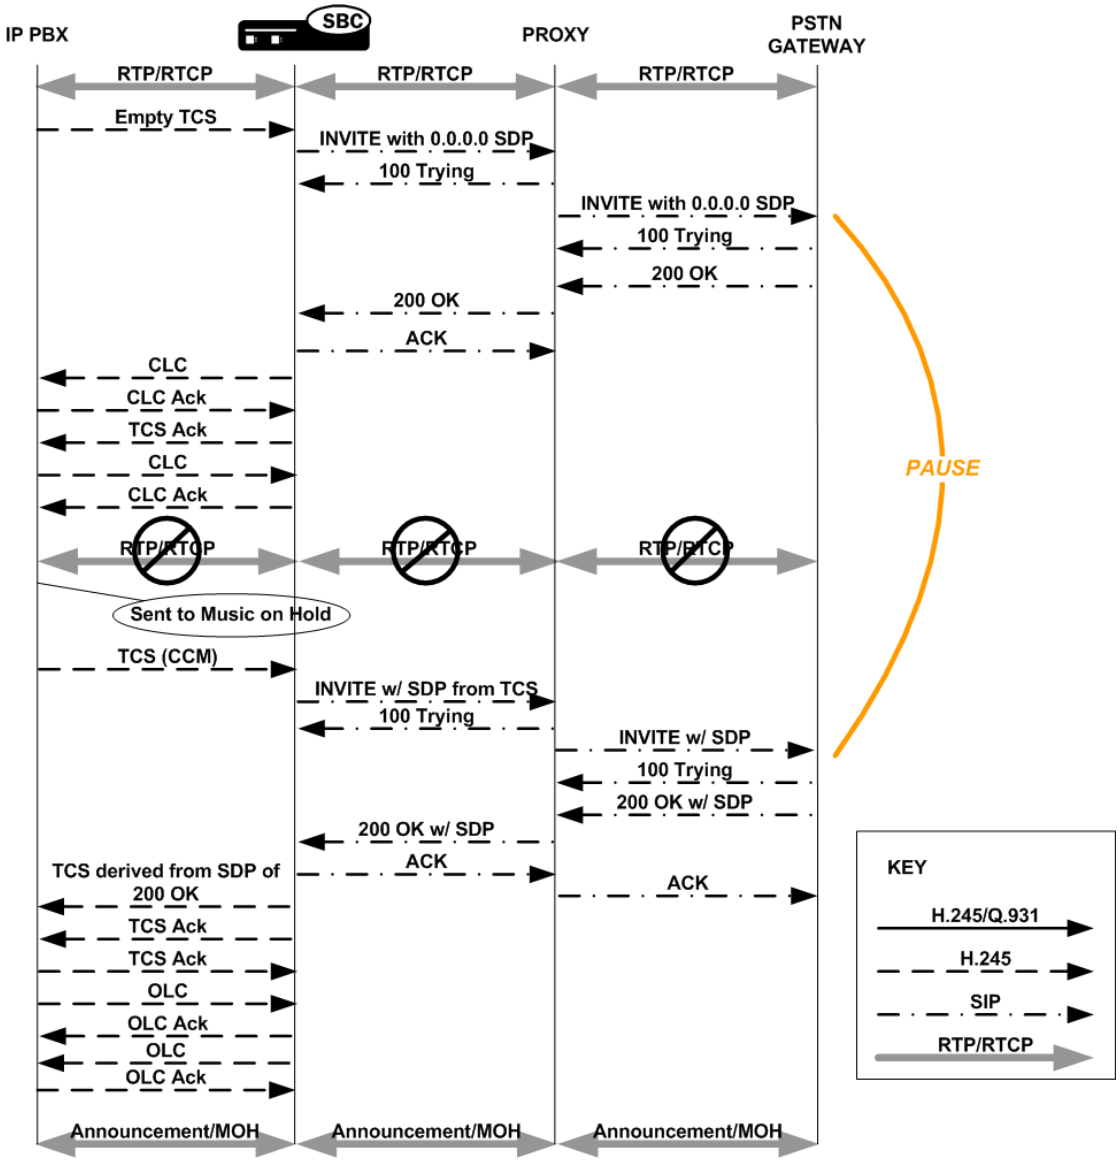
This sample call flow assumes that the IWF call is established and that the RTP/RTCP flow is already in progress. The hold button is pushed, and IP PBX A sends an empty TCS to the Oracle Communications Session Border Controller . The Oracle Communications Session Border Controller puts the called party on hold by sending an INVITE message with 0.0.0.0 SDP to the SIP side of the call. Using 0.0.0.0 as the media address effectively stops the media flow. This INVITE is acknowledged, and the Oracle Communications Session Border Controller closes the channels on the H.323 side, halting the RTP/RTCP flow.

When the caller on the H.323 side takes the call off hold, it resumes with a TCS that the Oracle Communications Session Border Controller receives and then translates on the SIP side as an INVITE with SDP. After that INVITE is acknowledged and received, the Oracle Communications Session Border Controller opens logical channels on the H.323 side and RTP/RTCP flows resume.



Music On Hold

This scenario is similar to the hold feature enabled for calls that require the IWF, except that after the RTP/RTCP flow between the H.323 and SIP sides stops, the call is sent to music on hold. Before the announcement or music plays, the Oracle Communications Session Border Controller sets up the necessary support for media to be exchanged.



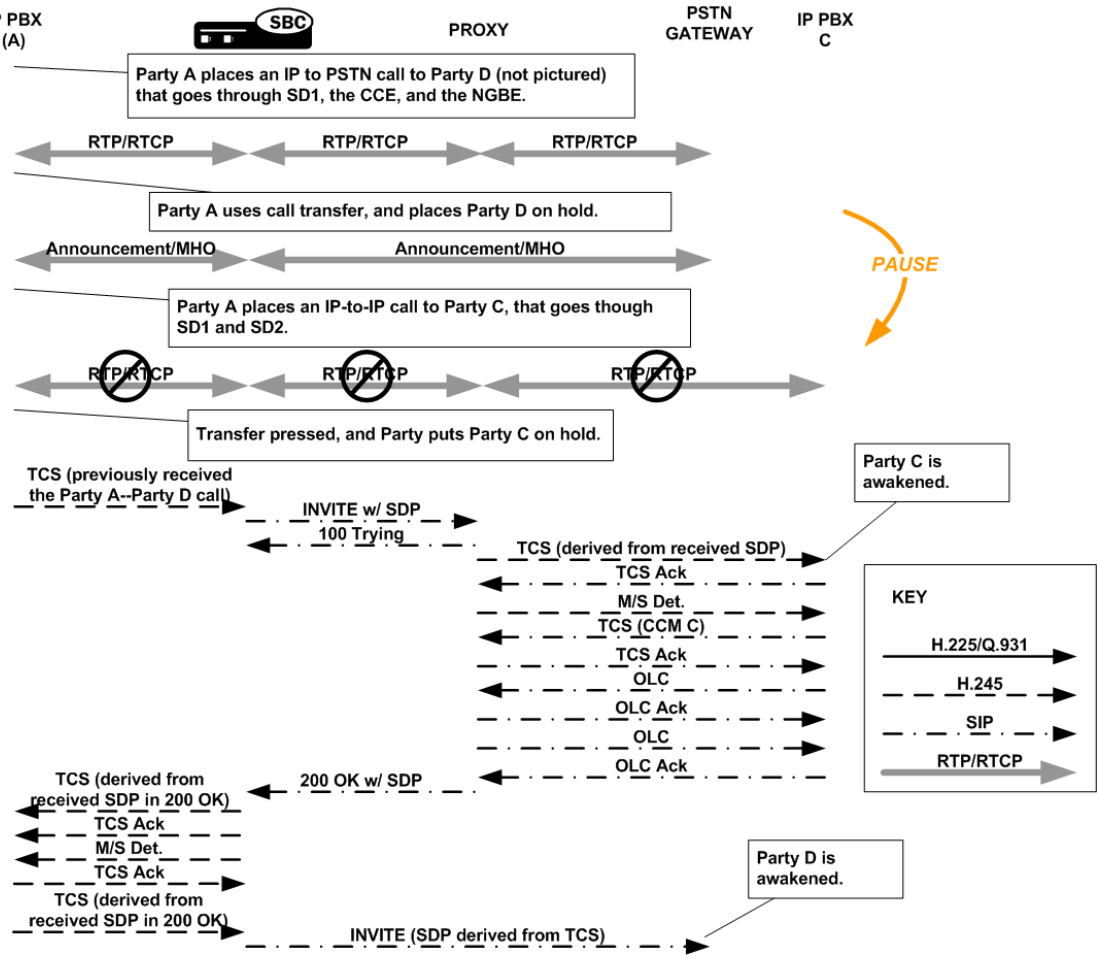
Transfer

The call flow described in this section recalls the diagram at the top of the H.323 Endpoint-Originated Call Hold and Transfer section, where endpoints A, B, and C are H.323 devices and endpoint D is a SIP device. When you follow the signaling and media flows, note that there are two Oracle Communications Session Border Controller s in the call transfer and two sets of SIP/H.323 translations that take place. The first Oracle Communications Session Border Controller translates H.323 to SIP, and the second performs the same operations with the protocols reversed.

In the scenario pictured, Party A is on a call with Party D, but wants to transfer Party C to Party D. Party A places Party D on hold, and then makes the call to Party C. Party A then puts Party C on hold, pressing the transfer button. You can see that Oracle Communications Session Border Controller 1 receives a TCS from the IP PBX, which is then translated to SIP. Oracle Communications Session Border Controller 2 receives it, performs the required protocol translations, and then opens a session with Party C via another IP PBX. Once this session is up and Party D is awakened, channels are established for media exchange.

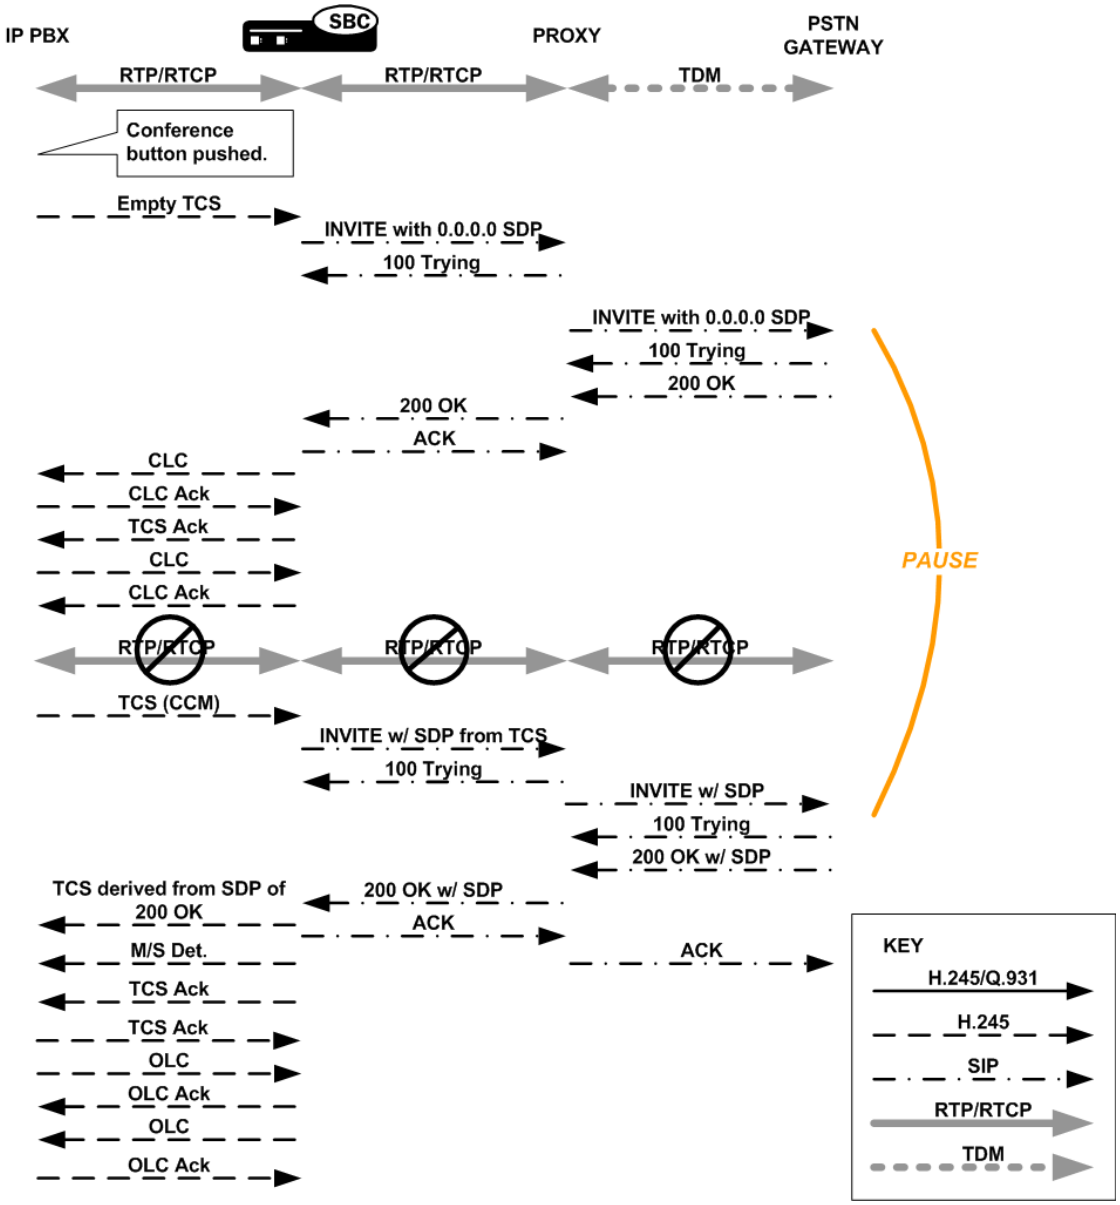
In order to redirect the media so that it flows between Party C and Party D, the Oracle Communications Session Border Controller 1 and IP PBX C exchange OLC and OLC Ack messages that contain address information for Party C and for Party D. Address information for both parties is contained in the OLC Ack messages that the Oracle Communications Session Border Controller exchanges with the IP PBX. IP PBX A does not move forward with the call until it has the necessary address information.

Even though Party A's participation in the call stops early in this scenario, the IP PBX with which it is associated keeps the signaling sessions with the Oracle Communications Session Border Controller alive to manage the transfer.



Conference

To conference a call that requires the IWF that starts in H.323, the Oracle Communications Session Border Controller uses a scenario much like the one used for holding a call that requires the IWF. Here again, the INVITE with 0.0.0.0 as the media address and the closing of logical channels stops the flow of RTP/RTCP. After signaling and SDP/media information are re-established, RTP/RTCP for the conference flows.



IWF Call Forwarding

This section describes the Oracle Communications Session Border Controller ’s IWF Call Forwarding feature, which is supported for calls initiated in SIP that require interworking to H.323.

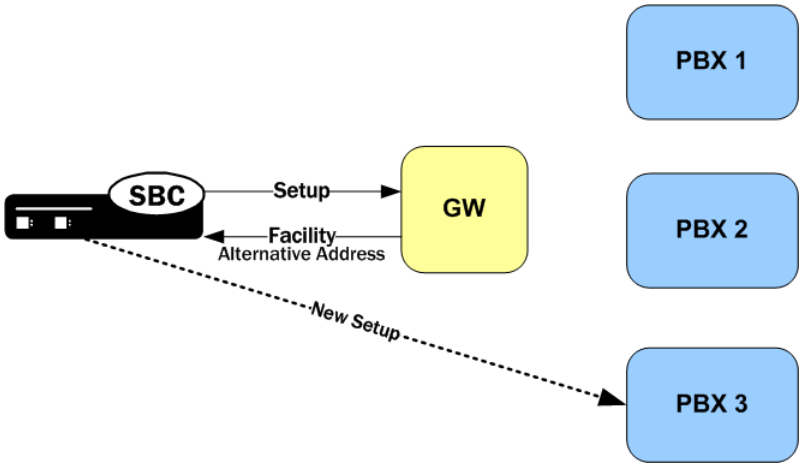
Prior to the implementation of this feature, the Oracle Communications Session Border Controller did not forward calls when the remote H.323 endpoint sent a Facility message with Call deflection as the reason and an alternate address for forwarding. Instead, it would either:

- Fail to release the initial call and initiate the forwarded call
- Drop the entire call when the remote endpoint for the call tore down the session

New Behavior

In the diagram below, you can see that the Oracle Communications Session Border Controller sends the initial Setup message to the gateway, and the gateway returns the Facility message with an alternate address for forwarding. Rather than engaging in its former behavior, the Oracle Communications Session Border Controller now releases the call with the gateway and sends a new Setup to the alternate address from the Facility message.

This new Setup up has no effect on the first call leg, which remains connected.



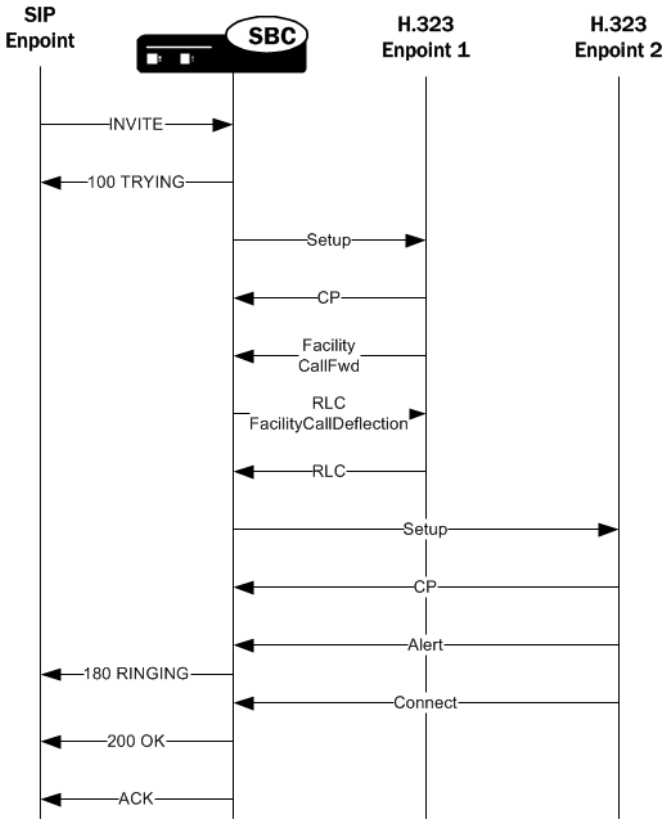
When it receives a Facility message with the reason CallForwarded, the Oracle Communications Session Border Controller looks for an alternate transport address in the Facility's alternativeAddress or alternativeAliasAddress element. The Oracle Communications Session Border Controller releases the egress call with the reason facilityCallDeflection. Then it takes one of two courses of action:

- If it does not find an alternative address, the Oracle Communications Session Border Controller releases the ingress call (with 486 BUSY HERE for a call being interworked from SIP to H.323).

If it finds an alternative address and the egress call has not been alerted or answered, the Oracle Communications Session Border Controller at this point tries to initiate a new egress call. The Oracle Communications Session Border Controller uses the alternative alias address to populate the calledPartyNumber information element (IE) and the destination address of the new Setup.

H.323 Sample Call Flow

The following diagram shows how the H.323 Call Forwarding feature works in a purely H.323 environment.



Media Release for H.323 SS-FS Calls for IWF

When the Oracle Communications Session Border Controller routes a slow-start to fast-start call, it is possible for the same fast-start call to be routed back through the Oracle Communications Session Border Controller making for a hairpin flow. If it does becomes a hairpin flow, then the Oracle Communications Session Border Controller routes it to its destination as a fast-start to fast-start call. This can result in one-way media if:

- The destination of the hairpin call is in the same realm as the originating slow-start to fast-start call
- The realm reference in the first bullet item is configured to disable in-realm media management
- The called endpoint accepts the proposed fast-start logical channels

The enhancements to the Oracle Communications Session Border Controller ’s behavior described in this section show how the Oracle Communications Session Border Controller follows additional procedures when setting up a hairpin flow to avoid one-way media when media release occurs.

H.323

For H.323 calls, the Oracle Communications Session Border Controller establishes media using the H.245 procedures described in the H.245 ITU-T recommendation: control protocol for multimedia communication. It also uses the Fast Connect procedure defined in the H.323 ITU-T recommendation: packet-based multimedia communication systems.

The latter ITU-T recommendation allows a calling endpoint to send a Setup message that contains a fastStart element, a sequence of OLC structures that describe the calling endpoint's proposed forward/reverse logical channels. If the called endpoint accepts this proposal, then logical channels are established.

When the Oracle Communications Session Border Controller translates a call originating in slow-start to fast-start, it uses a Fast Connect procedure in the outgoing leg by sending an outgoing Setup that includes a fastStart element with one or more OLC structures. But when the Oracle Communications Session Border Controller constructs this message, it is unaware of whether the call will become hairpinned or if media release will occur. Because it does not yet have this information, the Oracle Communications Session Border Controller sets the Network Address and the TSAP identifier in the OLC structures to the ingress IP address and port of a corresponding media flow allocated for media traveling between the calling and called endpoints. So if the called endpoint accepts the fastStart the Oracle Communications Session Border Controller proposes, the called endpoint would send its media to the Oracle Communications Session Border Controller . After acceptance, the system starts H.245 procedures on the slow-start side of the call to set up logical channels on that side. Then the Oracle Communications Session Border Controller updates the IP address and port of the media flows using OLC and OLCAck messages received from the calling endpoint.

This procedure works well for endpoints that are not in the same realm, or that are in the same realm for which media management is disabled, because each endpoint must send its media through the Oracle Communications Session Border Controller . When the endpoints are in the same realm and when media management is enabled, however, the Oracle Communications Session Border Controller must perform additional steps for media release in slow-start to fast-start calls.

To support media release in slow-start to fast-start calls, the Oracle Communications Session Border Controller performs a hold-and-resume procedure on the fast-start side. After it establishes channels on the slow-start side and if it detects media release being enabled, the Oracle Communications Session Border Controller sends and empty TCS to the fast-start side to put that side on hold. Then the called endpoint closes all the logical channels it previously opened in the Fast Connect procedure and stops transmitting to them. And the Oracle Communications Session Border Controller also closes it logical channels. Once the channels are closed, the Oracle Communications Session Border Controller resumes the call by sending a new, restricted TCS to the fast-start side. The restricted TCS only contains the receive and transmit capabilities of the codecs types that the called endpoint accepted in the Fast Connect procedure, and it forces the called endpoint to re-open logical channels of the same codec types accepted in the Fast Connect procedure. Once it receives and OLC from the called endpoint, the Oracle Communications Session Border Controller sends on OLCAck with the Network Address and TSAP identifier for the logical channel from the calling endpoint. Then the Oracle Communications Session Border Controller re-opens logical channels (of the same codec types that it open in the Fast Connect procedure). If the called endpoint has not changed its Network Address and TSAP identifier for its logical channels, media is re-established after the Oracle Communications Session Border Controller and the called endpoint exit the hold state. The last steps is for the Oracle Communications Session Border Controller to re-sends the full TCS message from the calling to the called endpoint to inform the called endpoint of the full capabilities of the calling endpoint.

Hold-and-Resume Procedure

The hold-and-resume procedure has three states:

- Media Hold—Starts when the Oracle Communications Session Border Controller sends the empty TCS to the called endpoint to put it on hold.

When it detects media release, the Oracle Communications Session Border Controller puts the called endpoint on hold. It can only do so if it has exchanged the TCS-TCSAck messages and completed primary-secondary determination with the calling endpoint.

When the Oracle Communications Session Border Controller receives a TCSAck in response to the empty TCS that it sent to the called endpoint, it closes the logical channels it opened as part of the Fast Connect procedure; the called endpoint likewise closes its logical channels. The two then exchange CLC and CLCAck messages, which signals the start of the Media Resume state.

- Media Resume—Starts when the Oracle Communications Session Border Controller sends a restricted TCS to resume the call.
  The restricted TCS the Oracle Communications Session Border Controller sends contains only the receive and transmit capabilities of the codec types previously accepted by the called endpoint in the Fast Connect procedure. This forces the called endpoint to re-open logical channels of the same codec type that were previously accepted in the Fast Connect procedure.

  After sending this TCS, the Oracle Communications Session Border Controller is ready (as specified in the ITU-T recommendations) to take part on the primary-secondary determination (MSD) process. However, the called party and not the Oracle Communications Session Border Controller initiates the MSD if it is required. The MSD is completed if necessary. Alternately, the called endpoint can start to re-open its logical channels. When it receives the first OLC from the called endpoint, the Oracle Communications Session Border Controller also starts to re-open its logical channels.
- Media Complete—Starts when all the logical channels that the Oracle Communications Session Border Controller re-opens are acknowledged by the called endpoint.
  When it enters the Media Complete state, the Oracle Communications Session Border Controller updates the called endpoint with the full capabilities of the calling endpoint by sending the full TCS.

Additional IWF Steps

For calls originating in slow-start H.323 that require interworking to SIP, the Oracle Communications Session Border Controller also takes addition steps for media release in hairpinned flows that the Oracle Communications Session Border Controller routes as SIP to fast-start H.323.

For such a call, after the Oracle Communications Session Border Controller has established logical channels on the slow-start H.323 side of the call, it sends a reINVITE on the SIP side. This reINVITE has an updated session description to correct the media connection information. The the Oracle Communications Session Border Controller performs the hold-and-resume procedure on the fast-start side of the call. This procedure re-establishes the logical channels between the Oracle Communications Session Border Controller and the called endpoint, avoiding the one-way media problem.

When you are configuring H.323 globally on your Oracle Communications Session Border Controller , you might choose to set the noReInvite option. This option stops the Oracle Communications Session Border Controller from sending a reINVITE after the logical channels are established on the slow-start H.323 side of the call. Instead, the Oracle Communications Session Border Controller ’s H.323 task communicates internally with its own SIP task a SIP UPDATE message that corrects the SDP; then the SIP task updates media flow destinations. But the Oracle Communications Session Border Controller does not send the UPDATE to the next hop, which can result in the one-way media problem if the call is hairpinned and media release occurs. For such cases, the default behavior for the noReInvite option is overridden. When the Oracle Communications Session Border Controller detects media release in an

H.323-SIP call, it forwards the UPDATE to the next hop even when you enable the noReInvite option.

Dependencies

This feature depends on:

- The H.323 endpoint supports the third-party-initiated pause and re-routing feature.
- The H.323 endpoint does not change its Network Address and TSAP identifier when it re-opens the logical channels.
- The H.323 endpoint does not immediately tear down the call when there is not established logical channel in the call.
- The fact that the SIP endpoint supports the UPDATE message if the noReInvite option is enabled.

Before You Configure

The Oracle Communications Session Border Controller 's IWF requires that there be complete configurations for both SIP and for H.323. These two sets of configurations function together when the interworking is configured and enabled.

You enable the Oracle Communications Session Border Controller 's interworking capability when you set the IWF configuration's state parameter to enabled, and all required H.323 and SIP configurations are established. This means that all of the following configurations must be established:

- A full SIP configuration, including SIP interfaces, SIP ports, SIP-NATs (if needed), and SIP features
- A full H.323 configuration, including H.323 global and H.323 interface configurations
- Local policy and local policy attributes (the IWF will not work without these configurations)
- Media profiles
- Session agents and, if needed, session agent groups

H.323 Configuration

You must have a complete configuration to support H.323 traffic on your Oracle Communications Session Border Controller , including any required support for H.323 Fast Start or Slow Start.

In the H.323 interface configuration, you are able to configure interfaces that enable communication between H.323 devices (for audio, video, and/or data conferencing sessions).

If you know that your Oracle Communications Session Border Controller will be handling traffic originating in Slow Start H.323, you must establish the appropriate list of media profiles in the IWF configuration. Handling Slow Start traffic also requires that you establish appropriate local policy (and local policy attribute) configurations, but configuring session agents and session agent groups is optional.

SIP Configuration

SIP functionality must also be configured on your Oracle Communications Session Border Controller that will perform IWF translations. You must use appropriate local policy (and local

policy attribute) configurations, but configuring session agents and session agent groups is optional. If you use session agents, then you must also configure the information you need for media profiles.

The Role of Local Policy

You must configure local policies (and local policy attributes, if necessary) in order for translations between SIP and H.323 to take place. These local policies determine what protocol is used on the egress side of a session. Local policy and local policy attribute configurations make routing decisions for the session that are based on the next hop parameter that you set. The next hop can be any of the following:

- IPv4 address of a specific endpoint
- Hostname or IPv4 address of a session agent
- Name of a session agent group

You can use the application protocol parameter in the local policy attributes configuration as a way to signal the Oracle Communications Session Border Controller to interwork the protocol of an ingress message into a different protocol as it makes its way to its egress destination (or next hop).

For example, if you set the application protocol parameter to SIP, then an inbound H.323 message will be interworked to SIP as it is sent to the next hop. An inbound SIP message would travel to the next hop unaffected. Likewise, if you set the application protocol parameter to H.323, then an incoming SIP message will be interworked to H.323 before the Oracle Communications Session Border Controller forwards it to the next hop destination.

The following example shows a configured local policy and its attributes used for IWF traffic.

```
local-policy
        from-address                            *
        to-address                              444
        source-realm                            *
        state                                   enabled
        last-modified-date                      2004-04-20 17:43:13
        policy-attribute
                next-hop                                sag:sag_internal
                realm                                   internal
                replace-uri                             disabled
                carrier
                start-time                              0000
                end-time                                2400
                days-of-week                            U-S
                cost                                    0
                app-protocol                            SIP
                state                                   enabled
                media-profiles
```

Local Policy in an IWF Session Initiated with H.323

In a session where the Oracle Communications Session Border Controller is interworking H.323 to SIP, it internally forwards the session on for interworking when:

- The next hop in the local policy is configured as a SIP session agent

- The next hop in the local policy is configured as a SIP session agent group
- The next hop in the local policy is not configured as a session agent or session agent group, and the application protocol parameter is set to SIP in the local policy attributes configuration.

Local Policy in an IWF Session Initiated with SIP

In a session where the Oracle Communications Session Border Controller is interworking SIP to H.323, it internally forwards the session on for interworking when:

- The next hop in the local policy is configured as an H.323 session agent
- The next hop in the local policy is configured as an H.323 session agent group
- The next hop in the local policy is not configured as a session agent or session agent group, and the application protocol parameter is set to H.323 in the local policy attributes configuration
  In this case the local policy should also define the egress realm, which you can set in the realm parameter of the local policy attributes configuration.

SIP-H.323 interworking with Dynamic Payload Types

The SIP and H.323 Protocols use Internet multimedia signaling over IP, and both use the Real-Time Transport Protocol (RTP) for transferring realtime audio/video data. The interworking function (IWF) provides a means of converting translation and signaling protocols and session descriptions between SIP and H.323. However, SIP and H.323 provide different mechanisms when exchanging payload types for media during IWF calls. Therefore, the International Telecomunications Union (ITU) modified the ITU H.245 recommendations in H.245 v16 to include a new “Dynamic Payload Type Replacement” capability that resolves this payload type conflict. This new capability provides a way for an H.323 endpoint to specify the payload type of a media stream for which the endpoint is willing to receive through the OLCacknowledgment (OLC-ACK) message in an audio/video call flow.

The Oracle Communications Session Border Controller supports this new “Dynamic Payload Type Replacement” capability by ensuring interworking of SIP and H.323 when audio/video call flows use dynamic payload types. The Oracle Communications Session Border Controller checks for the presence of this capability in the incoming TCS request. If it finds this capability in the TCS request, it sends an Open Logic Channel Acknowledgement (OLC-ACK) response with the payload type it is willing to receive.

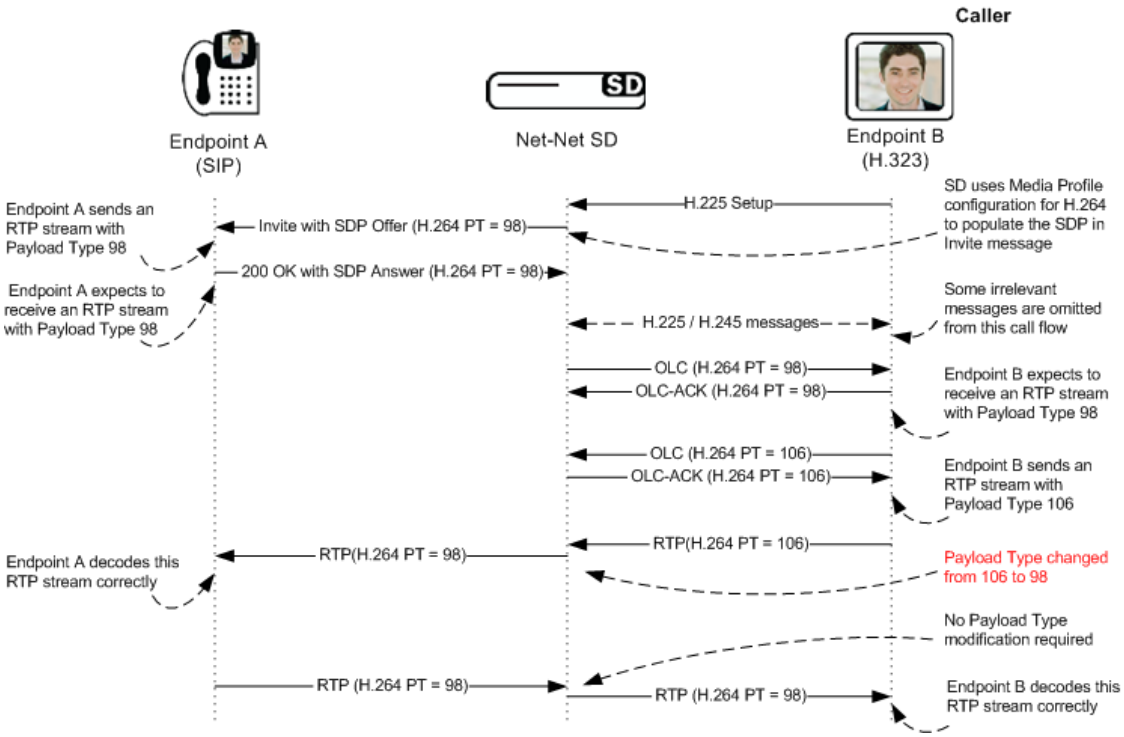
> **Note:**
>
> The Oracle Communications Session Border Controller always returns an OLC-ACK with a dynamic payload type value that it received in the incoming Session Description Protocol (SDP) from the SIP endpoint.

For devices that don't support the H.245 v16 recommendations, the Terminal Capability Set (TCS) request from the H.323 endpoint does not have the "Dynamic Payload Type Replacement" capability present. Therefore, the Oracle Communications Session Border Controller rewrites the payload type within the RTP packets when these packets traverse the Oracle Communications Session Border Controller. When devices in a session negotiate different payload types between SIP and H.323 packets, the RTP streams that they receive, always have the expected payload type in the RTP header.

> **Note:**
>
> The Oracle Communications Session Border Controller always maps the payload type on the RTP stream received from the H.323 endpoint, and sends it to the SIP endpoint for both audio and video. The Oracle Communications Session Border Controller does not support mapping of payload types in audio streams with 2833 DTMF packets.

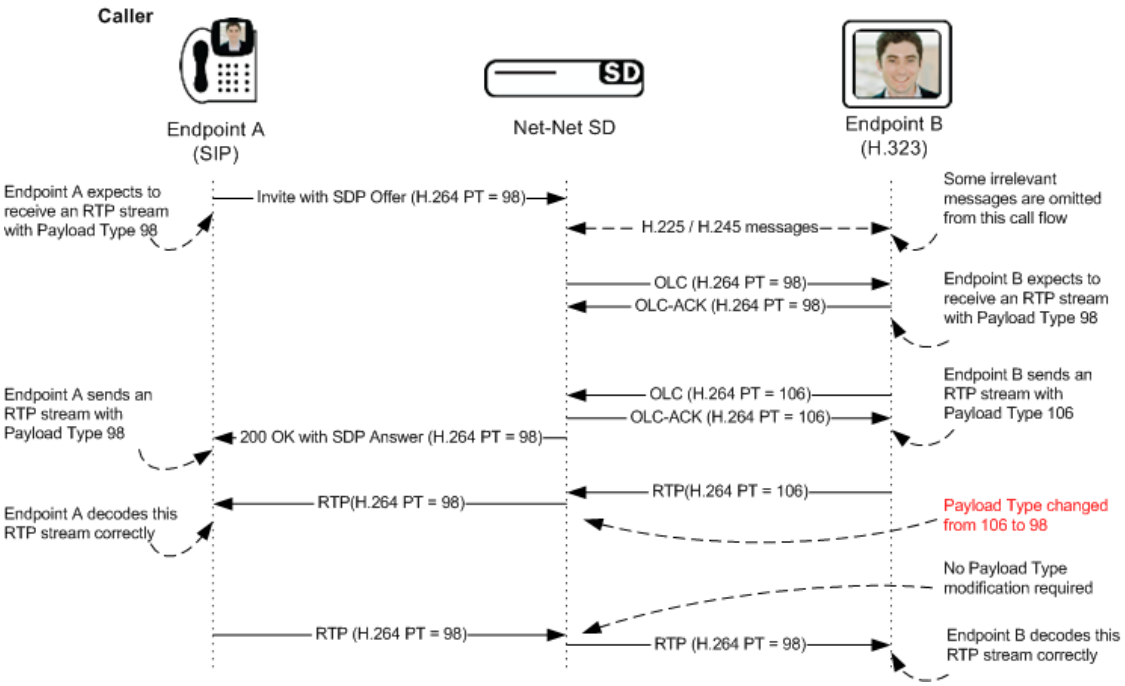
Figure 1a and 1b below shows the call flow from an H.323 Endpoint B to a SIP Endpoint A, and from a SIP Endpoint A to an H.323 Endpoint B, respectively. These illustrations show the negotiation of different dynamic payload types for the video streams but the Codec negotiated is the same. The Oracle Communications Session Border Controller dynamically replaces the payload type in the RTP header of the video stream received from the H.323 endpoint.

Figure 1a Endpoint B calling Endpoint A (H.323 endpoint does not have “Dynamic Payload Type Replacement” Capability)



The H.323 Endpoint B is not H.245 v16 compliant, and hence payload type replacement needs to be done in the RTP packets.

Figure 1b Endpoint A calling Endpoint B (H.323 endpoint does not have Dynamic Payload Type Replacement Capability)

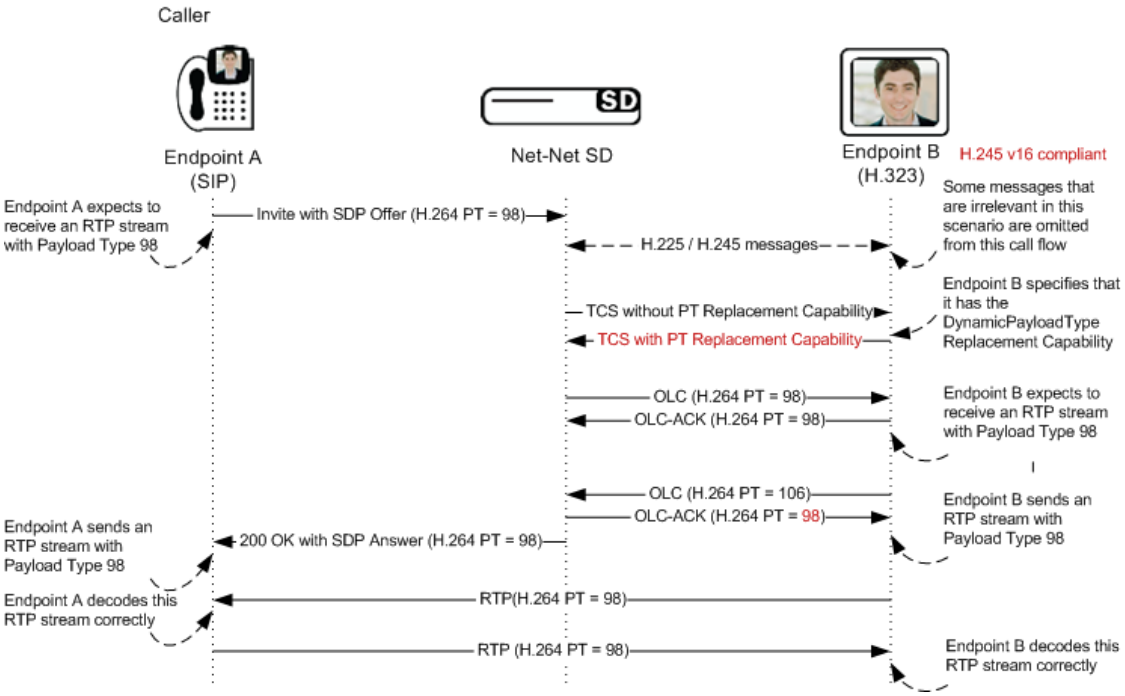


The H.323 Endpoint B is not H.245 v16 compliant, and therefore payload type replacement needs to be done in the RTP packets.

There is no concept of H.245 compliance for the SIP Endpoint A.

Figure 2a shows the call flow of SIP Endpoint A calling an H.323 Endpoint B using slow start. The Oracle Communications Session Delivery Manager modifies the dynamic payload type in the OLC-ACK based on payload type received in the incoming SDP OFFER in the "INVITE" message.

Figure 2a Endpoint A calling Endpoint B (H.323 endpoint has TCS with Dynamic Payload Type Replacement Capability)

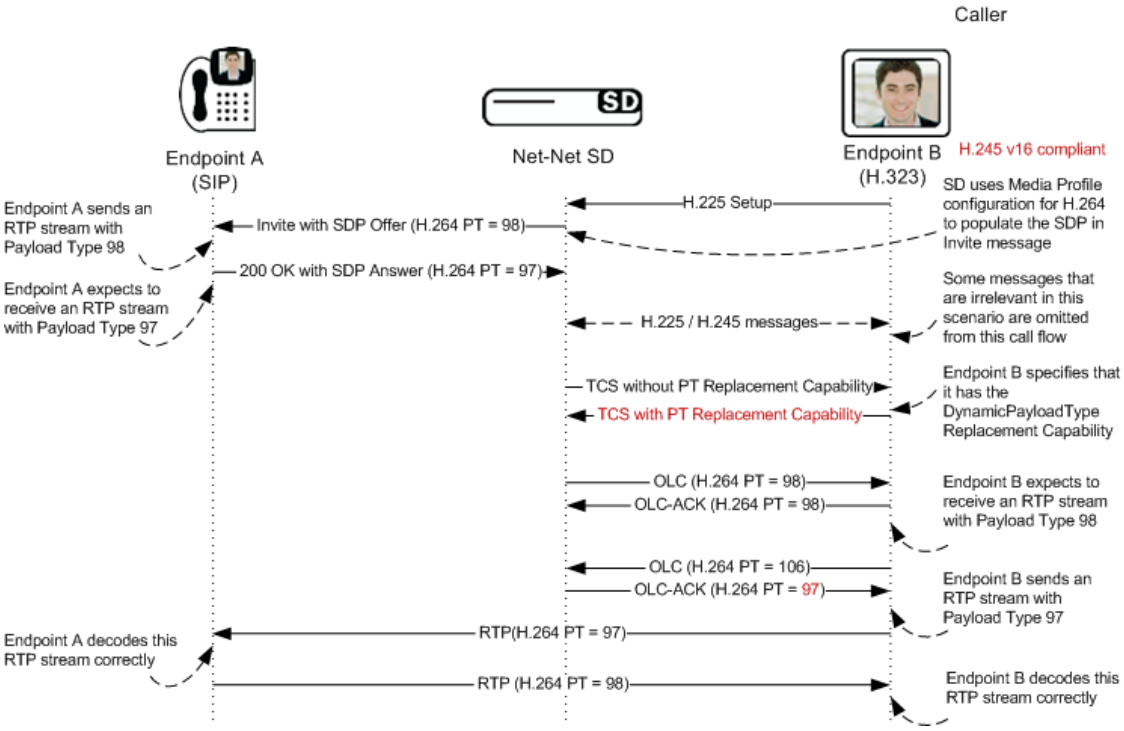


The H.323 Endpoint B is H.245 v16 compliant.

There is no concept of H.245 compliance for the SIP Endpoint A.

Figure 2b shows the call flow an H.323 Endpoint B using slow start, calling a SIP Endpoint A. The Oracle Communications Session Delivery Manager modifies the dynamic payload type in the OLC-ACK based on payload type received in the incoming SDP ANSWER in the "200 OK" message.

Figure 2b Endpoint B calling Endpoint A (H.323 endpoint here has TCS without “Dynamic Payload Type Replacement” Capability)



Configuring Interworking

If you have already completed the steps outlined in this chapter’s IWF Service Enhancements section, then enabling the IWF is a simple process. This section shows you how to enable the IWF, and how to enable certain features that you can use to supplement basic IWF functionality.

An IWF configuration might appear like this in the ACLI:

```
iwf-config
        state                           enabled
        media-profiles
                                        PCMU
                                        telephone-event
        logging                         disabled
```

Configure IWF

To enable the Inter-working Function (IWF) on your Oracle Communications Session Border Controller :

1. Access the **iwf-config** configuration element.

```
ORACLE# configure terminal
ORACLE(configure)# session-router
ORACLE(session-router)# iwf-config
ORACLE(iwf-config)#
```

2. **state**—Enable this parameter if you want to translate SIP and H.323 sessions on your Oracle Communications Session Border Controller . The default value is **disabled**. Valid values are:
   - enabled | disabled
3. **media-profiles**—Enter the name of the media profiles you want to use for IWF translations. This name is either the name of an SDP codec (such as PCMU), or it can be telephone-event if you are configuring your system for DTMF support.

   If you want to use more than one media profile for SIP/H.323 translations, enter the names in quotation marks with a space between each one.

```
ORACLE(iwf-config)# media-profiles "PCMU telephone-event"
```

4. **logging**—Enable this parameter if you want the Oracle Communications Session Border Controller to log SIP messages that are related to the IWF. The default value is **disabled**. Valid values are:
   - enabled | disabled
5. **forward source call**—Type **enable** if you want to the Oracle Communications Session Border Controller to add the `h225SourceCallSignalAddress` header to the egress SIP INVITE.
6. Type **done** to save your configuration.

Topology Hiding for IWF with an Internal Home-Realm

You can configure the Oracle Communications Session Border Controller to mask the IP address of the originating caller in the SIP From and/or P-Asserted-Identity headers when calls are placed from H.323 to SIP endpoints.

The option **NoPAssertedID** checks for incoming SETUP messages have the presentation indicator set to restricted and instructs the Oracle Communications Session Border Controller to send a Privacy header without the P-Asserted-Identity and not to make the From header anonymous.

The option **replace-call-origin-ip** removes the calling party's IP address in the SIP From header. The IP address from the internal home realm is used instead.

The topology hiding feature uses the presentation indicator field from an inbound H.323 setup message to determine if/how the headers will be masked. The following table summarizes the configurable Oracle Communications Session Border Controller parameters and the values for the From and P-asserted-identity headers.

H.255 Presentation Indicator Setting	P-Asserted-Identity Header Value	From Header Value	SD Session Agent Option
Allow	IP address from home realm of SD SIP Config	H.255 Calling Party IP/ Port	No Option Set

H.255 Presentation Indicator Setting	P-Asserted-Identity Header Value	From Header Value	SD Session Agent Option
Allow	IP address from home realm of SD SIP Config	IP address of Home Realm SIP-Interface	NoPAssertedID
Allow	IP address from home realm of SD SIP Config	IP address of Home Realm SIP-Interface	replace-call-origin-ip
Allow	IP address from home realm of SD SIP Config	IP address of Home Realm SIP-Interface	replace-call-origin-ip, NoPAssertedID
Restricted	PAI Header not present	Anonymous	No Option Set
Restricted	PAI Header not present	Anonymous	NoPAssertedID
Restricted	PAI Header not present	Anonymous	replace-call-origin-ip
Restricted	PAI Header not present	Anonymous	NoPAssertedID, replace-call-origin-ip

IWF Topology Hiding Configuration

To enable IWF topology hiding on your Oracle Communications Session Border Controller :

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the signaling-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ORACLE(session-router)#
   ```

3. Type **sip-config** and press Enter. The system prompt changes.

   ```
   ORACLE(session-router)# session-agent
   ORACLE(session-agent)#
   ```

4. Use the ACLI **select** command so that you can work with the session agent configuration to which you want to add these options.

   ```
   ORACLE(session-agent)# select
   ```

5. **options**—Set the options parameter by typing **options**, a Space, the option name preceded by a plus sign (+) (**replace-call-origin-ip**), and then press Enter. Follow the same steps to add the **NoPAssertedID** option.

   ```
   ORACLE(session-agent)# options +replace-call-origin-ip
   ORACLE(session-agent)# options +NoPAssertedID
   ```

   If you type either of these options without the plus (+) sign, you will remove any previously configured options. In order to append the new option to the options list, you must prepend the new option with a plus sign as shown in the example above.

DTMF Support

For calls that require the IWF, you can enable support for the relay of RFC 2833 DTMF digits. The availability of this feature means that the Oracle Communications Session Border Controller is compliant with RFC 2833, which defines two payload formats for DTMF digits. To learn more about this RFC, refer to http://www.ietf.org/rfc/rfc2833.txt.

Until the exchange of TCS messages with the H.323 endpoint, the Oracle Communications Session Border Controller has no information about the endpoint's RFC 2833 capabilities. The Oracle Communications Session Border Controller adds telephone-event to the SDP on the SIP side of the call.

For calls that require SIP/H.323 translation, you can enable support for the relay of RFC 2833 DTMF digits.

To use this feature, you need to configure a media profile called telephone-event and set relevant parameters for it. Application of the media profile can happen either in a session agent configuration or in the IWF configuration.

- The **name** parameter in the media profiles configuration
- The **media-profiles** list in the IWF configuration
- The **media-profiles** list in the session agent configuration

All of the scenarios outlined here assume that you have established a telephone-event media profile configuration.

You can configure DTMF support using the following parameters. The way that the Oracle Communications Session Border Controller uses these values is described below. The payload type, part of the media profiles configuration, is dynamic and varies with different endpoints, so there is no default configuration for the telephone-event media profile.

The telephone-event media profile is used as follows in these types of IWF sessions:

- **Calls that require the IWF originating in H.323 Slow Start**—There is no channel (media) information available on the H.323 side.
  - If the incoming H.323 endpoint is configured as a session agent on the Oracle Communications Session Border Controller , then the telephone-event parameter in the media profiles set for that session agent configuration will be used in the SDP on the SIP side of the session.
  - If the H.323 endpoint is not a session agent or the telephone-event media profile is not configured in the session agent configuration corresponding to the endpoint, then the Oracle Communications Session Border Controller refers to the media profile information configured for the IWF configuration.
- **Calls that require the IWF originating in SIP—**If the TCS was not exchanged before a 200 OK was sent on the SIP side, the Oracle Communications Session Border Controller will behave in one of these two ways.
  - If the outbound H.323 endpoint is configured as a session agent, then the media profiles from that session agent configuration will be used.
  - If the outbound H.323 endpoint is not configured as a session agent, the media profile configured within the IWF configuration with the telephone-event value will be used.

As mentioned above, DTMF support is configured by using a combination of the telephone-event media profile and either the session agent or IWF configuration. First you set up the media profile, then you apply it to a session agent or to the IWF configuration.

DTMF Configuration

DTMF support requires you to configure a media profile named telephone-event. This section shows you how to set it up.

To configure a telephone-event media profile:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **media-profile** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

   ```
   ORACLE(session-router)# media-profile
   ```

   From this point, you can configure parameters for media profiles. To view see all media profile configuration parameters, enter a **?** at the system prompt.

4. **name**—Enter the name telephone-event and press Enter.
5. **parameters**—Enter the parameters to be applied for the codec; these are the digits that endpoints can support.
6. **media-type**—Leave the default media type set to audio.
7. **payload-type**—Set the payload type to **101**, which is the dynamic payload type needed to support this feature.
8. **transport**—Leave the default transport protocol set to RTP/AVP.
9. **frames-per-packet**—You can leave this parameter set to **0** (default).
10. **req-bandwidth**—You can leave this parameter set to **0** (default).

Applying the Media Profile

After you have configured the telephone-event media profile, you need to apply it either to a H.323 session agent or the global IWF configuration.

DTMF for all IWF translations

To use DTMF for all IWF translations:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the session-related configurations.

   ```
   ORACLE(configure)# session-router
   ```

3. Type **iwf-config** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# iwf-config
```

From this point, you can configure IWF parameters. To view see all IWF configuration parameters, enter a **?** at the system prompt.

4. Add the telephone-event media profile to the media profiles list and save your work. If you already have a media profiles for the IWF configuration set up and want to keep them (adding telephone-event to the list), then you must type in all of the media profiles that you want to use.

```
ORACLE(iwf-config)# media-profiles "PCMU telephone-event"
ORACLE(iwf-config)# done
```

DMTF Support on a Per-Session-Agent Basis

To use DMTF support on a per-session-agent basis:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the session-related configurations.

```
ORACLE(configure)# session-router
```

3. Type **session-agent** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# session-agent
```

From this point, you can configure IWF parameters. To view see all IWF configuration parameters, enter a **?** at the system prompt.

4. When you configure a new H.323 session agent, you can configure DTMF support by simply adding the telephone-event media profile to the list of media profiles. You can add it along with the other media profiles you might want to use for that session agent.

```
ORACLE(session-agent)# media-profiles "telephone-event g711Ulaw64k"
```

5. When you want to add DTMF support to an H.323 session agent that you have already configured, you need to select that session agent, add the media profile, and save your work.

```
ORACLE(session-agent)# select
<hostname>:
1: 192.168.1.48 realm=         ip=
2: 192.168.1.49 realm=         ip=
3: 192.168.1.50 realm=external ip=
selection:3
ORACLE(session-agent)# media-profiles "telephone-event g711Ulaw64k"
ORACLE(session-agent)# done
```

RFC 2833 DTMF Interworking

This section explains the Oracle Communications Session Border Controller's support of transporting Dual Tone Multi-Frequency (DTMF) in Real-Time Transport Protocol (RTP) packets (as described in RFC 2833) to H.245 User Input Indication (UII) or SIP INFO method interworking.

Multimedia devices and applications must exchange user-input DTMF information end-to-end over IP networks. The Oracle Communications Session Border Controller provides the interworking capabilities required to interconnect networks that use different signaling protocols. Also, the Oracle Communications Session Border Controller provides DTMF translation to communicate DTMF across network boundaries.

The Oracle Communications Session Border Controller supports:

- RFC 2833 to H.245 UII translation for H.323-to-H.323 calls, when one side is a version 4 H.323 device requiring RFC-2833 DTMF event packets, and the other side is a pre-version 4 H.323 device that only uses H.245 UII.
- RFC 2833 to H.245 UII or INFO translation of H.323 to SIP (and SIP to H.323) IWF calls, when one side is a version 4 H.323 device requiring RFC 2833 DTMF event packets and the SIP endpoint only supports INFO messages. Or when one side is a pre-version 4 H.323 device that only uses H.245 UII and the SIP endpoint supports RFC-2833 DTMF event packets.

About RFC 2833

RFC 2833 specifies a way of encoding DTMF signaling in RTP streams. It does not encode the audio of the tone itself, instead a signal indicates the tone is being sent. RFC 2833 defines how to carry DTMF events in RTP packets. It defines a payload format for carrying DTMF digits used when a gateway detects DTMF on the incoming messages and sends the RTP payload instead of regular audio packets.

About H.245 UII

H.245 provides a capability exchange functionality to allow the negotiation of capabilities and to identify a set of features common to both endpoints. The media and data flows are organized in logical channels. H.245 provides logical channel signaling to allow logical channel open/close and parameter exchange operations. The H.245 signaling protocol is reliable, which ensures that the DTMF tones will be delivered.

H.245 User Input Indication (UII) plays a key role in all the services that require user interaction. For video messaging, typical uses of UII include selection of user preferences, message recording and retrieval, and typical mailbox management functions. H.245 UII provides two levels of UII, alphanumeric and signal.

About RFC 2833 to H.245 UII Interworking

The Oracle Communications Session Border Controller provides 2833 to H.245-UII interworking by checking 2833-enabled RTP streams for packets matching the payload type number for 2833. It then sends the captured packet to the host for processing and translation to H.245 UII messages. A H.245 UII message received by the Oracle Communications Session Border Controller is translated to 2833 packets and inserted into the appropriate RTP stream.

About DTMF Transfer

DTMF transfer is the communication of DTMF across network boundaries. It is widely used in applications such as interactive voice response (IVR) and calling card applications.

The multiple ways to convey DTMF information for packet-based communications include:

- In-band audio: DTMF digit waveforms are encoded the same as voice packets. This method is unreliable for compressed codecs such as G.729 and G.723
- Out-of-band signaling events:
  H.245 defines out-of-band signaling events (UII) for transmitting DTMF information. The H.245 signal or H.245 alphanumeric methods separate DTMF digits from the voice stream and send them through the H.245 signaling channel instead of through the RTP channel. The tones are transported in H.245 UII messages.

  All H.323 version 2 compliant systems are required to support the H.245 alphanumeric method, while support of the H.245 signal method is optional.

  SIP INFO – uses the SIP INFO method to generate DTMF tones on the telephony call leg. The SIP INFO message is sent along the signaling path of the call. Upon receipt of a SIP INFO message with DTMF content, the gateway generates the specified DTMF tone on the telephony end of the call.
- RTP named telephony events (NTE): uses NTE to relay DTMF tones, which provides a standardized means of transporting DTMF tones in RTP packets according to section 3 of RFC 2833.

Of the three RTP payload formats available, the Oracle Communications Session Border Controller supports RTP NTE. NTE is most widely used for SIP devices but is also supported in H.323 version 4 or higher endpoints.

RFC 2833 defines the format of NTE RTP packets used to transport DTMF digits, hookflash, and other telephony events between two peer endpoints. With the NTE method, the endpoints perform per-call negotiation of the DTMF transfer method. They also negotiate to determine the payload type value for the NTE RTP packets.

The NTE payload takes the place of codec data in a standard RTP packet. The payload type number field of the RTP packet header identifies the contents as 2833 NTE. The payload type number is negotiated per call. The local device sends the payload type number to use for 2833 telephone event packets using a SDP or H.245 Terminal Capability Set (TCS), which tells the other side what payload type number to use when sending the named event packets to the local device. Most devices use payload type number 101 for 2833 packets, although no default is specified in the standard.

The 2833 packet's RTP header also makes use of the timestamp field. Because events often last longer than the 2833 packets sending interval, the timestamp of the first 2833 packet an event represents the beginning reference time for subsequent 2833 packets for that same event. For events that span multiple RTP packets, the RTP timestamp identifies the beginning of the event. As a result, several RTP packets might carry the same timestamp.

See RFC 2833 and draft-ietf-avt-rfc2833bis-07.txt for more information.

Preferred and Transparent 2833

To support preferred (signaled) 2833 and transparent 2833, the Oracle Communications Session Border Controller provides 2833 detection and generation (if necessary) when the endpoint signals support for 2833.

- Preferred: the Oracle Communications Session Border Controller only generates and detects 2833 for endpoints if they negotiate support for 2833 through signaling
- Transparent: the Oracle Communications Session Border Controller offers and answers based on end-to-end signaling and transparently relaying 2833

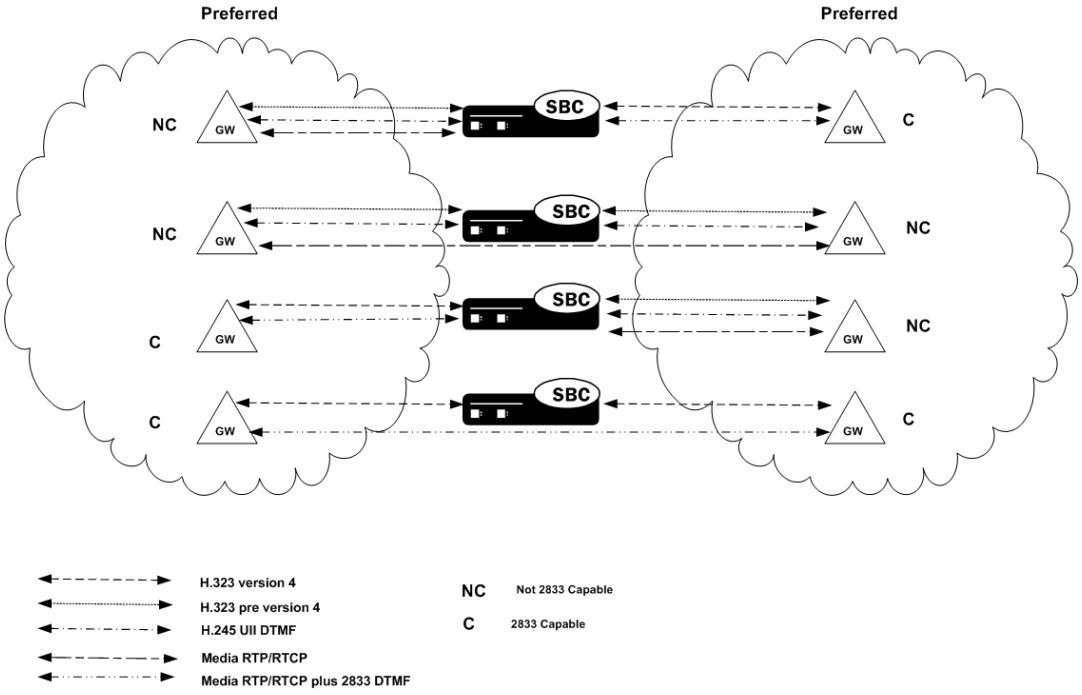
Preferred 2883 Support

If one side of the call, or a SIP interface, or a session agent, is configured for preferred 2833, the Oracle Communications Session Border Controller only generates and detects 2833 for endpoints if they signal support for 2833. The Oracle Communications Session Border Controller will offer 2833 in the TCS SDP, even if the originating caller did not.

- When the Oracle Communications Session Border Controller manages calls originating from a preferred source going to a preferred target, it:
  Performs 2833 translation for an endpoint when the originating side requests 2833 but the target does not negotiate 2833

  Allows 2833 to pass through if the originating side and target of the call are configured as preferred and negotiate 2833
- When the Oracle Communications Session Border Controller manages calls originating from a preferred source going to a transparent target, it:
  Performs 2833 translation when the originating side requests 2833 but the target is configured as transparent and does not negotiate 2833.

  Allows 2833 to pass through if the originating side and the target of the call are configured as transparent and negotiate 2833. The Oracle Communications Session Border Controller does not perform active translation because both ends support 2833.



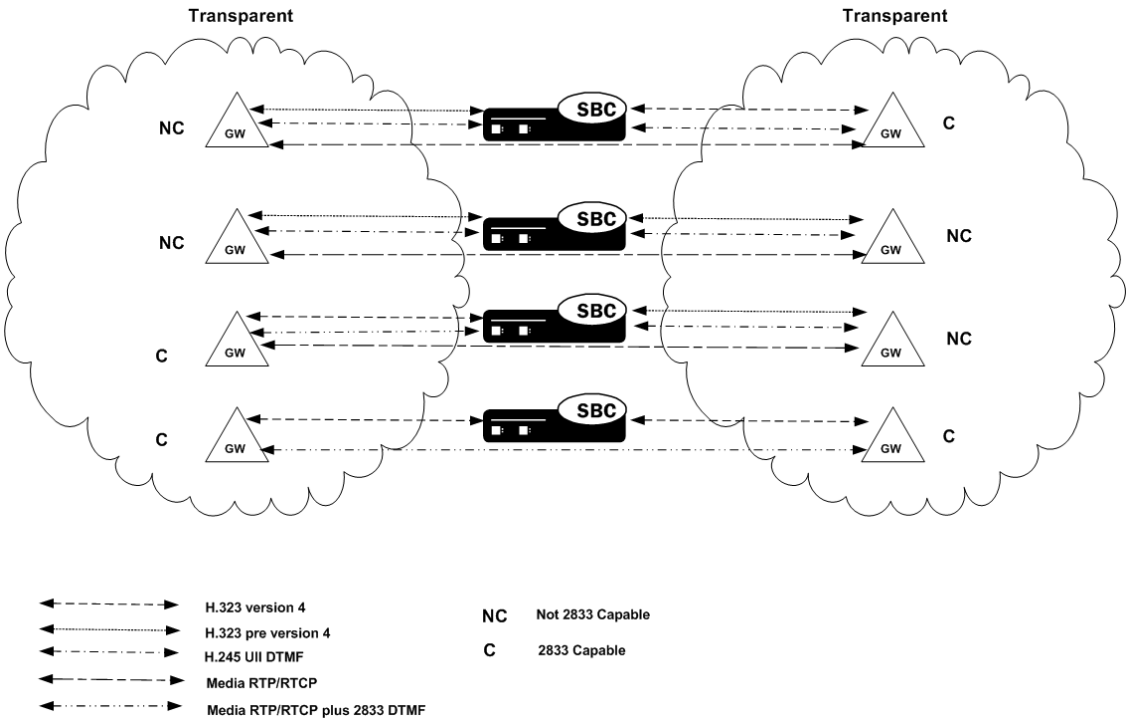
If one SIP endpoint does not signal 2833 capability, but the other SIP or H.323 endpoints do, the Oracle Communications Session Border Controller does not perform 2833 translation.

Transparent 2833 Support

The default configuration of the Oracle Communications Session Border Controller for H.323 is transparent 2833. The Oracle Communications Session Border Controller passes on the offered capabilities to the next-hop signaling element. If the next-hop endpoint is for a transparent 2833 target, typical capability negotiation determines the DTMF method. The Oracle Communications Session Border Controller transparently relays the DTMF as it has in previous releases.

With transparent 2833, the Oracle Communications Session Border Controller acts as a typical B2BUA or B2BGW/GK. However when the target of the call is configured as preferred 2833, the Oracle Communications Session Border Controller:

- Relays the 2833 packets if the originating endpoint signals 2833 and the next-hop endpoint for the preferred target signals 2833
- Performs 2833 translation if the originating endpoint does not signal 2833 and the next-hop endpoint for the preferred target does signal 2833
- Does not perform 2833 translation or transparently relay 2833 if the originating endpoint signals 2833 and the next-hop endpoint for the preferred target (or even a transparent 2833 target) does not signal 2833.



Payload Type Handling

The Oracle Communications Session Border Controller supports the RTP NTE for telephony events such as transport of DTMF digits and hook flash. Using RTP NTE, endpoints perform per-call negotiation of the DTMF transfer method and negotiate payload type value for the RTP NTE packets.

Although most endpoints use payload type number 101, the RTP payload type formats can become asymmetrical when being interworked between SIP and H.323 because there is no

default standard and endpoints use different types. This means that the payload type negotiated on one side of the Oracle Communications Session Border Controller, and that ends up being used for the call, might not be the same payload type negotiated on the other side of the Oracle Communications Session Border Controller. And while certain endpoints handle the asymmetry well, others do not.

Consider the simplified example of an IWF call initiated in SIP and translated to H.323. In this scenario, the SIP endpoint negotiates the payload type 106 with the Oracle Communications Session Border Controller. And despite the fact that the H.323 endpoint negotiates payload type 101, the Oracle Communications Session Border Controller returns type 106 and the call proceeds using type 106.

However, you can enable forced symmetric payload type handling so the Oracle Communications Session Border Controller changes the payload type of RFC 2833 packets to avoid using asymmetrical payload types.

For H.323 session agents and H.323 interfaces (stacks), you can configure an option that forces symmetric payload type use. The Oracle Communications Session Border Controller can detect when the payload types negotiated by the SIP and H.323 endpoints are symmetrical and when they are not. When it detects asymmetrical payload type use, the Oracle Communications Session Border Controller forces the remote endpoint to use the RFC 2833 payload type you configure in the SIP interface.

Basic RFC 2833 Negotiation Support

If H.323, SIP, or session agents on either side of the call are configured for preferred 2833 support, the Oracle Communications Session Border Controller supports end-to-end signaled negotiation of DTMF on a call-by-call basis. If the calling party is not configured for preferred support but sends 2833, the Oracle Communications Session Border Controller sends 2833 to the next-hop called party. If the calling party sends H.245 signals or alphanumeric UII, the Oracle Communications Session Border Controller sends H.245 signals or alphanumeric UII to the next-hop called party (if it is an H.323 next-hop).

The Oracle Communications Session Border Controller also supports hop-by-hop negotiation of DTMF capability on a call-by-call basis, if the signaling protocols or session agents on either side of the call are configured for preferred 2833 support.

H.323 to H.323 Negotiation

The Oracle Communications Session Border Controller serves as the H.323 called gateway. It answers RFC 2833 audio telephony event capability in the version 4 H.323/H.245 TCS when it receives a call from an H.323 endpoint configured for preferred RFC 2833.

If the Oracle Communications Session Border Controller is the answering device, configured for preferred support, and the calling device sends 2833, the Oracle Communications Session Border Controller accepts the 2833 regardless of the next-hop's DTMF capabilities. The received dynamic RTP payload type is used for detecting 2833 packets, while the response dynamic payload type is used for generating 2833 packets.

The Oracle Communications Session Border Controller supports:

- RFC-2833 audio telephony events in the version 4 H.323/H.245 TCS as the H.323 calling gateway, when the Oracle Communications Session Border Controller calls an H.323 endpoint configured for preferred RFC 2833 support. The Oracle Communications Session Border Controller sends 2833 to the called party regardless of whether the calling party sends it.

- H.245 UII and RFC-2833 packets sent at the same time, to the same endpoint, even if only half of the call is being provided 2833 support by the Oracle Communications Session Border Controller.
  If one half of the call supports H.245 UII, and the other half is being provided 2833 translation by the Oracle Communications Session Border Controller, the Oracle Communications Session Border Controller can also forward the H.245 UII it receives to the 2833 endpoint. For example, when the signaling goes through a gatekeeper or third party call control, sending the H.245 UII in the signaling path allows those devices to learn the DTMF digits pressed.

Signal and Alpha Type Support

The Oracle Communications Session Border Controller supports:

- H.245 signal and alpha type UII in the H.323/H.245 TCS as the H.323 calling gateway when the:
  Oracle Communications Session Border Controller calls an H.323 endpoint configured for transparent 2833 support

  calling endpoint's target is configured as preferred

  If the originating preferred side also sends 2833, the Oracle Communications Session Border Controller forwards it to the transparent side. The Oracle Communications Session Border Controller sends signal and alpha UII support to the called party regardless of whether the calling party sends it, if the call originates from a preferred side to a transparent side.
- H.245 alphanumeric UII for DTMF for H.323 endpoints that do not signal 2833 or contain explicit H.245 UII capability, for stacks configured for transparent 2833 support.
  When the other half of the call is an H.323 endpoint of a stack configured for preferred 2833, the Oracle Communications Session Border Controller translates incoming H.245 UII on the transparent side, to 2833 packets on the preferred side, and vice versa. If the other half of the call is an H.323 endpoint of a transparent stack, the Oracle Communications Session Border Controller relays the H.245 UII messages.
- H.245 signal type UII for DTMF for H.323 endpoints that do not signal 2833, but do signal explicit H.245 UII capability, for stacks configured for transparent 2833 support.
  When the other half of the call is an H.323 endpoint of a stack configured for preferred 2833, the Oracle Communications Session Border Controller translates incoming H.245 signaled UII on the transparent side, to 2833 packets on the preferred side, and vice versa. If the other half of the call is an H.323 endpoint of a transparent stack, the Oracle Communications Session Border Controller relays the H.245 UII messages if both sides support it.

H.323 to SIP Calls

This section explains DTMF interworking specific to H.323 to SIP calls.

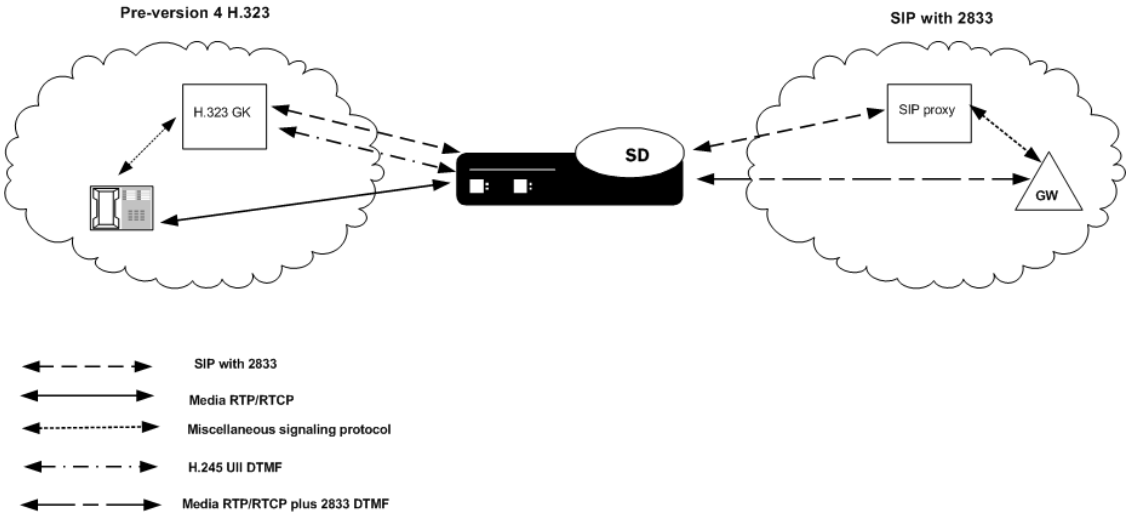
SIP Endpoints

SIP endpoints include those that support:

- RFC 2833
- SIP INFO method

H.323 Non-2833 Interworking with SIP

RFC 2833 and the SIP INFO method can be used for conveying DTMF information for SIP based-services. (RFC 2833 is the most widely used.) To provide end-to-end DTMF for SIP devices supporting RFC-2833 interworking with H.323 devices that do not, an RFC 2833 to H.323 UII interworking function is provided.



How H.323 to SIP Calls Work

For H.323 to SIP IWF calls, if 2833-related information is to be sent in the INVITE, the SIP interface of the SIP session agent has to be configured with the **rfc2833-mode** parameter set to preferred.

The following example shows an INVITE without 2833 in the SDP:

```
Apr  5 04:28:50.073 On 127.0.0.1:5070 sent to 127.0.0.1:5060
INVITE sip:780@192.168.200.6:5060 SIP/2.0
Via: SIP/2.0/UDP

SIP INFO—RFC 2833 Conversion

The Oracle Communications Session Border Controller can perform SIP INFO—RFC 2833 conversion. The Oracle Communications Session Border Controller also provides a way for you to enable a dual conversion mode, where the Oracle Communications Session Border Controller:

- Inserts telephone-event in the SDP offer
- Generates both RFC 2833 event packets and SIP INFO messages regardless of whether or not the SDP offer indicates RFC 2833

You can enable this feature either for SIP interfaces or session agents. The following apply:

- If the next hop SIP interface or session agent's **rfc2833-mode** is set to preferred, then the SD inserts RFC 2833 into the SDP offer/answer. This occurs regardless of whether:
  - The original SDP on the opposite side of the call does not support RFC 2833
  - The opposite side's SIP interface or session agent is set to transparent mode
- If the next hop SIP interface or session agent is set to transparent, then the behavior of the Oracle Communications Session Border Controller depends on the previous hop.
  - If the previous hop is a SIP interface or session agent configured for transparent mode, then the S Oracle Communications Session Border Controllerdoes not perform any conversion.
  - If the previous hop is a SIP interface or session agent configured for preferred mode, the Oracle Communications Session Border Controller does not insert RFC-2833 into the SDP on the transparent side. It does, however, translate from RFC 2833 to SIP INFO if the originating endpoint supports RFC 2833.

IPv6 SIP INFO to RFC 2833 Telephone Event Interworking

The Oracle Communications Session Border Controller can interwork SIP INFO and RFC Telephone Event messages for IPv4, IPv6—or for any session requiring interworking between IPv4 and IPv6. Other than installing the applicable lisences on your Oracle Communications Session Border Controller and enabling IPv6 support in your system configuration (**system-config**), you do not have to perform any configuration steps for this capability to work.

RFC 2833 Interworking Configuration

This section explains how to configure RFC 2833 to H.245 User Input Indication (UII) or SIP INFO method interworking.

RFC 2833 Mode for H.323 Stacks

To configure RFC 2833 mode for H.323 stacks:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the media-related configurations.

```
ORACLE(configure)# session-router
```

3. Type **h323** and press Enter.

```
ORACLE(session-router)# h323
```

4. Type **h323-stacks** and press Enter.

```
ORACLE(h323)# h323-stacks
ORACLE(h323-stack)#
```

From this point, you can configure H.323 stack parameters. To view all H.323 stack parameters, enter a **?** at the system prompt.

5. **rfc2833-mode**—Set the RFC2833 mode. The default value is **transparent**. Valid values are:
   - **transparent**—The Oracle Communications Session Border Controller and H.323 stack behave exactly the same way as before and the 2833 or UII negotiation is transparent to the Oracle Communications Session Border Controller.
   - **preferred**—The H.323 stack uses 2833 for DTMF transfer, which it signals in its TCS. However, the remote H323 endpoint makes the decision. If the endpoint supports 2833, 2833 is used. If not, the H.323 stack reverts back to using UII. You configure the payload format by configuring the h323-config element.

RFC 2833 Payload for H.323

To configure the RFC 2833 payload in preferred mode:

1. In Superuser mode, type **configure terminal** and press Enter.

```
ORACLE# configure terminal
```

2. Type **session-router** and press Enter to access the session-related configurations.

```
ORACLE(configure)# session-router
```

3. Type **h323** and press Enter. The system prompt changes to let you know that you can begin configuring individual parameters.

```
ORACLE(session-router)# h323
```

From this point, you can configure global H.323 parameters. To view all H.323 configuration parameters, enter a **?** at the system prompt.

4. **rfc2833-payload**—Enter a number that indicates the payload type the Oracle Communications Session Border Controller will use for RFC 2833 packets while interworking 2833 and UII. The default value is **101**.
   - Minimum—96
   - Maximum—127

Configuring the SIP Interface

You configure the 2833 mode and payload for the SIP interface. You must configure the payload the Oracle Communications Session Border Controllerwill use for RFC 2833 packets, while interworking 2833 and INFO/UII.

To configure the SIP interface:

1. In Superuser mode, type **configure terminal** and press Enter.

   ```
   ORACLE# configure terminal
   ```

2. Type **session-router** and press Enter to access the system-level configuration elements.

   ```
   ORACLE(configure)# session-router
   ```
